All efforts should be made to minimize family disruption resulting from the hospitalization. Children should be allowed to wear their own clothes (street clothes, especially for preadolescent and adolescent girls) and resume school and preinjury activities if able. A parent or siblings should be allowed to stay overnight and room-in with the hospitalized child to prevent the effects of family disruption. Visits from significant persons, such as family members and friends, offer occasions for emotional support and provide opportunities for learning how to care for the child. Privacy is necessary, especially for adolescents.

One of the most useful interventions to help children cope with immobility is participation in their own care. Self-care to the maximum extent is usually well received by children. They can help plan their daily routine; select their diet; and choose "street clothes," including innovative adornment, such as a baseball cap or brightly colored stockings to express their autonomy and individuality. They are encouraged to do as much for themselves as they are able to keep their muscles active and their interest alive.

Although most of the suggestions discussed relate to hospital care, the same consultations (physical therapist, occupational therapist, child life specialist, speech therapist) and environment may be considered in the home to help the child and family achieve independence and normalization (see Chapter 18). For a child with greatly restricted movement (e.g., child with a bilateral hip spica cast or confined to bed rest), care is often a challenge. These situations require long-term management either in the hospital or at home. Wherever the care occurs, consistent planning and coordination of activities with other health care workers and caregivers are vital nursing functions.

Family Support and Home Care

The needs of a child with severe disabilities can be complex, and family members require time to assimilate the teachings and demonstrations needed to understand the child's situation and care. Even a child who is confined on a short-term basis can be a challenge for the family, which is usually unprepared for the problems imposed by the child's special needs. Home modification is usually needed for facilitating care, especially when it involves traction, a large cast, or extended confinement. Suitable child care may be needed for times when all family members work.

Just as in the hospital, the child at home is encouraged to be as independent as possible and to follow a schedule that approximates his or her normal lifestyle as nearly as possible, such as continuing school lessons, regular bedtime, and suitable recreational activities.

TRAUMATIC INJURY

SOFT-TISSUE INJURY

Injuries to the muscles, ligaments, and tendons are common in children (Fig. 29.1). In young children, soft-tissue injury usually results from mishaps during play. In older children and adolescents, participation in sports is a common cause of such injuries.

Contusions

A contusion (bruise) is damage to the soft tissue, subcutaneous structures, and muscle. The tearing of these tissues and small blood vessels and the inflammatory response lead to hemorrhage, edema, and associated pain when the child attempts to move the injured part. The escape of blood into the tissues is observed as **ecchymosis**, a black-and-blue discoloration.

Large contusions cause gross swelling, pain, and disability, and usually receive immediate attention from health personnel. Smaller injuries may go unnoticed, allowing continued participation. However, they can become disabling after rest because of pain and muscle spasm. Immediate treatment consists of cold application, as in the treatment of sprains described later. Return to participation is allowed when the strength and range of motion of the affected extremity are equal to those of the opposite extremity or are demonstrated under conditions, such as sport-specific tests. **Myositis ossificans** may occur from deep contusions to the biceps or quadriceps muscles; this condition may result in a restriction of flexibility of the affected limb.

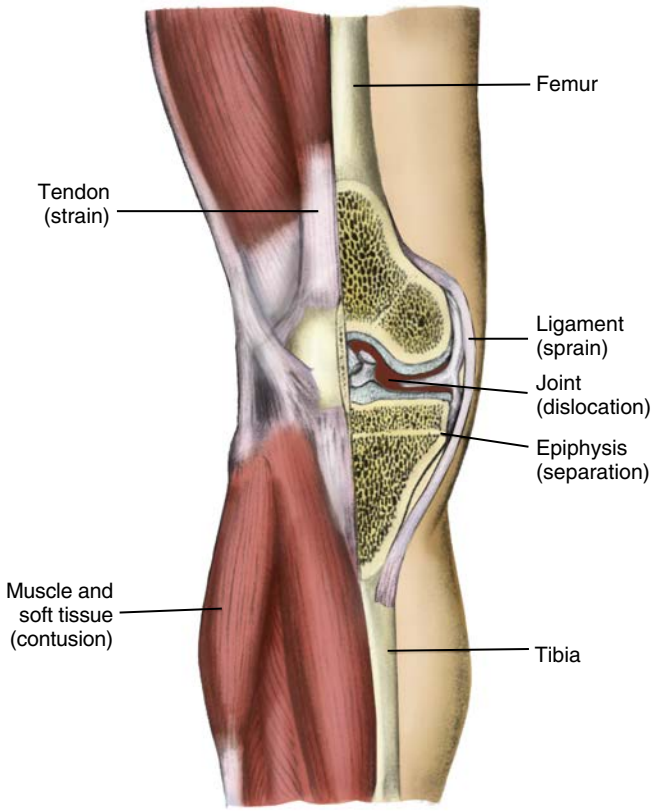

Fig. 29.1 Sites of injuries to bones, joints, and soft tissues.

Crush injuries occur when children's extremities or digits are crushed (e.g., fingers slammed in doors, folding chairs, or equipment) or hit (as when hammering a nail). A severe crush injury involves the bone, with swelling and bleeding beneath the nail (subungual) and sometimes laceration of the pulp of the nail. The **subungual hematoma** can be released by creating a hole at the proximal end of the nail with a special cautery device or a heated sterile 18-gauge needle.

Dislocations

Long bones are held in approximation to one another at the joint by ligaments. A dislocation occurs when the force of stress on the ligament is so great as to displace the normal position of the opposing bone ends or the bone end to its socket. The predominant symptom is pain that increases with attempted passive or active movement of the extremity. In dislocations, there may be an obvious deformity and inability to move the joint. Children with naturally lax joints are more prone to dislocation of joints. Dislocation of the phalanges is the most common type seen in children, followed by elbow dislocation. In the adolescent population, shoulder dislocations are more common and dislocation unaccompanied by fracture is rare.

A common injury in young children is subluxation, or partial dislocation, of the radial head, also called *pulled elbow* or **nursemaid's elbow**. In the majority of cases, the injury occurs in a child younger

than 5 years old who receives a sudden longitudinal pull or traction at the wrist while the arm is fully extended and the forearm pronated. It usually occurs when an individual who is holding the child by the hand or wrist gives a sudden pull or jerk to prevent a fall or attempts to lift the child by pulling the wrist or when the child pulls away by dropping to the floor or ground. The child often cries, appears anxious, complains of pain in the elbow or wrist, and refuses to use the affected limb. The practitioner manipulates the arm by applying firm finger pressure to the head of the radius and then supinates and flexes the forearm to return the bone structure to normal alignment. Alternatively, a hyperpronation method where the practitioner holds the child's flexed elbow with one hand while pronating the forearm with the other has also been shown to be effective. A click may be heard or felt, and functional use of the arm returns within minutes. Immobilization is not required. However, the longer the subluxation is present, the longer it takes for the child to recover mobility after treatment. No anesthetic is usually required, but a mild pain reliever such as acetaminophen or ibuprofen may be administered. In an older child, severe elbow injury or dislocation should be evaluated immediately by a practitioner. If a traumatic elbow injury in a younger child is not a subluxation or if attempts at reduction are unsuccessful, the child should be carefully evaluated, with the consideration of radiographs.

In children younger than 5 years old, the hip can be dislocated by a fall. The greatest risk after this injury is the potential loss of blood supply to the head of the femur. Relocation of the hip within 60 minutes after the injury provides the best chance for prevention of damage to the femoral head.

Shoulder dislocations and separations occur most often in older adolescents and are often sports related. Temporary restriction of the joint, with a sling or bandage that secures the arm to the chest in a shoulder dislocation, can provide sufficient comfort and immobilization until medical attention is received.

Simple dislocations should be reduced as soon as possible with the child under procedural sedation combined with local anesthesia. An unreduced dislocation may be complicated by increased swelling, making reduction difficult and increasing the risk of neurovascular problems. Treatment is determined by the severity of the injury.

Sprains

A sprain occurs when trauma to a joint is so severe that a ligament is partially or completely torn or stretched by the force created as a joint is twisted or wrenched, often accompanied by damage to associated blood vessels, muscles, tendons, and nerves. Common sprain sites include ankles and knees.

The presence of joint laxity is the most valid indicator of the severity of a sprain. In a severe injury, the child complains of the joint "feeling loose" or as if "something is coming apart" and may describe hearing a "snap," "pop," or "tearing." Pain may or may not be the principal subjective symptom, and in some children, it may prevent optimal examination of ligamentous instability. There is a rapid onset of swelling, often diffuse, accompanied by immediate disability and appreciable reluctance to use the injured joint.

Strains

A strain is a microscopic tear to the musculotendinous unit and has features in common with sprains. The area is painful to touch and swollen. Most strains are incurred over time rather than suddenly, and the rapidity of the appearance provides clues regarding severity. In general, the more rapidly the strain occurs, the more severe the injury. When the strain involves the muscular portion, there is more bleeding, often palpable soon after injury and before edema obscures the hematoma.

Therapeutic Management

The first 12 to 24 hours are the most critical period for virtually all soft-tissue injuries. Basic principles of managing sprains and other soft-tissue injuries are summarized in the acronyms **RICE** and **ICES**.

Rest	**I**ce
Ice	**C**ompression
Compression	**E**levation
Elevation	**S**upport

Soft-tissue injuries should be iced immediately. This is best accomplished with crushed ice wrapped in a towel, a screw-top ice bag, or a resealable plastic storage bag. Chemical-activated ice packs are also effective for immediate treatment but are not reusable and must be closely monitored for leakage. A wet elastic wrap, which transfers cold better than dry wrap, is applied to provide compression and to keep the ice pack in place. A cloth barrier should be used between the ice container and the skin to prevent trauma to the tissues. Ice has a rapid cooling effect on tissues that reduces edema and pain. Ice should never be applied for more than 30 minutes at a time.

> **NURSING TIP:** A plastic bag of frozen vegetables, such as peas, serves as a convenient ice pack for soft-tissue injuries. It is clean, watertight, and easily molded to the injured part. When available, snow placed in a plastic bag may also serve as an ice bag.

Elevating the extremity uses gravity to facilitate venous return and reduce edema formation in the damaged area. The point of injury should be kept several inches above the level of the heart for therapy to be effective. Several pillows can be used for elevation. Allowing the extremity to be dependent causes excessive fluid accumulation in the area of injury, delaying healing and causing painful swelling.

Torn ligaments, especially those in the knee, are usually treated by immobilization with a knee immobilizer or a knee brace that allows flexion and extension until the child is able to walk without a limp. Crutches are used for mobility to rest the affected extremity. Passive leg exercises, gradually increased to active ones, are begun as soon as sufficient healing has taken place. Parents and children are cautioned against using any form of liniment or other heat-producing preparation before examination. If the injury requires casting or splinting, the heat generated in the enclosed space can cause extreme discomfort and even tissue damage. In some cases, torn knee ligaments are managed with arthroscopy and ligament repair or reconstruction as necessary depending on the extent of the tear, the ligaments involved, and the child's age. Surgical reconstruction of the anterior cruciate ligament may be performed in young athletes who wish to continue in active sports.

FRACTURES

Bone fractures occur when the resistance of bone against the stress being exerted yields to the stress force. Fractures are a common injury at any age but are more likely to occur in children and older adults. Because childhood is a time of rapid bone growth, the pattern of fractures, problems of diagnosis, and methods of treatment differ in children compared with adults. In children, fractures heal much faster than in adults. Consequently, children may not require as long a period of immobilization of the affected extremity as an adult with a fracture.

Fracture injuries in children are most often a result of traumatic incidents at home, at school, in a motor vehicle, or in association with recreational activities. Children's everyday activities include vigorous play that predisposes them to injury, including climbing, falling down,

running into immovable objects, skateboarding, trampolines, skiing, playground activities, and receiving blows to any part of their bodies by a solid, immovable object.

Aside from automobile accidents or falls from heights, true injuries that cause fractures rarely occur in infancy. Up to 25% of fractures in children younger than 12 months old have been attributed to **nonaccidental trauma** (child abuse) (Flaherty, Perez-Rossello, Levine, et al., 2014). Therefore bone injury in children of this age-group warrants further investigation. In any small child, radiographic evidence of fractures at various stages of healing is, with few exceptions, a result of nonaccidental trauma. Any investigation of fractures in infants, particularly multiple fractures, should include consideration of **osteogenesis imperfecta (OI)** after nonaccidental trauma has been ruled out.

Fractures in school-age children are often a result of playground falls or bicycle/automobile or skateboard injuries. Adolescents are vulnerable to multiple and severe trauma because they are mobile on bicycles, all-terrain vehicles, skateboards, skis, snowboards, trampolines, and motorcycles and are active in sports.

A distal forearm (radius, ulna, or both) fracture is the most common fracture in children. The clavicle is also a common fracture sustained in childhood, with approximately half of clavicle fractures occurring in children younger than 10 years old. Common mechanisms of injury include a fall with an outstretched hand or direct trauma to the bone. In neonates, a fractured clavicle may occur with a large newborn and a small maternal pelvis. This may be noted in the first few days after birth by a unilateral Moro reflex or at the 2-week well-child check, when a fracture callus is palpated on the infant's healing clavicle.

Types of Fractures

A fractured bone consists of fragments—the fragment closer to the midline, or the **proximal** fragment, and the fragment farther from the midline, or the **distal** fragment. When fracture fragments are separated, the fracture is **complete**; when fragments remain attached, the fracture is **incomplete**. The fracture line can be any of the following:

Transverse: Crosswise at right angles to the long axis of the bone

Oblique: Slanting but straight between a horizontal and a perpendicular direction

Spiral: Slanting and circular, twisting around the bone shaft

The twisting of an extremity while the bone is breaking results in a spiral break. If the fracture does not produce a break in the skin, it is a **simple**, or **closed**, **fracture**. **Open**, or **compound**, **fractures** are those with an open wound through which the bone protrudes. If the bone fragments cause damage to other organs or tissues (e.g., lung, liver), the injury is said to be a **complicated fracture**. When small fragments of bone are broken from the fractured shaft and lie in the surrounding tissue, the injury is a **comminuted fracture**. This type of fracture is rare in children. The types of fractures that are seen most often in children are described in Box 29.1 and Fig. 29.2.

Growth Plate (Physeal) Injuries

The weakest point of long bones is the cartilage growth plate, or the physis. Consequently, this is a frequent site of damage in childhood trauma. Growth plate fractures are classified with the Salter-Harris classification system (Fig. 29.3). Detection of physeal injuries is sometimes difficult but critical. Close monitoring and early treatment, if indicated, is essential to prevent longitudinal or angular growth deformities (or both). Treatment of these fractures may include surgical open reduction and internal fixation to prevent or reduce growth disturbances.

Immediately after a fracture occurs, the muscles contract and physiologically splint the injured area. This phenomenon accounts for the muscle tightness observed over a fracture site and the deformity that is produced as the muscles pull the bone ends out of alignment. This muscle response must be overcome by traction or complete muscle relaxation (e.g., anesthesia) to realign the distal bone fragment to the proximal bone fragment.

BOX 29.1 Types of Fractures in Children

Plastic deformation: Occurs when the bone is bent but not broken. A child's flexible bone can be bent 45 degrees or more before breaking. However, if bent, the bone will straighten slowly but not completely, producing some deformity but without the angulation seen when the bone breaks. Bends occur most commonly in the ulna and fibula, often in association with fractures of the radius and tibia.

Buckle, or torus, fracture: Produced by compression of the porous bone; appears as a raised or bulging projection at the fracture site. These fractures occur in the most porous portion of the bone near the metaphysis (the portion of the bone shaft adjacent to the epiphysis) and are more common in young children.

Greenstick fracture: Occurs when a bone is angulated beyond the limits of bending. The compressed side bends, and the tension side fails, causing an incomplete fracture similar to the break observed when a green stick is broken.

Complete fracture: Divides the bone fragments. These fragments often remain attached by a **periosteal hinge**, which can aid or hinder reduction.

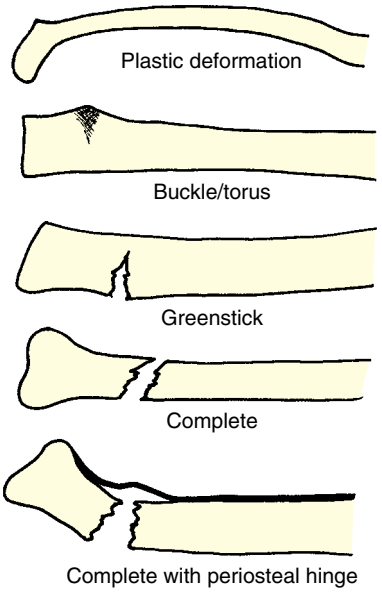

Fig. 29.2 Types of fractures in children.

Bone Healing and Remodeling

Bone healing is rapid in growing children because of the thickened periosteum and generous blood supply. When there is a break in the continuity of bone, the osteoblasts are stimulated to maximal activity. New bone cells are formed in immense numbers almost immediately after the injury and, in time, are evidenced by a bulging growth of new bone tissue between the fractured bone fragments. This is followed by deposition of calcium salts to form a **callus**. Remodeling is a process that occurs in the healing of long bone fractures in growing children. The irregularities produced by the fracture become indistinct as the angles and bone overgrowth are smoothed out, giving the bone a straighter appearance.

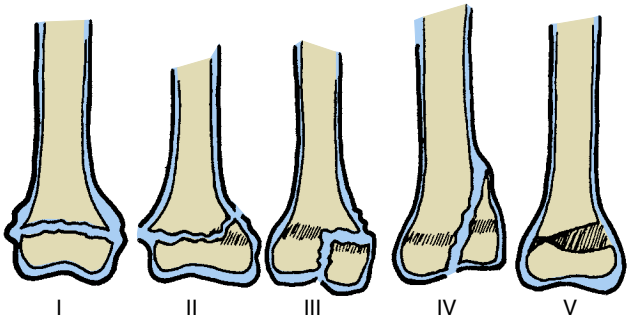

Fig. 29.3 Salter-Harris fracture classification. Types of epiphyseal injury in order of increasing risk for growth abnormalities. The injuries are classified as follows: *Type I,* separation or slip of growth plate without fracture of the bone; *type II,* separation of growth plate and breaking off of section of metaphysis; *type III,* fracture of epiphysis extending through joint surface; *type IV,* fracture of growth plate, epiphysis, and metaphysis; and *type V,* crushing injury of epiphysis (can be diagnosed only in retrospect). This classification of epiphyseal injuries was developed by orthopedists R. B. Salter and W. R. Harris. (First published in Salter, R. B., & Harris, W. R. [1963]. Injuries involving the physeal plate. *Journal of Bone and Joint Surgery, 45*[3], 587–622.)

BOX 29.2 Clinical Manifestations of a Fracture

Signs of injury:
- Generalized swelling
- Pain or tenderness
- Deformity
- Diminished functional use of affected limb or digit

May also demonstrate:
- Bruising
- Severe muscular rigidity
- Crepitus (grating sensation at fracture site)

Fractures heal in less time in children than in adults. For example, the approximate healing times for a femoral shaft are as follows:
Neonatal period: 2 to 3 weeks
Early childhood: 4 weeks
Later childhood: 6 to 8 weeks
Adolescence: 8 to 12 weeks

Diagnostic Evaluation

A history of the injury may be lacking in childhood injuries. Infants and toddlers are unable to communicate, and older children may not volunteer information (even under direct questioning) when the injury occurred during questionable activities. Whenever possible, it is helpful to obtain information from someone who witnessed the injury. In cases of nonaccidental trauma, providers may give false information to protect themselves or family members.

The child may exhibit the same manifestations seen in adults, which may include swelling, bruising, pain or tenderness, deformity, and diminished function (Box 29.2). However, often a fracture is remarkably stable because of intact periosteum. The child may even be able to use an affected arm or walk on a fractured leg. Because bones are highly vascular, a soft, pliable hematoma may be felt around the fracture site.

! NURSING ALERT

A fracture should be strongly suspected in a small child who refuses to walk or crawl.

Fig. 29.4 Fractured femur. Most fractured femurs in childhood are of the spiral type shown here. (From Mark, J. A., Hockberger, R. S., & Walls, R. M. [2013]. *Rosen's emergency medicine: Concepts and clinical practice* [8th ed.]. St. Louis, MO: Elsevier.)

Radiographic examination is the most useful diagnostic tool for assessing skeletal trauma. The calcium deposits in bone make the entire structure radiopaque. Radiographic films are taken after fracture reduction and in some cases may be taken during the healing process to determine satisfactory progress.

Therapeutic Management

The goals of fracture management are:
- To regain alignment and length of the bony fragments (reduction)
- To retain alignment and length (immobilization)
- To restore function to the injured parts
- To prevent further injury and deformity

The majority of children's fractures heal well, and nonunion is rare. Fractures are splinted or casted to immobilize and protect the injured extremity. Children with displaced fractures may have immediate surgical reduction and fixation (internal or external) rather than being immobilized by traction (Fig. 29.4). This practice is more common and holds true for all types of fractures, including femur fractures, although there is variation based on provider preference and institutional practice. Some conditions require immediate medical attention, including open fractures, compartment syndrome, fractures associated with vascular or nerve injury, and joint dislocations that are unresponsive to reduction maneuvers.

In children, immobilization is used until adequate callus is formed. The position of the bone fragments in relation to one another influences the rapidity of healing and residual deformity. Weight bearing and active movement for the purpose of regaining function may begin after the fracture site is determined to be stable by the medical provider. The child's natural tendency to be active is usually sufficient to restore normal mobility, and physical or occupational therapy is rarely indicated.

Children are most frequently hospitalized for fractures of the femur and supracondylar area of the distal humerus. If simple reduction cannot be achieved or a neurovascular problem is detected after the injury, observation in a hospital setting may be indicated. The trend is to avoid hospitalization. The major methods for immobilizing a fracture, casting and traction, are described later.

Nursing Care Management

Nurses are frequently the persons who make the initial assessment of a child with a suspected fracture (see Emergency Treatment box). The child and parents may be frightened and upset, and the child is often in pain. Therefore if the child is alert and there is no evidence of hemorrhage, the initial nursing interventions are directed toward calming and reassuring the child and parents so that a more extensive assessment can be more easily accomplished.

EMERGENCY TREATMENT

Fracture

Determine the mechanism of injury.
Assess the 6 Ps (see Box 29.3).
Move the injured part as little as possible.
Cover open wounds with a sterile or clean dressing.
Immobilize the limb, including joints above and below the fracture site; do not attempt to reduce the fracture or push protruding bone under the skin.
Use a soft splint (pillow or folded towel) or rigid splint (rolled newspaper or magazine).
Uninjured leg can serve as a splint for a leg fracture if no splint is available.
Reassess neurovascular status.
Apply traction if circulatory compromise is present.
Elevate the injured limb if possible.
Apply cold to the injured area.
Call emergency medical services or transport to medical facility.

While remaining calm and speaking in a quiet voice, the nurse can ask the parents and older child to describe what happened. The child may arrive with the limb supported in some manner; if not, careful support or immobilization may be provided to the affected site. In the event that the limb is supported or immobilized, it may be best not to touch the child but to ask him or her to point to the painful area and to wiggle the fingers or toes. By this time the child may feel relatively safe and will allow someone to gently touch the area just enough to feel the pulses and test for sensation. A child's anxiety is greatly influenced by previous experiences with injury and with health personnel. However, he or she needs to be told what will happen and what to do to help. The affected limb need not be palpated, and it should not be moved unless properly splinted. If the child is at home or if the practitioner is not present to examine the child, some type of splint is applied carefully for transport to the medical facility. Parental anxiety may be heightened by the child's pain reaction and fear and possibly by other events surrounding the accident. It is important to communicate to the parent that the child will receive the necessary care, including pain management.

THE CHILD IN A CAST

The completeness of the fracture, the type of bone involved, and the amount of weight bearing influence how much of the extremity must be included in the cast to immobilize the fracture site completely. In most cases, the joints above and below the fracture are immobilized to eliminate the possibility of movement that might cause displacement at the fracture site. Four major categories of casts are used for fractures: **upper extremity** to immobilize the wrist or elbow, **lower extremity** to immobilize the ankle or knee, spinal and cervical to immobilize the spine, and spica casts to immobilize the hip and knee (Fig. 29.5).

NURSING ALERT

Compartment syndrome is a serious complication that results from compression of nerves, blood vessels, and muscle inside a closed space. This injury may be devastating, resulting in tissue death, and thus requires emergency treatment (fasciotomy). The six Ps of ischemia from a vascular, soft-tissue, nerve, or bone injury should be included in an assessment of any injury:

1. Pain
2. Pulselessness
3. Pallor
4. Paresthesia
5. Paralysis
6. Pressure (Box 29.3)

Fig. 29.5 Spica cast with hip abductor. Note casts on doll as well.

The Cast

Casts are constructed from gauze strips and bandages impregnated with plaster of Paris or, more commonly, from synthetic lighter weight and water-resistant materials (e.g., waterproof liners, fiberglass and polyurethane resin).

Both types of casting produce heat from chemical reaction activated by water immediately after application. Plaster casts are able to be molded closely to the body part, take 10 to 72 hours to dry, have a smooth exterior, and are inexpensive. The newer synthetic casting material is lightweight, dries in 5 to 20 minutes, permits earlier weight bearing, and is water resistant when applied with a waterproof liner. It is always desirable to give children choices, and synthetic casting materials come in a variety of colors. The disadvantages of synthetic casting are its inability to mold closely to body parts and its rough exterior, which may scratch surfaces. Synthetic casts are also difficult to write on; a waterproof marker or color markers may be used.

Cast Application

The child's developmental age should be considered before the cast is applied. For preschoolers who fear bodily harm and fantasize about the loss of an extremity, it may be helpful to use a plastic doll or stuffed animal to explain the procedure beforehand. Toddlers and preschoolers do not have easily defined body boundaries; if an extremity is wrapped in a bandage, cast, or splint, to the young child the extremity

ceases to function or exist. It is also helpful to explain that some synthetic cast material will become warm during application but will not burn. During the application of the cast, various distraction methods can be used, including discussing favorite pets or activities at school, blowing bubbles, and so forth. In this age-group, explanations, such as "This will help your arm get better," are futile because the child has no concept of causality.

Before the cast is applied, the extremities are checked for any abrasions, cuts, or other alterations in the skin surface and for the presence of rings or other items that might cause constriction from swelling; such objects are removed. A tube of cloth stockinette or Gore-Tex liner is stretched over the area to be casted, and bony prominences are padded with soft cotton sheeting. Dry rolls of casting material are immersed in a pail of water. The wet rolls are put on in a bandage fashion and molded to the extremity. During application of the cast, the underlying stockinette is pulled over the rough edges of the cast and secured with casting material to form a padded edge to protect the skin.

Nursing Care Management

The complete evaporation of the water from a hip spica cast can take 24 to 48 hours when older types of plaster materials are used. Drying occurs within minutes with fiberglass cast material. The cast must remain uncovered to allow it to dry from the inside out. Turning the child in a plaster cast at least every 2 hours will help dry a body cast evenly and prevent complications related to immobility. A regular fan or cool-air hair dryer to circulate air may be helpful when the humidity is high.

! NURSING ALERT

Heated fans or dryers are not used because they cause the cast to dry on the outside and remain wet beneath or cause burns from heat conduction by way of the cast to the underlying tissue.

A wet plaster cast should be supported by a pillow that is covered with plastic and handled by the palms of the hands to prevent indenting the cast, which can create pressure areas. A dry plaster-of-Paris cast produces a hollow sound when it is tapped with the finger. After it has dried, "hot spots" felt on the cast surface or a foul-smelling odor may indicate an infection. This should be reported for further evaluation, and if concern continues, an opening, or a "window," may be exposed over the area of concern to evaluate the site.

During the first few hours after a cast is applied, the chief concern is that the extremity may continue to swell to the extent that the cast becomes a tourniquet, shutting off circulation and producing neurovascular complications (**compartment syndrome**) (see Box 29.3). To reduce the likelihood of this potential problem, the body part can be elevated, thereby increasing venous return. If edema is excessive, casts are bivalved (i.e., cut to make anterior and posterior halves that are held together with an elastic bandage). The cast and the involved extremity are observed frequently for neurovascular integrity and any signs of compromise. Permanent muscle and tissue damage can occur within a few hours.

BOX 29.3 Compartment Syndrome Evaluation

Assess the extent of injury—"the 6 Ps":

1. **Pain:** Severe pain that is not relieved by analgesics or elevation of the limb, movement that increases pain
2. **Pulselessness:** Inability to palpate a pulse distal to the fracture or compartment
3. **Pallor:** Pale-appearing skin, poor perfusion, capillary refill greater than 3 seconds
4. **Paresthesia:** Tingling or burning sensations
5. **Paralysis:** Inability to move extremity or digits
6. **Pressure:** Involved limb or digits may feel tense and warm; skin is tight, shiny; pressure within the compartment is elevated

! NURSING ALERT

Observations such as pain (unrelieved by pain medication 1 hour after administration, especially with passive range of motion), swelling, discoloration (pallor or cyanosis) of the exposed portions, decreased pulses, decreased temperature, paresthesia, or the inability to move the distal exposed part(s) should be reported immediately. Pallor, paralysis, and pulselessness are late signs (see Box 29.3).

When an extremity that has sustained an open fracture is casted, a window is often left over the wound area to allow for observation and dressing of the wound. For the first few hours after surgery, substantial bleeding may soak through the cast. Periodically, the circumscribed bloodstained area should be outlined with a waterproof marker and the time indicated to provide a guide for assessing the amount of bleeding.

Appropriate cast care guidelines for the child's caregiver are necessary before discharge. Instructions are also given for checking for signs and symptoms that indicate that the cast is too tight (see Family-Centered Care box). Parents should also be told to take the child to the health professional for attention if the cast becomes too loose because a loose cast no longer serves its purpose and can cause skin irritation or pressure sores.

FAMILY-CENTERED CARE

Cast Care

Keep the casted extremity elevated on pillows or similar support for the first day or as directed by the health professional.

Avoid denting the plaster cast with fingertips (use palms of hand to handle) while it is still wet to avoid creating pressure points.

Expose the plaster cast to air until dry.

Observe the extremities (fingers or toes) for any evidence of swelling or discoloration (darker or lighter than a comparable extremity) and contact the health professional if noted.

Check movement and sensation of the visible extremities frequently.

Follow health professional's orders regarding any restriction of activities.

Restrict strenuous activities for the first few days:

- Engage in quiet activities but encourage use of muscles.
- Move the joints above and below the cast on the affected extremity.

Encourage frequent rest for a few days, keeping the injured extremity elevated while resting.

Avoid allowing the affected limb to hang in a dependent position for any length of time:

- Keep an injured upper extremity elevated (e.g., in a sling) while upright.
- Elevate a lower limb when sitting and avoid standing for too long.

Do not allow the child to put anything inside the cast. Keep small items that might be placed inside the cast away from small children.

Keep a clear path for ambulation. Remove toys, hazardous floor rugs, pets, and other items over which the child might stumble.

Use crutches appropriately if lower limb fracture requires non–weight bearing on affected extremity.

The crutches should fit properly, have a soft rubber tip to prevent slipping, and be well padded at the axilla.

With crutch walking, the child's body weight is supported on the hand grips, not the axilla.

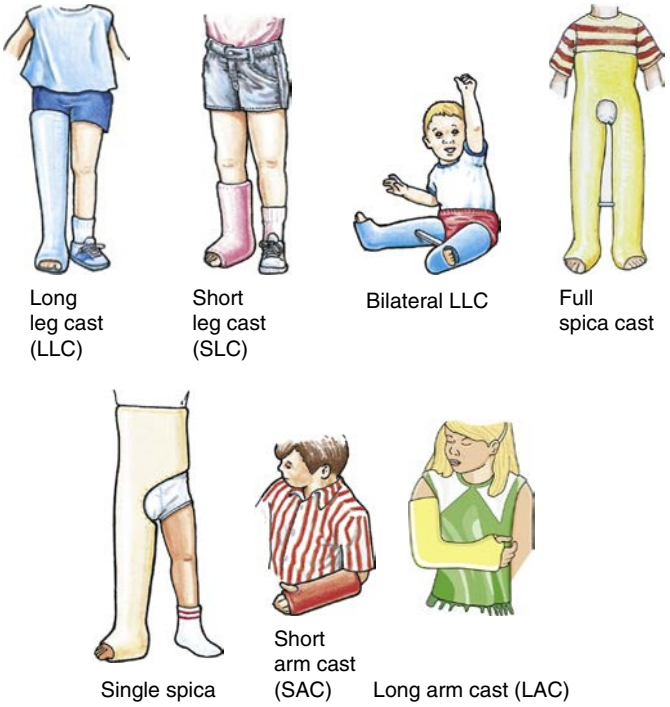

Fig. 29.6 Types of casts.

Nurses can help families adapt the child's home environment to meet the temporary encumbrance of a large cast or one that restricts the child's mobility (e.g., a long leg or spica cast [Fig. 29.6]). Commonplace situations become problematic (e.g., transporting a child safely and comfortably in a car). Standard seat belts and car seats may not be readily adapted for use by children in certain casts. Specially designed car seats and restraints that meet safety requirements are available.[a] Alterations to standard car seats to accommodate the cast are not recommended because the structure may be adversely altered and fail to properly restrain the child. A bedside commode or rental wheelchair maybe be necessary equipment for a child who is nonambulatory.

Parents are taught the proper care of the cast or brace, and are helped to devise means for maintaining cleanliness. A superabsorbent disposable diaper is tucked beneath the entire perineal opening of the cast. A larger diaper can be applied and fastened over the small diaper and cast to hold the smaller diaper in place. In the event that the larger diaper becomes wet or soiled, it is likely the cast is as well.

For tightly fitting casts, transparent film dressings can be cut into strips for petaling, with one edge applied to the cast edge and the other directly to the perineum; this forms a continuous, waterproof bridge between the perineum and the cast to prevent leakage. An additional advantage to the use of this transparent dressing is that it keeps both the skin and the cast dry while allowing for observation of skin beneath the dressing.

[a]For information on specially adapted molded-plastic chairs for children who have spica casts, contact R82 Inc. at 844-876-6245; http://www.r82.com. The E-Z-On vest is a special safety harness for larger children with poor trunk control. Additional safety restraints and a list of distributors are available from SafetyBeltSafe U.S.A., http://www.carseat.org. Another resource is the National Center for the Safe Transportation of Children with Special Health Care Needs; 800-543-6227; http://www.preventinjury.org/Special-Needs-Transportation/Child-Seats-for-Children-with-Special-Needs.

Fig. 29.7 Single spica cast. Note diaper to maintain dryness. (Courtesy Texas Children's Hospital, Houston, TX.)

Older infants and small children may stuff bits of food, small toys, or other items under the cast; parents should be alerted to this possibility so that they can initiate suitable preventive measures.

Feeding an infant in a hip spica cast offers problems in positioning. Very young infants can be fed in the supine position with the head elevated. With the infant's hips and legs supported on a pillow at the side, the parent can cuddle the infant in his or her arms during feeding. A somewhat similar position can be used for breastfeeding (i.e., with the infant supported on pillows or held in a "football" hold facing the mother with the legs behind her). An alternate position is to hold the infant upright on the caregiver's lap with the legs of the infant astride the adult's leg.

Children in spica casts usually find the prone position easier for self-feeding from a small table placed next to the dining table; alternatively, they may manage a semisitting position in bed or in a wheelchair (Fig. 29.7). The use of a conventional toilet is almost impossible. A bedside toilet can be adapted for use. Small bedpans or other containers offer alternatives for elimination. The nurse may suggest waterproofing methods by devising plastic wraps for elimination and showers. Baths are possible only if the plaster cast is kept out of the water and covered to prevent it from becoming wet.

Cast Removal

Cutting the cast to remove it or to relieve tightness is frequently a frightening experience for children. They fear the sound of the cast cutter and are terrified that their flesh, as well as the cast, will be cut. The oscillating blade vibrates rapidly back and forth and will not cut when placed *lightly* on the skin. Children have described it as producing a "tickly" sensation. The vibration also generates heat that may be felt by the child. Both of these feelings should be explained.

Preparation for the procedure will help reduce anxiety, especially if a trusting relationship has been established between the child and the nurse. Many young children come to regard the cast as part of themselves, which intensifies their fear of removal (Fig. 29.8). They need continual reassurance that all is going well and that their behavior is accepted. After the cast is removed, the parents and child should be given the option of keeping the cast. If the cast has been in place for a lengthy period, decreased muscle mass will be noted. The child should be reassured that resuming exercise and routine activities will return function and appearance (provided that there was no significant trauma beforehand).

Fig. 29.8 Young children come to regard a cast as part of their body.

After the cast is removed, the skin surface will be caked with desquamated skin and sebaceous secretions. Application of mineral oil (e.g., baby oil) or lotion may remove the particles as well as provide comfort. Soaking the extremity in a bathtub is usually sufficient for their removal, but it may take several days to eliminate the accumulation completely. The parents and child should be instructed not to pull or forcibly remove this material with vigorous scrubbing because it may cause excoriation and bleeding.

THE CHILD IN TRACTION

The ever-changing health care arena has witnessed the demise of many long-term treatments involving lengthy hospitalization; one such change is in the area of traction. Most balanced skeletal traction is applied in children after a severe or complex injury to allow physiologic stability, align bone fragments, and permit closer evaluation of the injured site. Newer technology has produced orthopedic fixation devices that allow partial or full mobility, thus preventing long-term immobilization and its consequences. In many situations, surgical intervention may be carried out within a matter of days; therefore skeletal traction devices described herein may be used infrequently in pediatrics.

Purposes of Traction

The six primary purposes of traction are:

1. To fatigue the involved muscles and reduce muscle spasm so that bones can be realigned
2. To position the distal and proximal bone ends in desired realignment to promote satisfactory bone healing
3. To immobilize the fracture site until realignment has been achieved and sufficient healing has taken place to permit casting or splinting
4. To help prevent or improve contracture deformity
5. To provide immobilization of specific areas of the body
6. To reduce muscle spasms (rare in children)

The three essential components of traction management are traction, countertraction, and friction (Fig. 29.9). To reduce or realign a fracture site, **traction** (forward force) is produced by attaching weight to the distal bone fragment. Body weight provides **countertraction** (backward force), and the patient's contact with the bed constitutes the **frictional** force. These forces are used to align the distal and proximal

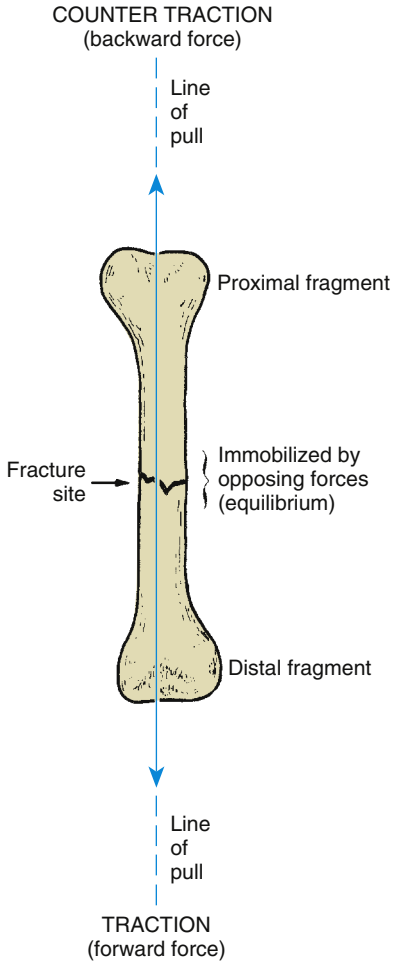

Fig. 29.9 Application of traction for maintaining equilibrium.

bone fragments by adjusting the line of pull upward or downward and adducting or abducting the extremity.

To attain equilibrium, the amount of forward force is adjusted by adding weight to or subtracting weight from the traction, or countertraction can be increased by elevating the foot of the bed to create a greater gravitational pull to the backward force.

The **all-or-none law**, characteristic of muscle contractibility, influences the complete relaxation. When muscles are stretched, muscle spasm ceases, which permits the realignment of the bone ends. The continuous maintenance of traction is important during this phase because releasing the traction allows the muscle's normal contracting ability to again cause a malpositioning of the bone ends.

The realignment of the fragments is a gradual process that is achieved more rapidly in infants, who have limited muscle tone, than in muscular teenagers. The desired vector force and callus formation are checked periodically by radiographic examination. The traction pull to some degree immobilizes the fracture site; however, adjunctive immobilizing devices such as splints or casts are sometimes used with skeletal traction. Immobilization with traction is maintained until the bone ends are in satisfactory realignment, after which a less confining type of immobilization—a cast, pins, or external stabilization device—is applied.

Types of Traction

The pull needed for traction can be applied to the distal bone fragment in several ways (Box 29.4). The type of traction applied is determined primarily by the child's age, the condition of the soft tissues, and the

BOX 29.4 Types of Traction

Manual traction: Applied to the body part by the hand placed distal to the fracture site. Manual traction may be provided during application of a cast but more commonly when a closed reduction is performed.

Skin traction: Applied directly to the skin surface and indirectly to the skeletal structures. The pulling mechanism is attached to the skin with adhesive material or an elastic bandage. Both types are applied over soft, foam-backed traction straps to distribute the traction pull.

Skeletal traction: Applied directly to the skeletal structure by a pin, wire, or tongs inserted into or through the diameter of the bone distal to the fracture.

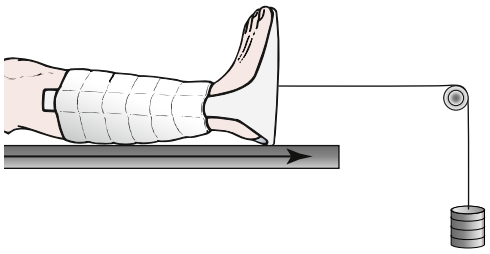

Fig. 29.10 Buck extension traction.

type and degree of displacement of the fracture. Fractures most commonly treated by application of traction are those involving the femur and vertebrae. The major types of traction for specific fractures are briefly discussed in the following paragraphs.

The use of upper extremity traction in children is uncommon. Newer surgical techniques allow for early mobilization and optimal results without traction. Nursing care of the child with upper extremity traction is the same as that for lower extremity traction, which is discussed later.

The frequent site for a femoral fracture is in the middle third of the shaft. With this fracture, there may be significant overriding but minimal displacement. In a fracture in the lower third of the shaft, the pull of the gastrocnemius muscle causes the distal fragment to become downwardly displaced.

Fractures of the femur can often be reduced with immediate application of a hip spica cast in young children. When traction is required, several types may be used based on the initial assessment.

Bryant traction is a type of running traction in which the pull is in only one direction. Skin traction is applied to the legs, which are flexed at a 90-degree angle at the hips. The child's trunk (with the buttocks raised slightly off the bed) provides countertraction.

Buck extension traction (Fig. 29.10) is a type of traction with the legs in an extended position. Except for fracture cases, turning from side to side with care is permitted to maintain the involved leg in alignment. Buck extension traction is used primarily for short-term immobilization, such as preoperative management of a child with a dislocated hip, or for correction of contractures or bone deformities, such as in Legg-Calvé-Perthes disease. Buck extension traction may be accomplished with either skin straps or a special foam boot designed for traction.

Russell traction uses skin traction on the lower leg and a padded sling under the knee. Two lines of pull, one along the longitudinal line of the lower leg and one perpendicular to the leg, are produced. This combination of pulls allows realignment of the lower extremity and immobilizes the hip and knee in a flexed position. The hip flexion must be kept at the prescribed angle to prevent fracture malalignment because there is no direct support under the fracture and the skin traction may slip. Special nursing measures include carefully checking the position of the traction so that the amount of desired hip flexion is maintained and damage to the common peroneal nerve under the knee does not produce foot drop.

A common skeletal traction is **90-degree–90-degree traction** (90-90 traction). The lower leg is supported by a boot cast or a calf sling, and a skeletal Steinmann pin or Kirschner wire is placed in the distal fragment of the femur, resulting in a 90-degree angle at both the hip and the knee. From a nursing standpoint, this traction facilitates position changes, toileting, and prevention of complications related to traction.

Balanced suspension traction may be used with or without skin or skeletal traction. Unless used with another traction, the balanced suspension merely suspends the leg in a desired flexed position to relax the hip and hamstring muscles and does not exert any traction directly on a body part. A **Thomas splint** extends from the groin to midair above the foot, and a **Pearson attachment** supports the lower leg. Towels or pieces of felt covered with stockinette are clipped or pinned to the splints for leg support. When the child is lifted off the bed, the traction lifts with the child without loss of alignment. This traction requires careful checking of splints and ropes to make certain that no slippage or fraying has occurred. The traction is of great value in an older and heavier child when it is essential to lift the patient for care.

The cervical area is a vulnerable site for flexion or extension injuries to muscle, vertebrae, or the spinal cord. Cervical muscle trauma without other complications is treated with a cervical hard collar to relieve the weight of the head from the fracture site. When a child displaces or fractures a cervical vertebra, it may be necessary to reduce and immobilize the site with cervical skeletal traction. The spinal cord runs through the intravertebral canal, and dislocation or fracture of the vertebrae can also cause spinal cord injury. Nursing assessment of neurologic function is essential to prevent further injury during the application and use of cervical skeletal traction.

Most cervical traction is accomplished with the use of a **halo brace** or **halo vest** (Fig. 29.11A). This device consists of a steel halo attached to the head by four screws inserted into the outer skull; several rigid bars connect the halo to a vest that is worn around the chest, thus providing greater mobility of the rest of the body while avoiding cervical spinal motion altogether. If the injury has been limited to a vertebral fracture without neurologic deficit, a halo brace can be applied to permit earlier ambulation. Gardner-Wells tongs may be used with cervical traction to immobilize the cervical spine (see Fig. 29.11B). Gardner-Wells tongs are spring loaded, so making burr holes and shaving hair are not required; a local anesthetic may be used during application. As the neck muscles fatigue with constant traction pull, the vertebral bodies gradually separate so that the cord is no longer pinched between the vertebrae. Immobilization until fracture healing or surgical fixation can occur is an essential goal of cervical traction. If immobilization is required in an infant or young child, a special cervical spine cast (Minerva cast) is applied.

Nursing Care Management

To assess the child in traction, it is essential to know the purpose for which the traction is applied and to understand the basic principles of traction. Regular assessment of both the child and the traction apparatus is required (see Nursing Care Guidelines box). Many of the nursing problems associated with a child in traction are related to immobility. Modifying the child's diet, encouraging fluids, increasing fiber, and offering a mild stool softener may be necessary to prevent constipation.

NURSING CARE GUIDELINES

Traction Care

Understand Therapy

Understand purpose of traction.
Understand function of traction in each specific situation.

Maintain Traction

Check desired line of pull and relationship of distal fragment to proximal fragment. Check whether fragment is being directed upward, adducted, or abducted.
Check function of each component:
- Position of bandages, frames, splints, specialized boot
- Ropes: In center track of pulley, taut, no fraying, knots tied securely
- Pulleys: In original position on attachment bar; have not slid from original site; wheels freely movable
- Weights: Correct amount of weight, hanging freely, in safe location

Check bed position: Head or foot elevated as directed for desired amount of pull and countertraction.
Do not remove skeletal traction or adhesive traction straps on skin traction.

Maintain Alignment

Observe for correct body alignment with emphasis on alignment of shoulder, hip, and leg.
Check after child has moved.
Maintain correct angles at joints.

Skin Traction

Replace nonadhesive straps or elastic bandage on skin traction *when permitted* or absolutely necessary, but make certain that traction on limb is maintained by someone during procedure.
Assess straps or bandages to ascertain if they are correctly applied (diagonal or spiral) and not too loose or too tight, which could cause slippage and malalignment of traction.
Assess traction boot to ensure that it has not slipped and is not causing compression of the foot, thus impairing the circulation.

Skeletal Traction

Check pin sites frequently for signs of bleeding, inflammation, or infection.
Cleanse and dress pin sites per institution protocol or as ordered.
Apply topical antiseptic or antibiotic to pin sites daily as ordered.
Cover ends of pins with protective rubber or padding to prevent child being scratched by pin.
Note pull of traction on pin; pull should be even.
Check pin screws to be certain that screws are tight in metal clamp that attaches traction apparatus to pin.

Prevent Skin Breakdown

Provide alternating-pressure mattress underneath hips and back.
Make total-body skin checks for redness or breakdown, especially over areas that receive greatest pressure.
Wash and dry skin at least daily.
Inspect pressure points daily or more often if risk for breakdown is observed.
Use a skin breakdown assessment scale, such as Braden Q.
Stimulate circulation with gentle massage over pressure areas.
Change position at least every 2 hours to relieve pressure.
Encourage increase in intake of oral fluids.
Provide and encourage patient to eat a balanced diet, including vegetables and fruits.

Prevent Complications

Check pulses in affected area and compare with pulses in contralateral site.
Assess circular dressings for excessive tightness.
Assess restrictive bandages or devices used to maintain traction on affected limb:
1. Make certain that they are not too loose or too tight.
2. Remove periodically and check for skin breakdown or pressure areas.

Encourage deep breathing or use of incentive spirometry:
- Monitor the 6 Ps (see Box 29.3).

Take immediate action to correct problem or report to practitioner if neurovascular changes are present.
Record findings of neurovascular changes.
Carry out passive, active, or active-with-resistance exercises of uninvolved joints.
Note if any tightness, weakness, edema, or contractures are developing in uninvolved joints and muscles.
Take measures to correct or prevent further development of weakness, such as applying footboard or foot orthoses to prevent foot drop.
When indicated by the attending practitioner, the nurse may remove nonadhesive skin traction. In these cases, intermittent traction is periodically released and reapplied as ordered. A child may have several types of traction at one time, and each one must be assessed separately to avoid problems.

NURSING ALERT

Skeletal traction is never released by the nurse (except under direct supervision by the practitioner). This precaution includes not lifting the weights that are applying traction (e.g., for moving the child in bed, for repositioning).

In addition to routine skin observation and care, the child in skeletal traction will need special skin care at the pin sites according to hospital policy or practitioner preference. Pin sites should be frequently assessed and cleaned to prevent infection; after the first 48 to 72 hours, pin site care may be performed once daily or weekly for mechanically stable pins (Holmes, Brown, & Pin Site Care Expert Panel, 2005). Use of a 2-mg/ml chlorhexidine solution has been proposed as best practice care for skeletal pin sites by the National Association of Orthopaedic Nurses (Smith, Dahlen, Bruemmer, et al., 2013). A pressure-reduction device, such as a pressure-reduction mattress, decreases the chance of skin breakdown.

NURSING TIP: A small hand mirror facilitates visualization of inaccessible skin areas.

When the child is first placed in traction, increased discomfort is common as a result of the traction pull fatiguing the muscle. It has been determined that orthopedic conditions are associated with a higher-than-average number of painful events and a higher percentage of bodily symptoms than other common conditions. Analgesics, including IV opioids, and muscle relaxants help during this phase of care and should be administered liberally.

NURSING ALERT

For skeletal traction to be effective, ensure that the weights are hanging freely at all times.

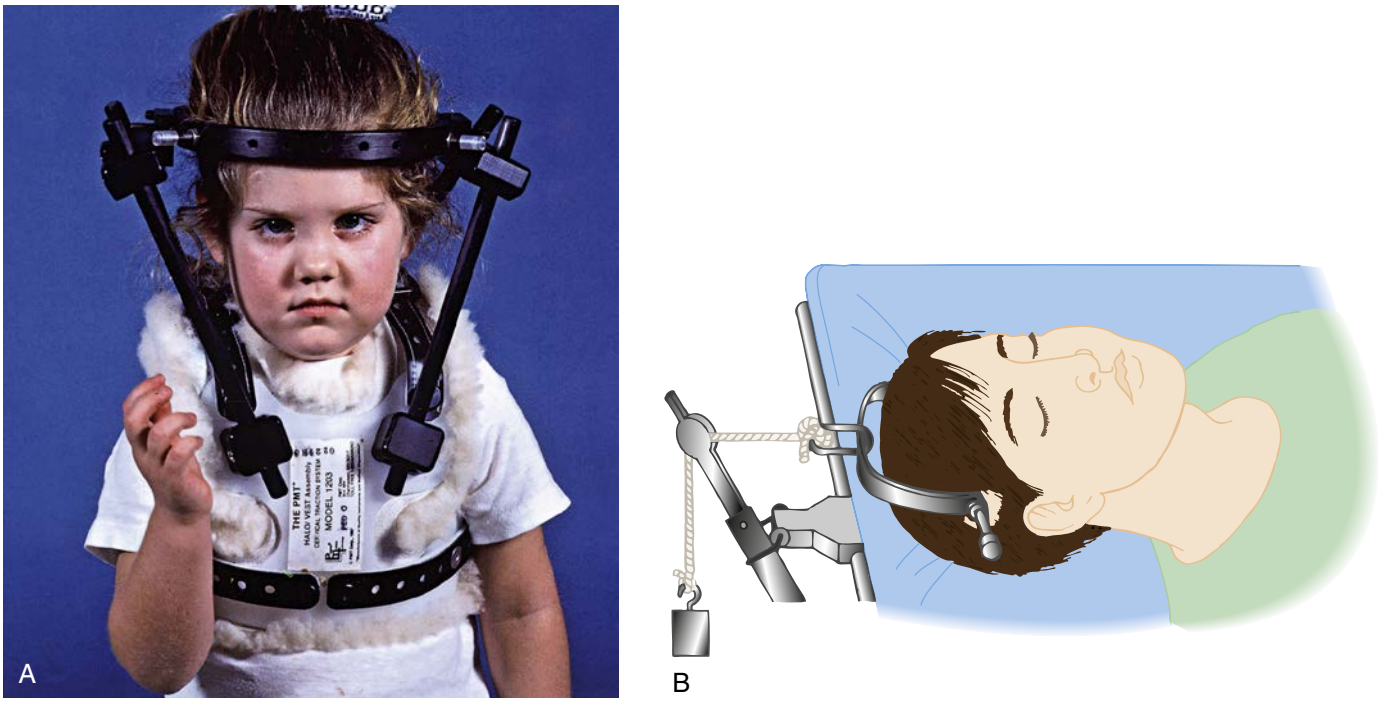

Fig. 29.11 A, Halo vest. B, Cervical traction with Gardner-Wells tong.

The specific nursing responsibilities for the patient in traction are outlined in the Nursing Care Guidelines box earlier.

DISTRACTION

Unlike traction, which helps bones realign and fuse properly, **distraction** is the process of separating opposing bone to encourage regeneration of new bone in the created space. Distraction can also be used when limbs are of unequal lengths and new bone is needed to elongate the shorter limb.

External Fixation

Monolateral, Taylor Spatial Frame, and **Ilizarov external fixators (IEFs)** are common external fixation devices. The IEF uses a system of wires, rings, and telescoping rods that permits limb lengthening to occur by manual distraction (Fig. 29.12). In addition to lengthening bones, the device can be used to correct angular or rotational defects or to immobilize fractures. The device is attached surgically by securing a series of external full or half rings to the bone with wires. External telescoping rods connect the rings to each other. Manual distraction is accomplished by manipulating the rods to increase the distance between the rings. A percutaneous osteotomy is performed when the device is applied to create a "false" growth plate. A special osteotomy or corticotomy involves cutting only the cortex of the bone while preserving its blood supply, bone marrow, endosteum, and periosteum. Capillary blood flow to the transected area is essential for proper bone growth. Cut bone ends typically grow at a rate of 1 cm (0.4 inch) per month. The IEF can result in up to a 15-cm (6-inch) gain in length.

Nursing Care Management

Success of the fixation devices depends on the child's and family's cooperation; therefore, before surgery, they must be fully informed of the appearance of the device, how it accomplishes bone growth and limits bone mobility, alterations in activities, and home and follow-up care. Children are involved in learning to adjust the device to accomplish distraction. Children and parents should be instructed in pin care, including observation for infection and loosening of the pins. Cleaning routines for the pin sites vary among practitioners but should not traumatize the skin.

Fig. 29.12 Child with Ilizarov external fixator (IEF; on right leg) during physical therapy on parallel bars.

Children who participate actively in their care report less discomfort. Because the device is external, the child and family need to be prepared for the reactions of others and assisted in camouflaging the device with appropriate apparel, such as wide-legged pants that close with self-adhering fasteners around the device. A loose sock or stockinette may also be used over the device to decrease public awareness. Partial weight bearing is allowed, and the child learns to walk with crutches. Alterations in activity include modifications at school and in physical education (PE). Full weight bearing is not allowed until the distraction is completed and bone consolidation has occurred. Follow-up care is

essential to maintain appropriate distraction until the desired limb length is achieved. The device is removed surgically after the bone has consolidated, and the child may need to use crutches or have a cast for 4 to 6 weeks after removal to reduce the risk of fracture.

AMPUTATION

A child may be born with the congenital absence of an extremity, have a traumatic loss of an extremity, or need a surgical amputation for a pathologic condition such as **osteosarcoma** (see later in chapter). With today's surgical technology and the quick thinking of bystanders who save a traumatically amputated body part, some children have had fingers and arms sewn back on with variable degrees of functional use regained.

! NURSING ALERT

For an amputated limb or body part that may be reattached, do the following:

1. Rinse limb gently with normal saline.
2. Loosely wrap limb in sterile gauze.
3. Place wrapped limb in a watertight bag.
4. Cool (without freezing) bag in ice water (do not pack in ice because this may harm tissue).
5. Label with child's name, date, and time, and transport with the child to the hospital.

Surgical amputation or the surgical repair of a permanently severed limb focuses on constructing an adequately nourished residual limb. A smooth, healthy, padded stump, free of nerve endings, is important in prosthesis fitting and subsequent ambulation. In some situations in which there is no vascular or neurologic deficit, a cast is applied to the stump immediately after the procedure, and a pylon, metal extension, and artificial foot are attached so that the patient can walk on the temporary prosthesis within a few hours.

Nursing Care Management

Stump shaping is done postoperatively with special elastic bandaging using a figure-eight bandage, which applies pressure in a cone-shaped fashion. This technique decreases stump edema, controls hemorrhage, and aids in developing desired contours so that the child will bear weight on the posterior aspect of the skin flap rather than on the end of the stump. Stump elevation may be used during the first 24 hours, but after this time the extremity should not be left in this position because contractures in the proximal joint will develop and seriously hamper ambulation. Monitoring proper body alignment will further decrease the risk of flexion contractures.

For older children and adolescents, arm exercises, bed pushups, and prosthesis-training programs using parallel bars help build up the arm muscles necessary for walking with crutches. Full range-of-motion exercises of joints above the amputation must be performed several times daily using active and isotonic exercises. Young children are often spontaneously active and require little encouragement.

Depending on the child's age, children or their parents will need to learn hygiene, including carefully washing with soap and water every day and checking for skin irritation, breakdown, and infection. A tube of stockinette or powder is used to slide the prosthesis on more easily. Skin must be checked carefully every time the prosthesis is removed, and prosthesis tolerance time must be adjusted to prevent skin breakdown.

For children who have had an amputation, **phantom limb sensation** is an expected experience because the nerve-brain connections

Fig. 29.13 A number of injuries may occur with sports participation.

are still present. Gradually, these sensations fade, although in many people who have had amputations, they persist for years. Preoperative discussion of this phenomenon will aid a child in understanding these "unusual feelings" and not hiding the experiences from others. Limb pain, especially pain that increases with ambulation, should be evaluated for the possibility of a **neuroma** at the free nerve endings in the stump or other problems such as a poorly fitting prosthesis or joint instability.

SPORTS PARTICIPATION AND INJURY

Every sport has the potential for injury to participants—whether an adolescent engages in serious competition or participates for enjoyment. Serious injury occurs most often during rough contact sports or to persons who are not physically prepared for the activity. Injuries also occur when the children's or adolescents' bodies are not suited to the sport, when their muscles and body systems (respiratory and cardiovascular) are not conditioned to endure physical stress, or when they lack the insight and judgment to recognize that an activity exceeds their physical abilities. Rapidly growing bones, muscles, joints, and tendons are especially vulnerable to unusual strain. In general, more injuries occur during recreational sports participation than during organized athletic competition.

The environment and the sports or recreational equipment can also present risks (Fig. 29.13). Children and adolescents who participate in physical activity or sports do so in many different environments, including indoors and outdoors, on floors, on the ground and snow, on or beneath water surfaces, and sometimes in free air space. Most of these activities also involve equipment, which children and adolescents may not be physically mature enough to manage safely. A common example is skateboarding when the child or adolescent does not take safety precautions and perceives increased risk taking as a part of the sport.

Acute overload injuries are those that occur suddenly during an activity and produce immediate symptoms. A blow or overstretching, twisting, or sudden stress to tissues can cause these injuries. For descriptions and management of traumatic injuries, see earlier in the chapter.

OVERUSE SYNDROMES

To excel in sports, young athletes are forced to train longer, harder, and earlier in life than previously. The rewards are an increased level of fitness, better performance, faster times, and the satisfaction of

attaining a personal goal. However, risks are associated when young people overtrain; these risks include recurrent upper respiratory infections, sleep and mood disturbances, loss of appetite, decreased interest in training and competition, and inability to concentrate (Winsley & Matos, 2011). Annually, 3.5 million children are injured participating in sports and athletic activities (Mickalide & Hansen, 2012). Growing numbers of young people participate in organized sports, resulting in an increase in overuse injuries. Nearly half of all injuries evaluated in pediatric sports medicine are overuse injuries (Biber & Gregory, 2010).

The risk of overuse injury is always present and can be related to several factors, including training errors, muscle or tendon imbalance, anatomic malalignment (e.g., femoral anteversion, excessive lumbar lordosis, tibial torsion), incorrect footwear or playing surface, an associated disease state, and growth (growth cartilage is less resistant to microtrauma). Chronic pain in athletes is often associated with overuse injury, which can occur at any level of athletic participation. The common feature in overuse injuries is the **repetitive microtrauma** that occurs to a particular anatomic structure. Performing the same movements repeatedly can cause several types of injury:

1. **Frictional,** or rubbing of one structure against another
2. **Tractional,** or repeated pull on a ligament or tendon
3. **Cyclic,** or repetitive loading of impact forces (stress fractures)

The end result is inflammation of the involved structure with complaints of pain, tenderness, swelling, and disability.

Stress Fractures

Stress fractures are a consequence of repetitive, excessive stress on the bone that causes microfractures within the bone. Continued stress to the bone can lead to spread of the microfracture and eventual macrofracture. The pathogenesis of stress injury to the bone is multifactorial and includes everything from the footwear to the fitness level of the athlete. Stress fractures occur most commonly in the lower extremities, particularly the tibia. High school athletes at high risk for stress fractures are those who participate in cross country running and gymnastics (Changstrom, Brou, Khodaee, et al., 2015).

The most common symptom of stress fracture is a sharp, persistent, progressive pain or a deep, persistent dull ache located over the bone. Sometimes there is pain on impact (heel strike), but the most important clinical sign is pain over the involved bony surface. Diagnosis is based on clinical observation and history. Plain radiographs are rarely diagnostic of stress fractures during the initial few weeks because callus formation is not yet evident. Magnetic resonance imaging (MRI) is used when other causes of pain must be ruled out.

Therapeutic Management

Development of inflammation is common to all overuse syndromes; therefore management involves rest or alteration of activities, physical therapy, and medication. Rest is the primary therapy, usually interpreted as reduced activity and the use of alternative exercise—not bed rest or immobilization with an orthosis. The main purpose is to alleviate the repetitive stress that initiated the symptoms. It is important to keep the adolescent mobile, and training can be continued. Alternative exercise that maintains conditioning without aggravating the injury is selected. For example, pool running (treading water in the deep end of a pool) can use the same movements as running but without the weight bearing; bicycling, swimming, and rowing are viable alternatives.

Other modalities include cryotherapy and cold whirlpool baths. Sometimes taping, bracing, splinting, and other orthoses are used, depending on the injury. **Nonsteroidal antiinflammatory drugs (NSAIDs)** are often prescribed to reduce inflammation and pain. Topical medications are of questionable value.

NURSE'S ROLE IN SPORTS FOR CHILDREN AND ADOLESCENTS

Nurses are often involved in sports activities in the areas of preparation and evaluation for activities, prevention of injury, treatment of injuries, and rehabilitation after injury. Selecting an appropriate sport for both recreation and competition is a joint effort of the adolescent, parents, and health professionals. The best approach to counseling children, adolescents, and parents regarding sports participation is to encourage activities that are most likely to provide pleasure and physical benefits throughout childhood and into adulthood. Exposure to a variety of activities is better for young children than limiting them to one sport. Parents should be cautioned against overcommitting children to sports activities so that they have time for other activities.

When children sustain athletic injuries, nurses are often responsible for instructions regarding care. Instructions (e.g., schedule for appointments, application of ice, any restrictions in activity) should be clear and accompanied by written directions. The importance of taking medications as prescribed is emphasized, especially if medications are needed for an extended period and if adherence is an issue. Antiinflammatory medications given an hour before practice or competition may help children continue their activities.

Prevention of sports injuries is the most important aspect of athletic programs. Children should be suited to the activity, and the environment and the equipment must be safe. Children should be prepared for the sport, especially if it requires strenuous or continuous physical exertion. Nurses, coaches, and athletic trainers must collaborate to ensure that safety measures are implemented. Stretching exercises, warm-up and cool-down activities, and appropriate training are requirements for safe participation. Protective measures such as pads, taping, and wrapping are also important to prevent injury. Finally, nurses must be aware of environmental safety risks (see Chapter 27, Head Injury).

BIRTH AND DEVELOPMENTAL DEFECTS

Some skeletal defects may be diagnosed at birth or within days, weeks, or months after birth. In other cases, the deviation may be difficult to detect without careful inspection. Therefore it is imperative that nurses become acquainted with signs of these defects and understand the principles of therapy in order to direct families in the care and management of these children.

DEVELOPMENTAL DYSPLASIA OF THE HIP

The broad term **developmental dysplasia of the hip (DDH)** describes a spectrum of disorders related to abnormal development of the hip that may occur at any time during fetal life, infancy, or childhood. A change in terminology from *congenital hip dysplasia* and *congenital dislocation of the hip* to DDH more properly reflects a variety of hip abnormalities in which there is a shallow acetabulum, subluxation, or dislocation.

The incidence of hip dysplasia varies depending on ethnicity or race but is approximately 1 to 2 infants per 1000 live births in the United States. Girls are affected more commonly than boys, and a positive family history increases a child's risk of having DDH. Approximately 7% to 40% of infants with DDH have a breech intrauterine position (Loder & Skopelja, 2011a).

Pathophysiology

The cause of DDH is unclear but is likely multifactorial. Certain factors such as gender, birth order, family history, intrauterine position, joint laxity, and postnatal positioning are believed to affect the risk of DDH.

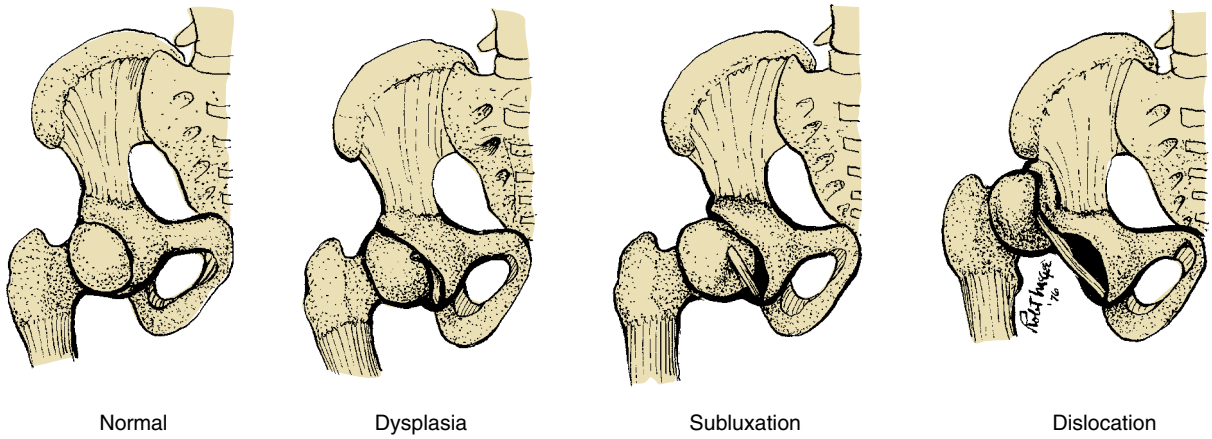

Fig. 29.14 Configuration and relationship of structures in developmental dysplasia of the hip (DDH).

Predisposing factors associated with DDH may be divided into three broad categories: (1) physiologic factors, which include maternal hormone secretion and intrauterine positioning; (2) mechanical factors, which involve breech presentation, multiple fetus, oligohydramnios, and large infant size as well as swaddling where the hips are maintained in adduction and extension, which in time may cause a dislocation; and (3) genetic factors, which entail a higher incidence of DDH in siblings of affected infants and an even greater incidence of recurrence if a sibling and one parent were affected.

Some experts categorize DDH into two major groups: (1) **idiopathic**, in which the infant is neurologically intact, and (2) **teratologic**, which involves a neuromuscular defect, such as arthrogryposis or myelodysplasia. The teratologic forms usually occur in utero and are much less common.

Three degrees of DDH are illustrated in Fig. 29.14.

1. **Acetabular dysplasia:** This is the mildest form of DDH, in which there is a delay in acetabular development evidenced by osseous hypoplasia of the acetabular roof that is oblique and shallow, although the cartilaginous roof is comparatively intact. The femoral head remains in the acetabulum.
2. **Subluxation:** The largest percentage of DDH, subluxation, implies incomplete dislocation of the hip. The femoral head remains in contact with the acetabulum, but a stretched capsule and ligamentum teres cause the head of the femur to be partially displaced. Pressure on the cartilaginous roof inhibits ossification and produces a flattening of the socket.
3. **Dislocation:** The femoral head loses contact with the acetabulum and is displaced posteriorly and superiorly over the fibrocartilaginous rim. The ligamentum teres is elongated and taut.

Factors related to infant handling are indicated in the Cultural Considerations box.

CULTURAL CONSIDERATIONS

Developmental Dysplasia of the Hip

A striking relationship exists between the development of hip dislocation and methods of swaddling the hips. Among the cultures with the highest incidence of dislocation (Navajo Indians and Canadian Natives), newly born infants are tightly wrapped with the hips adducted and extended in blankets or other swaddling material or are strapped to cradle boards. In cultures such as those in Central and South America, Asia, and Africa, where mothers traditionally carry infants on their backs with the infants' hips in the abducted and flexed position, hip dysplasia is much less common.

Recently, several prominent orthopedic specialty organizations recommended that infants' hips be placed in slight flexion and abduction during swaddling. It was further recommended that infants' knees be maintained in slight flexion and that forced or sustained passive hip extension in the first few months should be avoided (Price & Schwend, 2011). These recommendations were supported by evidence that demonstrated a significant relationship between tight swaddling and hip dysplasia, and are aimed at decreasing the incidence of hip dysplasia in infants.

Diagnostic Evaluation

DDH is often not detected at the initial examination after birth; thus all infants should be carefully monitored for hip dysplasia at follow-up visits throughout the first year of life at routine well-child checks. In the newborn period, hip dysplasia usually appears as hip joint laxity rather than as outright dislocation. Subluxation and the tendency to dislocate can be demonstrated by the Ortolani or Barlow maneuvers (Fig. 29.15D). The Ortolani and Barlow tests are most reliable from birth to 4 weeks of age. With the Barlow test, the thigh is adducted and light pressure is applied to see if the femoral head can be felt to slip posteriorly out of the acetabulum. The Ortolani test involves abducting the thighs and placing anterior pressure at the hip to see if the femoral head slips forward into the acetabulum. Other signs of DDH are shortening of the limb on the affected side (see Fig. 29.15C), asymmetric thigh and gluteal folds (see Fig. 29.15A), and decreased hip abduction on the affected side (see Fig. 29.15B). See Box 29.5.

! NURSING ALERT

These tests must be performed by an experienced clinician to prevent an injury to the infant's hip.

Radiographic examination in early infancy is not reliable because ossification of the femoral head does not normally take place until the fourth to sixth month of life. However, the cartilaginous head can be visualized directly by ultrasonography. Universal newborn screening with ultrasonography has been proposed; however, numerous studies reveal that this approach has a high rate of false-positive results and subsequent overtreatment. Therefore ultrasonography is recommended as an adjunct to the physical examination (Shaw & Segal, 2016).

In infants older than 6 months of age and in children, radiographic examination is useful in confirming the diagnosis. An upward slope in the roof of the acetabulum (acetabular angle) greater than 30 degrees with upward and outward displacement of the femoral head is seen in an infant with hip dysplasia, and the acetabular angle should continue to decrease with age.

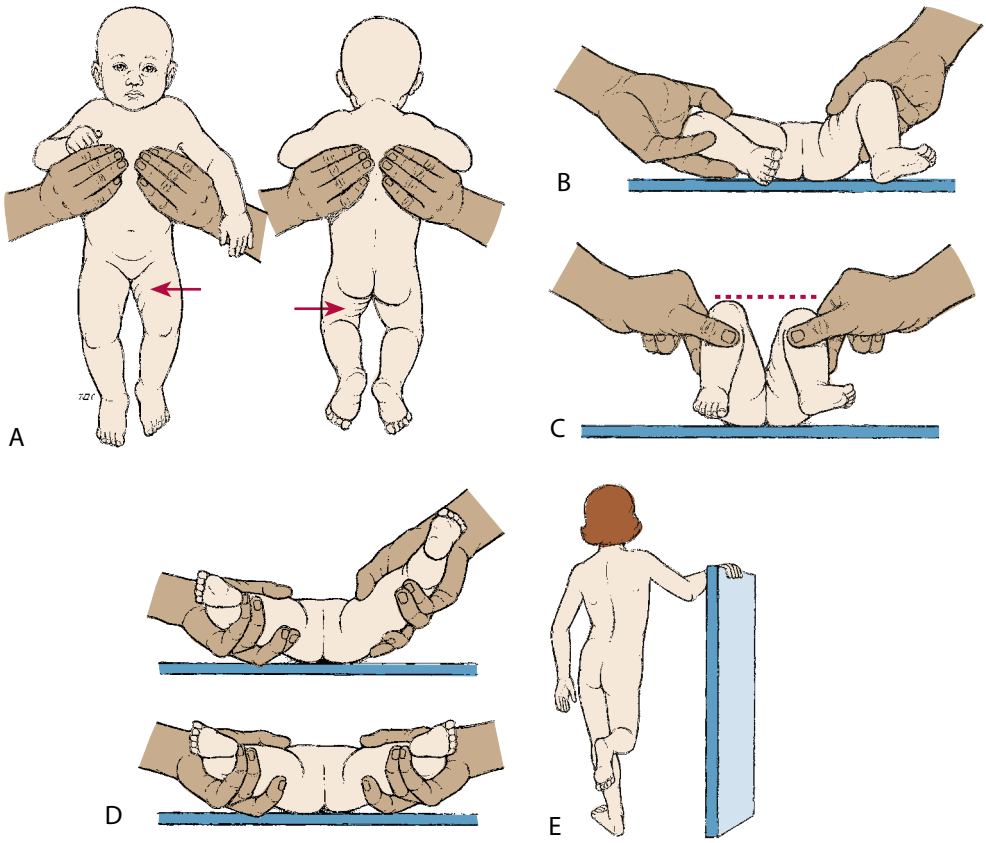

Fig. 29.15 Signs of developmental dysplasia of the hip (DDH). **A,** Asymmetry of gluteal and thigh folds. **B,** Limited hip abduction, as seen in flexion. **C,** Apparent shortening of the femur, as indicated by the level of the knees in flexion (Galeazzi sign). **D,** Ortolani maneuver with clunk elicited. **E,** Positive Trendelenburg sign (if child is weight bearing).

BOX 29.5 Clinical Manifestations of Developmental Dysplasia of the Hip

Infants

Shortening of limb on affected side (Galeazzi sign)
Restricted abduction of hip on affected side
Unequal gluteal folds (best visualized with infant prone)
Positive Ortolani test (hip is reduced by abduction)
Positive Barlow test (hip is dislocated by adduction)

Older Infants and Children

Affected leg appears shorter than the other
Telescoping or piston mobility of joint: Head of femur felt to move up and down in buttock when extended thigh is pushed first toward child's head and then pulled distally
Trendelenburg sign: When child stands first on one foot and then on the other (holding onto a chair, rail, or someone's hands) bearing weight on affected hip, pelvis tilts downward on normal side instead of upward, as it would with normal stability
Greater trochanter prominent and appearing above a line from anterosuperior iliac spine to tuberosity of ischium
Marked lordosis and waddling gait (bilateral hip dislocation)

Therapeutic Management

Treatment is begun as soon as the condition is recognized because early intervention is more favorable to the restoration of normal bony architecture and function. The longer treatment is delayed, the more severe the deformity, the more difficult the treatment, and the less favorable the prognosis. The treatment varies with the child's age and the extent of the dysplasia. The goal of treatment is to obtain and maintain a safe, congruent position of the hip joint to promote normal hip joint development.

Newborns to Age 6 Months

The hip joint is maintained, by dynamic splinting, in a safe position with the proximal femur centered in the acetabulum in a degree of flexion. Of the numerous devices available, the **Pavlik harness** is the most widely used, and with time, motion, and gravity, the hip works into a more abducted, reduced position (Fig. 29.16). The harness is worn continuously, 22 to 24 hours per day depending on the severity of dysplasia, until the hip is proved stable on both clinical and ultrasound examination, usually within 6 to 12 weeks.

When there is difficulty in maintaining stable reduction of the femoral head, a surgical closed reduction of the hip and application of a hip spica cast is performed. The cast is changed periodically to accommodate the child's growth. Once sufficient stability is acquired, after approximately 3 months, the child is transitioned to a removable hip abduction orthosis. The duration of treatment in the orthosis depends on development of the acetabulum.

Ages 6 to 24 Months

In this age-group, the dislocation is often not recognized until the child begins to stand and walk, when shortening of the limb and contractures of hip adductor and flexor muscles become apparent. In less severe DDH or acetabular dysplasia, use of a hip abduction orthosis may be initiated. Duration of treatment depends on development of the acetabulum. When adduction contracture is present, devices such

Fig. 29.16 Child in Pavlik harness. (Courtesy Amanda Politte, St. Louis, MO.)

as traction may be used to slowly and gently stretch the hip to full abduction, after which wide abduction is maintained until stability is attained. A surgical closed reduction of the hip is performed in cases of hip subluxation or dislocation, and in the event that the hip remains unstable, an open reduction may be necessary. The child is placed in a spica cast for approximately 12 weeks, and a hip abduction orthosis may be used following casting.

Older Children

Correction of the hip deformity in older children is inherently more difficult than in the preceding age-groups because secondary adaptive changes and other etiologic factors (such as juvenile arthritis and cerebral palsy) complicate the condition. Operative reduction, which may involve preoperative traction, lengthening of contracted muscles, and pelvic osteotomy procedures designed to construct an acetabular roof, often combined with proximal femoral osteotomy, are usually required. After cast removal, range-of-motion exercises help restore movement. Other rehabilitation measures may include muscle strengthening, a period of crutch or walker use, and gait training.

Nursing Care Management

Nurses are in a unique position to detect DDH in early infancy. During the infant assessment process and routine nursing activities, the hips and extremities are inspected for any deviations from normal. Any observations or concerns are reported to the attending provider. An ambulatory child who displays a limp or an unusual gait should be referred for evaluation. This may indicate an orthopedic or neurologic problem. Nonambulatory children with cerebral palsy should also be assessed for evidence of hip problems throughout their growing years.

The major nursing problems in the care of an infant or child in a cast or other device are related to maintenance of the device and adaptation of nurturing activities to meet the patient's needs. Generally, treatment and follow-up care of these children are carried out in an outpatient setting.

! NURSING ALERT

The former practice of double or triple diapering for developmental dysplasia of the hip (DDH) is not recommended because there is no evidence to support its efficacy.

The primary nursing goal is teaching parents to apply and maintain the reduction device. The Pavlik harness allows for easy handling of the infant and usually produces less apprehension in the parent than heavy braces and casts. It is important that parents understand the correct use of the harness, which may or may not allow for its removal during bathing. Removing the harness is determined individually on the basis of the provider's recommendation, the degree of hip instability, and the family's level of understanding. Parents are instructed to not adjust the harness. The child should be examined by the provider before any adjustment is attempted to make certain the hips are in correct placement.

Skin care is an important aspect of the care of an infant in a harness. The following instructions for preventing skin breakdown are stressed:

- Check frequently (at least two or three times a day) for red areas or skin irritation in skin folds or under the straps.
- Gently massage healthy skin under the straps once a day to stimulate circulation. In general, avoid lotions and powders because they can cake and irritate the skin.
- Always place the diaper under the straps.

Parents are encouraged to hold the infant with a harness and continue care and nurturing activities. The nurse can assist by being available for parents' questions about the necessary adaptations to daily care to decrease the parents' anxiety and possible feelings about the child being hurt by routine caring.

Casts and orthotic devices (braces) offer more challenging nursing and caregiver problems because they cannot be removed for routine care, although sometimes a brace may be removed for bathing. Care of an infant or small child with a cast requires nursing innovation to reduce irritation and to maintain cleanliness of both the child and the cast, particularly in the diaper area (see earlier in the chapter for care of the child in a cast).

It is important for nurses, parents, and other caregivers to understand that children in corrective devices need to be involved in all typical age-appropriate activities. Confinement in a cast or appliance should not exclude children from family (or unit) activities. They can be held astride the lap for comfort and transported to areas of activity. An adapted wheelchair, stroller, or wagon can offer mobility to an older infant or child.

CLUBFOOT

Clubfoot or talipes equinovarus (TEV) is a complex deformity of the ankle and foot that includes forefoot adduction, midfoot supination, hindfoot varus, and ankle equinus. The foot is pointed downward (plantarflexed) and inward in varying degrees of severity (Fig. 29.17). Clubfoot may occur as an isolated deformity or in association with other disorders or syndromes, such as chromosomal abnormalities, arthrogryposis, or spina bifida.

The incidence of clubfoot in the general population is approximately 1 per 1000 live births, with boys affected twice as often as girls. Bilateral clubfeet occur in 50% of the cases (Winell & Davidson, 2020). The precise cause of clubfoot is unknown. However, there is a strong familial tendency, with a 1 in 10 chance that a parent with clubfoot will have an affected offspring. Other possible theories as to the cause of clubfoot include arrested or abnormal fetal development or abnormal positioning and restricted movement in utero, although the evidence is not conclusive. Whereas arrested development during this early stage tends to result in a rigid deformity, mechanical pressures from intrauterine positioning are likely causes of more flexible deformities (Shyy, Wang, Sheffield, et al., 2010).

Clubfoot may be further divided into three categories: (1) positional clubfoot (also called *transitional, mild,* or *postural clubfoot*), which is

Fig. 29.17 Bilateral congenital talipes equinovarus (TEV; clubfoot) in a 2-month-old infant. (From Zitelli, B. J., McIntire, S. C., & Nowalk, A. J. [2012]. *Zitelli and Davis' atlas of pediatric physical diagnosis* [6th ed]. St. Louis, MO: Saunders/Elsevier.)

Fig. 29.18 Feet casted for correction of bilateral talipes equinovarus (TEV).

believed to occur primarily from intrauterine crowding and responds to simple stretching and casting; (2) congenital clubfoot, also referred to as *idiopathic*, which may occur in an otherwise normal child and has a wide range of rigidity and prognosis; and (3) syndromic (or teratologic) clubfoot, which is associated with other congenital anomalies (such as myelomeningocele or arthrogryposis) and is a more severe form of clubfoot that is often resistant to typical treatment.

Classification

The positional clubfoot may correct spontaneously or may require passive exercise or serial casting. There is no bony abnormality, but there may be tightness and shortening of the soft tissues medially and posteriorly. The teratologic clubfoot usually requires surgical correction and has a high incidence of recurrence. The congenital idiopathic clubfoot, or "true clubfoot," almost always requires casting coupled with surgical intervention, usually a heel-cord tenotomy.

Diagnostic Evaluation

The deformity is readily apparent at birth if it has not been detected prenatally through ultrasonography. However, it must be differentiated from some positional deformities that can be passively corrected. Once it is detected, a careful yet comprehensive physical assessment of the affected foot (or feet) should be completed to allow for appropriate decision making regarding treatment plans and prognosis. The affected foot (or feet) is usually smaller and shorter with an empty heel pad and midfoot medial crease. When the deformity is unilateral, the affected limb may be shorter and calf atrophy is present. Radiographs of the feet are generally not necessary. A thorough hip examination should be performed for all infants with clubfoot; an increased risk of hip dysplasia is associated with clubfoot deformities.

Therapeutic Management

The goal of treatment for clubfoot is to achieve a painless, plantigrade, and functional foot. Treatment of clubfoot involves three stages: (1) correction of the deformity, (2) maintenance of the correction until normal muscle balance is regained, and (3) follow-up observation to avert possible recurrence of the deformity. Some feet respond to treatment readily; some respond only to prolonged, vigorous, and sustained efforts; and the improvement in others remains disappointing even with maximal effort.

Recommended treatment of clubfoot is with the use of the Ponseti method. Serial casting is begun shortly after birth. Weekly gentle manipulation and stretching of the foot along with placement of serial long leg casts allow for gradual improvement in the alignment of the foot (Fig. 29.18). The extremity or extremities are casted until maximum correction is achieved, usually within 6 to 10 weeks. The majority of the time, a percutaneous heel-cord tenotomy is performed at the end of casting to correct the equinus deformity. After the tenotomy, a long leg cast is applied and left in place for 3 weeks. After casting is completed, children are transitioned to using Ponseti sandals with a bar set in abduction to help maintain the correction and prevent a recurrence of the foot deformity. Inability to achieve normal foot alignment after casting and tenotomy indicates the need for surgical intervention (Ponseti, 1996).

Nursing Care Management

Nursing care of the child with clubfoot is the same as for any child who has a cast (see earlier in the chapter). Because the child will spend considerable time in a corrective device, nursing care plans include both long- and short-term goals. Careful observation of the skin and circulation is particularly important in young infants because of their rapid growth rate.

Because treatment and follow-up care are handled in the orthopedic clinic or outpatient department, parent education and support are important in nursing care of these children. It is important for parents to understand the diagnosis, the overall treatment program, the importance of regular cast changes, and the role they play in the long-term effectiveness of the therapy. Reinforcing and clarifying the orthopedic provider's explanations and instructions, teaching parents about care of the cast or bracing (including vigilant observation for potential problems), and encouraging parents to facilitate normal development within the limitations imposed by the treatment are all part of nursing responsibilities.

METATARSUS ADDUCTUS (VARUS)

Metatarsus adductus, or metatarsus varus, is probably the most common congenital foot deformity. In most instances, it is a result of abnormal intrauterine positioning, particularly in a firstborn child, and is usually detected at birth. The deformity is characterized by medial adduction of the toes and forefoot, frequently in association with inversion and convexity of the lateral border of the foot (kidney shaped). Metatarsus adductus may be divided into three categories:

- Type I: The forefoot is flexible and corrects easily with manipulation
- Type II: The forefoot is only partial flexible and corrects passively past neutral position but only to neutral position with active manipulation
- Type III: The forefoot is rigid and will not stretch to neutral position with manipulation

Unlike a clubfoot, with which it is often confused, the angulation occurs at the tarsometatarsal joint while the heel and ankle remain in a neutral position. Ankle range of motion is normal. This deformity may cause a pigeon-toed or intoeing gait in the child. A thorough hip examination should be performed for all infants with metatarsus adductus, as an increased risk of hip dysplasia is associated with foot deformities.

Management depends on the rigidity and type of the deformity. Most cases of metatarsus adductus are types I and II and generally correct spontaneously. Gentle manipulation and passive stretching of the foot, which the parent is taught to perform, can be added and may help in this correcting more quickly. With type III, the child usually requires serial manipulation and casting to correct the deformity, after which a corrective shoe or orthosis may be used. Surgical correction is rarely required for the condition but may be performed in children older than 4 to 6 years of age who have considerable pain on ambulation or functional difficulties as a result of the deformity (Winell & Davidson, 2020).

Nursing Care Management

The nursing role primarily involves identifying the defect so that early therapy and instruction of the parents can be initiated. The nurse teaches the parents how to hold the heel firmly and to stretch only the forefoot; otherwise, undue force on the heel may produce a valgus deformity. If casting or an orthosis is required, the nurse instructs the parents in cast care and use of the brace.

SKELETAL LIMB DEFICIENCY

Congenital limb deficiencies, or reduction malformations, are manifested by a variety of degrees of loss of functional capacity. They are characterized by underdevelopment of skeletal elements of the extremities. The range of malformation can extend from minor defects of the digits to serious abnormalities, such as **amelia**, absence of an entire extremity, or **meromelia**, partial absence of an extremity, which includes **phocomelia** (seal limbs), an interposed deficiency of long bones with relatively good development of hands and feet attached at or near the shoulder or the hips. Most reduction defects are primary defects of development of the limb, but prenatal destruction of the limb can occur, such as full or partial amputation of a limb in utero from constriction of an amniotic band (**amniotic band syndrome**). Neonates with congenital limb deficiencies often have associated malformations and should be thoroughly assessed for cardiovascular, central nervous system (CNS), renal, and digestive abnormalities (Stoll, Alembik, Dott, et al., 2010).

Pathophysiology

Limb deficiencies can be attributed to both heredity and environment and can originate at any stage of limb development. Formation of limbs may be suppressed at the time of limb bud formation, or there may be interference in later stages of differentiation and growth. Heredity appears to play a prominent role, and prenatal environmental insults have been implicated in a number of cases, such as the well-publicized **thalidomide** tragedy of the 1950s and early 1960s, which demonstrated a clear relationship between the time of exposure of the pregnant woman to the antiemetic drug and the presence and type of limb deformity in the newborn. There are still drugs that may have similar **teratogenic** effects in the first trimester of pregnancy. Therefore medication administration during this period should be carefully evaluated by the provider.

Therapeutic Management

The child with a limb deficiency should be fitted with prosthetic devices, and the devices should be applied at the earliest possible stage of development in an attempt to match the infant's motor readiness. This favors natural progression of prosthetic use. For example, an infant with an upper extremity deficiency is fitted with a simple passive device between 3 to 6 months old to encourage limb exploration, sitting (with the extremities needed for support), and bilateral hand activities. Lower limb prostheses are applied when the infant is ready to pull to a standing position.

In preparation for prosthetic devices, surgical modification of the residual limb may be necessary to ensure the most effective use of the device or prosthetic. Phocomelic digits are preserved for controlling switches of externally powered appliances in the upper extremities. Digits (in both the upper and the lower extremities) provide the child with surfaces for tactile exploration and stimulation. Prostheses are replaced to accommodate the child's growth and increasing capabilities.

Nursing Care Management

Prosthetic application, training, and use are most successfully carried out in a center that specializes in meeting the special needs of these children, especially very young children and those with multiple amputations or missing limbs. Management involves a **prosthetist**, who specializes in the development, fitting, and maintenance of prosthetic limbs, and other health care providers, such as physical and occupational therapists. Parents need support and are encouraged to assist the child in making age-appropriate adjustments to the environment. Although these children need assistance, overprotection may produce overdependence, with later maladjustment to school and other situations.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI) is a rare genetic disorder characterized by bones that fracture easily. Although inheritance follows an autosomal dominant pattern in most cases, rare autosomal recessive inheritance exists. Most types of OI have defects in the *COL1A1* or *COL1A2* genes, which code for polypeptide chains in type 1 procollagen, a precursor of type 1 collagen, which is a major structural component of bone. The error results in faulty bone mineralization, abnormal bone architecture, and increased susceptibility to fracture. There are at least 12 described types of OI, which accounts for significant disease variability. Clinical features may include varying degrees of bone fragility and deformity, short stature, blue sclerae, hearing loss, and dentinogenesis imperfecta (hypoplastic discolored teeth) (Marini & Blissett, 2013).

Classification is based on clinical features and patterns of inheritance (Box 29.6). Clinically, type I is the most common and mildest form, with most fractures occurring before puberty. Stature is near normal and bone deformity is minimal or absent. Type II is the most severe and is considered lethal in infancy. Type III OI is characterized by multiple fractures often present at birth, short stature, severe bone deformity, and disability with a shortened life expectancy. Type IV is similar to type I although slightly more severe, with short stature and mild to moderate bone deformities. Types V and VI do not have a type 1 collagen defect and are clinically similar to type IV. Both types demonstrate a unique pattern to their bone. Individuals affected have hypertrophic callus formation at fracture sites, a radiodense metaphyseal band, and calcification of the interosseous membrane of the forearm. In type VI, bone has

BOX 29.6 Classification of Osteogenesis Imperfecta[a]

Type I[a,b]
- **A:** Mild bone fragility; blue sclerae; normal teeth; hearing loss (occurs between 20 and 30 years old); autosomal dominant inheritance
- **B:** Same as A except dentinogenesis imperfecta instead of normal teeth
- **C:** Same as B but no bone fragility

Type II: Lethal; stillborn or die in early infancy; severe bone fragility, multiple fractures at birth; 10% of cases of OI; autosomal recessive inheritance

Type III: Severe bone fragility leading to severe progressive deformities; normal sclerae; marked growth failure; most autosomal recessive inheritance; few autosomal dominant inheritance

Type IV
- **A:** Mild to moderate bone fragility; normal sclerae; normal teeth; short stature; variable deformity; autosomal dominant inheritance
- **B:** Same as A except dentinogenesis imperfecta instead of normal teeth; approximately 6% of cases of OI

Type V: Clinically similar to type IV; hyperplastic callus; collagen mutation negative

Type VI: Sclerae and dentition normal; moderate to severe bone fragility; diagnosis by bone biopsy because of similarities to other types

Types VII and VIII (recessive form): Clinically overlap types II and III but have white sclerae, rhizomelia, and small to normal head circumference; severe osteochondroplastica and short stature in survivors. Type VII is associated with *CRTAP* gene, and type VIII is associated with the *LEPRE1* genetic mutation.

[a] Two-thirds of cases are type I.
[b] This classification is based on that proposed by Sillence, D. O., Senn, A., & Danks, D. M. (1979). Genetic heterogeneity in osteogenesis imperfecta. *Journal of Medical Genetics, 16*(2), 101–116, which originally included OI types I to IV. Additional types have been described but are not included herein.
OI, Osteogenesis imperfecta.

a characteristic mineralization defect or microscopic "fish scale" appearance with elevated alkaline phosphatase activity. Types VII through XII are rare, recessive forms of OI with different genetic defects being found. Clinical severity is variable and overlaps types II and III in relation to clinical features. Those who survive have white sclerae, short stature, and rhizomelia (Marini & Blissett, 2013).

Therapeutic Management

The treatment for OI has historically been primarily supportive, although patients and families are optimistic about new research advances. The use of bisphosphonate therapy with IV pamidronate to promote increased bone density and prevent fractures has become standard therapy for many children with OI. However, bisphosphonate therapy is reportedly more beneficial for increasing vertebral bone density and less effective for long bones (Marini, 2020).

The goals of a rehabilitative approach to management are directed toward preventing (1) positional contractures and deformities, (2) muscle weakness and osteoporosis, and (3) malalignment of lower extremity joints prohibiting weight bearing. Lightweight braces and splints help support limbs, prevent fractures, and aid in ambulation. Physical therapy helps prevent disuse osteoporosis and strengthens muscles, which in turn improves bone density. Surgery is sometimes used to help treat the manifestations of the disease. Surgical techniques are used to prevent or correct deformities that interfere with bracing, standing, or walking. The placement of intramedullary rods into the long bones can provide stability to bone, as well as prevent or correct deformities.

Nursing Care Management

Infants and children with this disorder require careful handling to prevent fractures. They must be supported when they are being turned, positioned, moved, and held. Even changing a diaper may cause a fracture in severely affected infants. These children should never be held by the ankles when being diapered but should be gently lifted by the buttocks or supported with pillows. However, nurses should not be afraid to touch or handle the infant or child with OI. Such children need compassionate handling and care as much as any other patient.

Both parents and the affected child need education on the child's limitations and guidelines in planning suitable activities that promote optimal development and protect the child from harm. Realistic occupational planning and genetic counseling are part of the long-term goals of care. Educational materials and information can be obtained from the Osteogenesis Imperfecta Foundation,[b] which also has a network that places families in contact with other families with a similar condition.

Children with current fractures or healing fractures should be screened for OI; the assumption that abuse or neglect is the cause of fractures in children must be carefully evaluated by a multidisciplinary team. A detailed history, no evidence of associated soft-tissue injury, and the presence of other symptoms related to OI help determine the diagnosis.

ACQUIRED DEFECTS

LEGG-CALVÉ-PERTHES DISEASE

Legg-Calvé-Perthes disease is a self-limiting disorder in which there is avascular necrosis of the femoral head. The disease affects children 2 to 12 years old, but most cases occur as an isolated event in boys between 4 and 8 years old, with a male-to-female ratio of 4:1. In approximately 10% of cases, the involvement is bilateral; most of the affected children have a skeletal age significantly below their chronologic age. Caucasian children are affected 10 times more frequently than African American children (Loder & Skopelja, 2011b).

Pathophysiology

The cause of the disease is unknown, but a temporary disturbance of circulation or vascular supply to the femoral capital epiphysis produces an ischemic avascular necrosis of the femoral head. During middle childhood, circulation to the femoral epiphysis is more tenuous than at other ages and can become obstructed by trauma, inflammation, coagulation defects, and a variety of other causes. The pathologic events seem to take place in four stages (Box 29.7). The entire disease process may encompass as little as 18 months or continue for several years. The reformed femoral head may be severely altered or minimally affected.

Clinical Manifestations and Diagnostic Evaluation

The onset of Legg-Calvé-Perthes disease is usually insidious, and the history may reveal only intermittent appearance of a limp on the affected side or a symptom complex, including hip soreness, ache, or stiffness, which can be constant or intermittent. The parents may report seeing the child limping, and the limp becomes more pronounced with increased activity. The pain may be experienced in the hip, along the entire thigh, or in the vicinity of the knee joint. The pain and limp are usually most evident on arising and at the end of a long day of activities. The pain is usually accompanied by joint dysfunction and limited range of motion at the hip. There may be a vague history of trauma but not necessarily. The diagnosis is established by characteristic radiographic findings, including medial joint space widening,

[b] 804 W. Diamond Ave., Suite 210, Gaithersburg, MD 20878; 844-889-7579; http://www.oif.org.

BOX 29.7 Radiographic Stages of Legg-Calvé-Perthes Disease

Stage I: Initial, or **avascular, stage:** Avascular necrosis or infarction of the proximal femoral epiphysis with degenerative changes producing flattening of the upper surface of the femoral head or a decrease in femoral head height

Stage II: Fragmentation, or **resorptive, stage:** Femoral head resorption and revascularization produces collapse of the femoral head and fragmentation that gives a mottled appearance on radiographs

Stage III: Reossification stage: New bone formation, which is represented on radiographs as calcification and ossification or increased density in the areas of radiolucency; this filling-in process appears to begin in the periphery of the femoral head and progress centrally

Stage IV: Healing, or **remodeling, stage:** Gradual reformation of the head of the femur without radiolucency; this occurs until skeletal maturity

flattening of the femoral head with irregular ossification, and possible subchondral fracture. A perfusion MRI of the hip may be obtained to assess the blood flow to the femoral head.

Therapeutic Management

Because deformity occurs early in the disease process, the aims of treatment are to restore and maintain adequate hip range of motion; prevent femoral head collapse, extrusion, or subluxation; and preserve as well-rounded a femoral head as possible at the time of healing. Treatment varies according to the child's age at the time of diagnosis and the appearance of the femoral head and position within the acetabulum. Activity causes microfractures of the soft ischemic epiphysis, which tend to induce synovitis, stiffness, and adductor contracture.

The initial therapy is rest or activity restrictions and limited weight bearing, which helps reduce inflammation and irritability of the hip. The use of NSAIDs can provide relief of pain or discomfort; physical therapy or range-of-motion exercises help restore hip motion. In rare cases, traction is applied to stretch tight adductor muscles and improve containment of the femoral head. Abduction braces or casting may also be used for containment of the femoral head. If nonsurgical or conservative management is unsuccessful, surgical reconstruction or containment procedures such as a pelvic or proximal femoral osteotomy may be necessary.

The disease is self-limiting, but the ultimate outcome of therapy depends on early and efficient treatment. Children 5 years old and younger, whose epiphyses are more cartilaginous, tend to have the best prognosis or outcome. Children older than 8 years of age have a significant risk for degenerative arthritis, especially if they have femoral head deformity at the time of diagnosis. The later the diagnosis is made, the more femoral damage will have occurred before treatment is implemented (Herring, 2011).

Nursing Care Management

Because these children are largely cared for on an outpatient basis, the major emphasis of nursing care is teaching the family the required care and management. The family needs to comprehend the diagnosis and understand the purpose and function of activity restrictions and limitations in achieving the desired outcome. The child and family may rely on the nurse to help them understand and adjust to therapeutic measures.

One of the most difficult aspects associated with the disorder is the need to cope with a normally active child who feels well but must remain relatively inactive. It is important to emphasize that children should continue to attend school and engage in activities that can be adapted to the prescribed regimen. Suitable activities must be devised to meet the needs of a child in the process of developing a sense of initiative or industry. Activities that fulfill creative urges are well received.

BOX 29.8 Clinical Manifestations of Slipped Capital Femoral Epiphysis

Very often obese (body mass index >95%)
Limp on affected side
Possible inability to bear weight because of severe pain
Pain in groin, thigh, or knee
- May be acute, chronic, or acute-on-chronic
- Continuous or intermittent

Affected leg is externally rotated
Loss of hip flexion, abduction, and internal rotation as severity increases
Affected leg may appear shorter

SLIPPED CAPITAL FEMORAL EPIPHYSIS

Slipped capital femoral epiphysis (SCFE) refers to the spontaneous displacement of the proximal femoral epiphysis in a posterior and inferior direction. It develops most frequently shortly before or during accelerated growth and the onset of puberty (children between 8 and 15 years old; median age of 12 years old for boys and 11 years old for girls) and is seen more often in boys and obese children. The incidence is 0.3 to 24 cases per 100,000 children. Bilateral involvement occurs in up to 50% of cases (Loder & Skopelja, 2011c).

Pathophysiology

In a hip with SCFE, the capital femoral epiphysis remains in the acetabulum, but the femoral neck slips, deforming the femoral head and stretching blood vessels to the epiphysis. Most cases of SCFE are idiopathic, although it can be associated with endocrine disorders, such as hypothyroidism, low growth hormone levels, pituitary tumors, and renal osteodystrophy. The cause of idiopathic SCFE is multifactorial and includes obesity, physeal architecture and orientation, and pubertal hormone changes that affect physeal strength. Although obesity stresses the physeal plate, SCFE can also occur in children who are not obese.

Diagnostic Evaluation

SCFE is suspected when an adolescent or preadolescent displays clinical signs of a limp or complains of hip, groin, thigh, or knee pain. See Box 29.8 for additional clinical manifestations. The diagnosis is confirmed by anteroposterior and frog-leg hip radiographs that reflect a change in position of the proximal femoral epiphysis. Radiographs show medial displacement of the epiphysis and uncovered upper portion of the femoral neck adjacent to the physis. There is a widened growth plate and irregular metaphysis.

Therapeutic Management

The treatment goals of SCFE are to prevent further slipping of the femoral epiphysis until physeal closure, avoid further complication such as avascular necrosis, and maintain adequate hip function (Peck & Herrara-Soto, 2014). If the diagnosis is suspected or has been established, the child should be non–weight bearing to prevent further slippage. Surgical intervention is necessary and most often occurs within 24 hours to avoid further slippage and potential complications such as avascular necrosis.

Currently, in situ pinning using a single screw or alternatively multiple screws through the femoral neck into the proximal femoral epiphysis is the treatment of choice. For moderate to severe SCFE, an experienced surgeon may choose to perform a surgical hip dislocation to improve the

anatomy at the site of the deformity (Tibor & Sink, 2013). Postsurgical care includes non–weight bearing or limited weight bearing with use of crutches for ambulation for weeks to months. Children may be restricted from certain sports or activities until fusion or closure of the proximal femoral physis has occurred in order to prevent further slippage.

Nursing Care Management

Nursing care involves preparing the child and family for the surgical procedure and recovery. Postoperative care involves hemodynamic stabilization, pain management, and assessment for complications. The adolescent is taught the proper use of crutches and the importance of avoiding weight bearing on the affected hip. Self-care and performance of activities of daily living to capability are encouraged to promote confidence and decrease a sense of helplessness.

! NURSING ALERT

Children with hip issues, such as Legg-Calvé-Perthes or slipped capital femoral epiphysis (SCFE), often present with groin, thigh, or knee pain. This is often because of referred pain and is anatomically related to the obturator nerve. Any time a child presents with groin, thigh, or knee pain, a complete hip examination is paramount to rule out underlying hip pathology.

KYPHOSIS AND LORDOSIS

The spine, which consists of numerous segments, can acquire deformity curves of three types: kyphosis, lordosis, and scoliosis (Fig. 29.19). **Kyphosis** is the lateral convex angulation in the curvature of the thoracic spine (see Fig. 29.19B). If it is increased (>45 degrees), it may occur secondary to disease processes, such as tuberculosis (TB), chronic arthritis, osteodystrophy, or compression fractures of the thoracic spine. The most common form of hyperkyphosis is posture related. Children, especially during the time when skeletal growth outpaces growth of muscle, are prone to exaggeration of a normal kyphosis. This is particularly common in self-conscious adolescent girls who assume a round-shouldered slouching posture in an attempt to hide their developing breasts and increasing height. **Scheuermann kyphosis** is a thoracic curve greater than 45 degrees with wedging of more than 5 degrees of at least three adjacent vertebral bodies and vertebral irregularity.

Postural (flexible) hyperkyphosis is almost always accompanied by a compensatory postural lordosis, an abnormally exaggerated concave lumbar curvature. Treatment of kyphosis consists of exercises to strengthen shoulder and abdominal muscles and bracing for more marked deformity. With adolescents who are significantly self-conscious about their appearance, the best approach is to emphasize the cosmetic value of corrective therapy and to place the responsibility on the adolescent for carrying out an exercise program at home with regular visits to and assessments by a physical therapist. Treatment with a brace may be indicated until skeletal maturity, and surgical fusion may be considered for severe, painful, or progressive thoracic curves, such as Scheuermann kyphosis.

Lordosis is the lateral inward curve of the cervical or lumbar curvature (see Fig. 29.19C). Hyperlordosis may be a secondary complication of a disease process, a result of trauma, or idiopathic. Hyperlordosis is a normal observation in toddlers and, in older children, is often seen in association with flexion contractures of the hip, obesity, DDH, and SCFE. During the pubertal growth spurt, lordosis of varying degrees is observed in teenagers, especially girls. In obese children, the weight of the abdominal fat alters the center of gravity, causing a compensatory lordosis. Unlike kyphosis, severe lordosis is usually accompanied by pain.

Treatment involves management of the predisposing cause when possible, such as weight loss and correction of deformities. Postural exercises or support garments are helpful in relieving symptoms in some cases; however, these do not usually provide a permanent cure.

IDIOPATHIC SCOLIOSIS

Scoliosis is a complex spinal deformity in three planes, usually involving lateral curvature, spinal rotation causing rib asymmetry, and when in the thoracic spine, often thoracic hypokyphosis (see Fig. 29.19E to G). It is the most common spinal deformity and is classified according to age of onset: *congenital* occurs in fetal development; *infantile* occurs at birth up to 3 years old; *juvenile* occurs in children ages 3 to 10 years old; and *adolescent* occurs at 10 years old or older.

Scoliosis can be caused by a number of conditions and may occur alone or in association with other diseases, particularly neuromuscular conditions (neuromuscular scoliosis). In most cases, however, there is no apparent cause, hence the name *idiopathic scoliosis.* There appears to be a genetic component to the etiology of idiopathic scoliosis; however, the exact relationship has yet to be established. The following section is limited to a discussion of adolescent idiopathic scoliosis.

Clinical Manifestations

Idiopathic scoliosis is most commonly identified during the preadolescent growth spurt. Parents frequently bring a child for follow-up on an abnormal school scoliosis screening or because of ill-fitting clothes, such as poorly fitting jeans. School screening is controversial because there are no controlled studies to demonstrate improved outcomes and a reported number of false-positive results lead to referrals. A recent US Preventive Services Task Force found insufficient evidence to determine whether screening for scoliosis in adolescents was of benefit (US Preventive Services Task Force, 2018). Nevertheless, a number of specialty organizations, including the American Academy of Orthopaedic Surgeons, Scoliosis Research Society, Pediatric Orthopaedic Society of North America, and American Academy of Pediatrics, advocate for routine screening of scoliosis in adolescents (Hresko, Talwakar, & Schwend, 2015). According to a joint statement released by the organizations, a medical professional educated in the detection of spinal deformity should screen girls at 10 and 12 years old and boys once at either 13 or 14 years old (Hresko et al., 2015).

Diagnostic Evaluation

Observation is performed behind a standing child wearing only shorts or undergarments. The child with scoliosis may exhibit asymmetry of shoulder height, scapular or flank shape, and hip height or pelvic obliquity. When the child bends forward at the waist so that the trunk is parallel with the floor and the arms hang free (the Adams forward bend test), asymmetry of the ribs and flanks may be appreciated (see Fig. 29.19G). A scoliometer is used in the initial screening to measure truncal rotation. Often a primary curve and a compensatory curve will place the head in alignment with the gluteal cleft. However, with an uncompensated curve, the head and hips are not aligned (see Fig. 29.19E and F).

Definitive diagnosis is made by radiographs of the child in the standing position and use of the Cobb technique, a standard measurement of angle curvature. The Risser scale is used to evaluate skeletal maturity on the radiograph. This scale assists in making a determination of the likely progression of the spinal curvature based on growth potential. The sexual maturity rating is also used to evaluate the risk of curve progression in adolescents. Not all spinal curvatures are scoliosis. A curve of less than 10 degrees is considered a postural variation. Curves measured between 10 and 25 degrees are mild and, if nonprogressive, do not require treatment (Hresko, 2013).

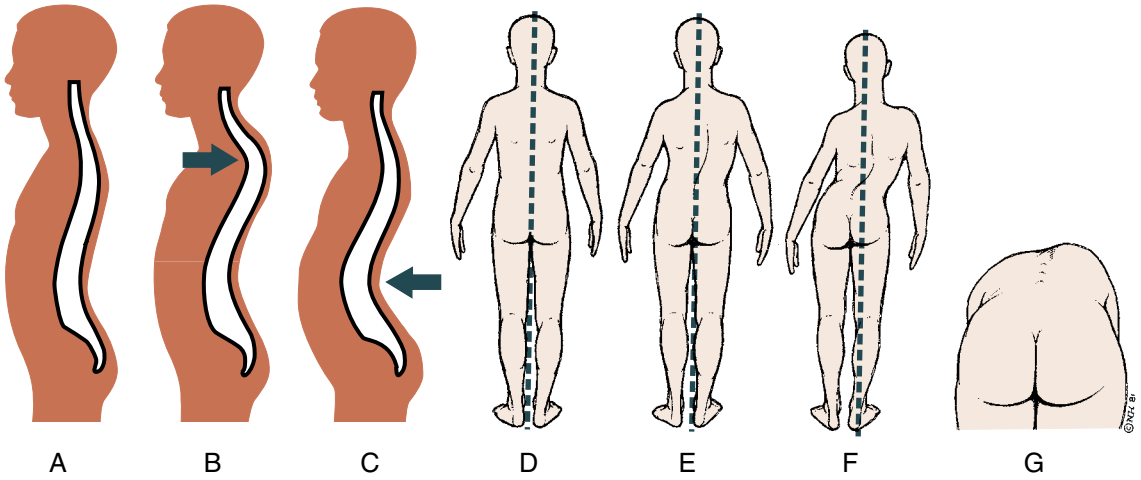

Fig. 29.19 Defects of spinal column. **A,** Normal spine. **B,** Kyphosis. **C,** Lordosis. **D,** Normal spine in balance. **E,** Mild scoliosis in balance. **F,** Severe scoliosis not in balance. **G,** Rib hump and flank asymmetry seen in flexion caused by rotary component. (Redrawn from Hilt, N. E., & Schmitt, E. W. [1975]. *Pediatric orthopedic nursing.* St. Louis, MO: Mosby.)

Intraspinal conditions or other disease processes that can cause scoliosis must be ruled out. The presence of pain, sacral dimpling or hairy patches, cutaneous vascular changes, absent or abnormal reflexes, bowel or bladder incontinence, or a left thoracic curve may indicate an intraspinal abnormality, such as syringomyelia, diastematomyelia, or tethered cord syndrome. An MRI scan of the spine is usually obtained for evaluation.

Therapeutic Management

Current management options include observation with regular clinical and radiographic evaluation, orthotic intervention (bracing), and surgical spinal fusion. Treatment decisions are based on the magnitude, location, and type of curve; the age and skeletal maturity of the child or adolescent; and any underlying or contributing disease process.

Bracing and Exercise

For moderate curves (25 to 45 degrees) in the growing child and adolescent, bracing may be the treatment of choice. Historically, bracing has not been shown to be curative; the goal is to slow the progression of the curvature to allow skeletal growth and maturity. The two most common types of bracing are the Boston and Wilmington braces, which are underarm orthoses customized from prefabricated plastic shells, with corrective forces using lateral pads and decreasing lumbar lordosis, and a thoracolumbosacral orthosis (TLSO), which is an underarm orthosis made of plastic that is custom molded to the body and then shaped to correct or hold the deformity (Fig. 29.20). The Milwaukee brace, which is an individually adapted brace that includes a neck ring, is rarely used in scoliosis but is sometimes used in the treatment of kyphosis. The Charleston nighttime bending brace is worn only when the child is in bed, as it prevents walking because of the severity of the trunk bend. Brace wear can be challenging due to the child's age and preoccupation with body image and appearance. Although bracing is not curative, using a rigid TLSO has been shown to be effective in reducing the likelihood of a curve progressing to a surgical magnitude while an individual finishes his or her growth. Bracing is discontinued once growth is complete and risk for further progression is negligible. One study found that of those with idiopathic progressive scoliosis, only 28% who used a TLSO progressed to needing surgery, whereas 52% who did not use a brace required surgery; in addition, the success rate of TLSO management increased with the more hours a brace was worn (Weinstein, Dolan, Wright, et al., 2013). There is very limited evidence regarding the effect of exercises and chiropractic treatment in the prevention of curve progression in scoliosis. Transcutaneous electrical nerve stimulation has proved to be an ineffective treatment. Exercises are of benefit when used in conjunction with bracing to maintain and increase the strength and range of motion of the spine.

Operative Management

Surgical intervention may be required for treatment of severe curves, which are typically greater than 45 to 50 degrees, as these curves generally continue to progress over time even after skeletal maturity is reached (Mistovich & Spiegel, 2020). The child's age, location of the curvature, and curve magnitude influence the decision for surgery. Any progressive or severe curve that does not respond to conservative orthotic measures (such as bracing) requires surgical correction. Bracing and exercise have been found to be ineffective in managing curves greater than 45 degrees. Neuromuscular, dysplastic, and congenital curves, which eventually progress, are best treated with surgical stabilization. Difficulties with balance or seating, respiratory compromise, or pain are also considered.

There are a number of surgical techniques for severe scoliosis. A spinal fusion consists of realignment and straightening of the spine with internal fixation and instrumentation combined with bony fusion (arthrodesis). Posterior and/or anterior surgical approaches may be implemented. The goals of surgical intervention are to improve the curvatures in the sagittal and coronal planes and to provide a solid, pain-free fusion in a well-balanced torso, with maximum mobility of the remaining spinal segments.

Advances in surgical technology currently being evaluated include thoracoscopic spinal fusion and placement of implants; metallic staples may also be placed into the vertebral bodies to achieve spinal fusion and to correct the deformity (Mistovich & Spiegel, 2020). The use of minimally invasive surgical techniques has gained acceptance for their small incisions, decreased blood loss, decreased recovery time, earlier mobilization, and decreased pain and need for pain medications (Sarwahi, Wollowick, Sugarman, et al., 2011).

Nursing Care Management

Treatment for scoliosis extends over a significant portion of the affected child's period of growth. In adolescents, this period is the one in which their identity, both physical and psychologic, is formed. The

Fig. 29.20 A, Standard thoracolumbosacral orthotic (TLSO) brace for idiopathic scoliosis. The brace may be decorated to make it more acceptable to adolescents. B, Posterior view of the same brace.

identification of scoliosis as a "deformity," in combination with unattractive braces and a significant surgical procedure, can have a negative effect on the already fragile adolescent body image. The adolescent and family require excellent nursing care to meet not only physical needs but also psychologic needs associated with the diagnosis, surgery, postoperative recovery, and eventual rehabilitation.

Although adolescents with scoliosis are encouraged to participate in most peer activities, necessary therapeutic modifications are likely to make them feel different and isolated. Nursing care of the adolescent who is facing scoliosis surgery, potential social isolation, pain, and uncertainty, not to mention misunderstood emotions and body image issues, must be evaluated from the adolescent's perspective to be successful in meeting the individual's needs.

When a child or adolescent first faces the prospect of a prolonged period in a brace or other device, the therapy program and the nature of the device must be explained thoroughly to both the child and the parents so that they will understand the anticipated results, how the appliance corrects the defect, the freedoms and constraints imposed by the device, and what they can do to help achieve the desired goal. Management involves the skills and services of a team of specialists, including the orthopedist, physical therapist, orthotist (a specialist in fitting orthopedic braces), nurse, social worker, and sometimes a thoracic or pulmonary specialist.

Preoperative Care

The preoperative workup usually involves a radiographic series, including bending or traction spine films, pulmonary function studies, and serologic laboratory studies (including prothrombin, partial thromboplastin, and platelet function test; blood count; electrolyte levels; urinalysis and urine culture; and blood levels of any medications). Spinal surgery typically results in considerable blood loss, so several options are considered preoperatively to maintain or replace blood volume. These options include autologous blood donations obtained from the patient before the surgery; intraoperative blood salvage; intraoperative hemodilution; erythropoietin administration; and controlled induced hypotension, which must be carefully monitored at all times to prevent physiologic instability.

Surgery for spinal fusion is complex, and often adolescents who require the procedure due to idiopathic scoliosis are not familiar with medical terms or procedures. Preoperative teaching is critical for the adolescent to be able to cooperate and participate in his or her treatment and recovery. Because the surgery is extensive, the patient is taught how to manage his or her own patient-controlled analgesia (PCA) pump; how to log roll; and the use and function of other equipment, such as a chest tube (for anterior repair) and Foley urinary catheter. It is recommended that the child or adolescent bring a favorite toy (age dependent) or personal items such as a favorite stuffed animal, laptop computer, cell phone, MP3 player, or movie player for postoperative use. Meeting with a peer who has undergone a similar surgery may also be valuable.

Postoperative Care

Following surgery, patients are monitored in an acute care setting and log rolled when changing position to prevent damage to the fusion and instrumentation. In some cases, an immobilization brace or cast is used postoperatively depending on the type of surgical intervention and underlying diagnosis. Skin care is important, and pressure-relieving mattresses or beds may be needed to prevent pressure wounds (see Chapter 20, Maintaining Healthy Skin).

In addition to the usual postoperative assessments of wound, circulation, and vital signs, the neurologic status of the patient's extremities requires special attention. Prompt recognition of any neurologic impairment is imperative because delayed paralysis that requires surgical intervention may develop. Postoperative problems after spinal fusion may include neurologic injury or spinal cord injury, hypotension from acute blood loss, wound infection, syndrome of inappropriate antidiuretic hormone secretion, atelectasis, pneumothorax, ileus, delayed neurologic injury, and implanted hardware complications (Freeman, 2013). Superior mesenteric artery syndrome may occur several days after spinal surgery; this involves duodenal compression by the aorta and superior mesenteric artery and may result in acute partial or complete duodenal obstruction. Clinical manifestations include epigastric pain, nausea, copious vomiting, and eructation; symptoms are aggravated in the supine position and often relieved with the patient in a left lateral decubitus or prone position.

The adolescent usually has considerable pain for the first few days after surgery and requires frequent administration of pain medication, preferably opioids administered intravenously on a regular schedule. For children able to understand the concept, PCA is recommended (see Chapter 5, Pain Assessment and Pain Management). In addition to pain management, the patient is evaluated for skin integrity, adequate urinary output, fluid and electrolyte balance, and ileus. Discharge planning should include a timetable for follow-up with the provider and resumption of regular activities.

In most cases, the patient begins ambulation as soon as possible. Depending on the instrumentation used and the surgical approach, most patients are walking by the second or third postoperative day and discharged within 5 to 7 days. The patient may start physical therapy as soon as he or she is able, beginning with range-of-motion exercises on the first postoperative day and many of the activities of daily living in the following days. Self-care, such as washing and eating, is always encouraged. Throughout the hospitalization, age-appropriate activities and contact with family and friends are important parts of nursing care and planning (see Immobilization earlier in the chapter). The family is encouraged to become involved in the patient's care to facilitate the transition from hospital to home management. An organization that provides education and services to both families and professionals is the National Scoliosis Foundation.[c]

INFECTIONS OF BONES AND JOINTS

OSTEOMYELITIS

Osteomyelitis, an infectious process in the bone, can occur at any age but most frequently is seen in children 10 years old or younger. Boys are more commonly affected than girls, and the median age of diagnosis is 5 to 6 years old. The limbs most commonly affected include the foot, femur, tibia, and pelvis. *Staphylococcus aureus* is the most common causative organism. Neonates are also likely to have osteomyelitis caused by group B streptococci. Children with sickle cell disease may develop osteomyelitis from *Salmonella* organisms as well as *S. aureus*. *Neisseria gonorrhoeae* is a potential causative organism in sexually active adolescents. *Kingella kingae* has been reported as one of the most causative organisms in children younger than 5 years old (Robinette & Shah, 2020a).

Acute hematogenous osteomyelitis results when a bloodborne bacterium causes an infection in the bone. Common foci include infected lesions, upper respiratory tract infections, otitis media, tonsillitis, abscessed teeth, pyelonephritis, and infected burns. **Exogenous osteomyelitis** is acquired from direct inoculation of the bone from a puncture wound, open fracture, surgical contamination, or adjacent tissue infection. **Subacute osteomyelitis** has a longer course and may be caused by less virulent microbes with a walled-off abscess or **Brodie abscess**, typically in the proximal or distal tibia. **Chronic osteomyelitis** is a progression of acute osteomyelitis and is characterized by dead bone, bone loss, and drainage and sinus tracts.

Generally, healthy bone is not likely to become infected. Factors that contribute to infection include inoculation with a large number of organisms, presence of a foreign body, bone injury, high virulence of an organism, immunosuppression, and malnutrition; certain types and locations of bone are also more vulnerable to infection.

Typically, children with acute hematogenous osteomyelitis are seen with a 2- to 7-day history of pain, warmth, tenderness, and decreased range of motion in the affected limb along with systemic symptoms of fever, irritability, and lethargy (Box 29.9). Infants may have an adjacent joint effusion as well. Symptoms often resemble those observed in other conditions involving bones, such as arthritis, leukemia, or sarcoma.

Pathophysiology

In acute osteomyelitis, bacteria adhere to bone, causing a suppurative infection with inflammatory cells, edema, vascular congestion, and small-vessel thrombosis; the result is bone destruction, abscess formation, and dead bone (sequestra). Infection within the bone can rupture through the cortex into the subperiosteal space, stripping loose periosteum and forming an abscess. As dead bone is resorbed, new bone is formed along the live bone and infection borders. This surrounding sheath of live bone is called an **involucrum**. Sinus tracts from perforations in the involucrum may drain pus through soft tissue to the skin.

The pathology of osteomyelitis is different in infants, children older than 1 year old, and adults. In infants, blood vessels cross the growth plate into the epiphysis and joint space, which allows infection to spread into the joint. In children, the infection is contained by the growth plate, and joint infection is less likely (unless the infection is intracapsular). In older adolescents (with a closed growth plate), the

infection is poorly contained and the joint is compromised. Adult periosteum is attached to bone; consequently, rupture through the periosteum and sinus drainage is more common in adults.

Diagnostic Evaluation

Organism identification and antibiotic susceptibility testing are essential for effective therapy. Cultures of aspirated purulent drainage along with cultures of blood, joint fluid, and infected skin samples should be obtained. Bone biopsy is indicated if blood culture results and radiographic findings are not consistent with osteomyelitis. Supporting evidence for osteomyelitis includes leukocytosis and elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Radiographic signs, except for soft-tissue swelling, are evident only after 2 to 3 weeks. A three-phase technetium bone scan can show areas of increased blood flow, such as occurs in early stages in infected bone, and is useful in locating multiple sites; however, it is not a diagnostic test. Computed tomography (CT) scan can detect bone destruction, and MRI provides anatomic details useful in delineating the area of involvement, especially if surgical intervention is planned. MRI is reported to be the most sensitive diagnostic radiologic tool for diagnosing osteomyelitis (Robinette & Shah, 2020a). Sometimes the osteomyelitis may be unrecognized if it occurs as a complication of a severe toxic and debilitating disease. Neonates may not present with clinical manifestations other than limited mobility of the affected extremity; fever may or may not be present, and the neonate may not appear to be sick (Robinette & Shah, 2020a).

Therapeutic Management

After culture specimens are obtained, empiric therapy is started with IV antibiotics covering the mostly likely organisms. For *S. aureus,* nafcillin or clindamycin is generally used. Consideration should be given to the increased rates of community-acquired methicillin-resistant *S. aureus* (MRSA) in the selection of first-line antibiotic therapy; MRSA may require vancomycin, or in some cases, clindamycin may be appropriate. When the infectious agent is identified, administration of the appropriate antibiotic is initiated and continued for at least 3 to 4 weeks, but the length of therapy is determined by the duration of the symptoms, the response to treatment, and the sensitivity of the organism; 6 weeks to 4 months may be required in some cases (Robinette & Shah, 2020a). In selected cases, oral antibiotic therapy may follow the IV treatment. Because of the prolonged duration of high-dose antibiotic therapy, it is important to monitor for hematologic, renal, hepatic, ototoxic, and other potential side effects. To prevent antibiotic-associated diarrhea in some children, administration of a probiotic may be considered.

Surgery may be indicated if there is no response to specific antibiotic therapy, a penetrating injury exists, persistent soft-tissue abscess is seen, or the infection spreads to the joint. Opinions differ regarding surgical intervention, but many advocate sequestrectomy and surgical drainage to decompress the metaphyseal space before purulent fluid erupts and spreads to the subperiosteal space, forming abscesses that strip the periosteum from bone or form draining sinuses. When these complications occur, a chronic infection usually persists, which may require antibiotic therapy for several months.

Nursing Care Management

During the acute phase of illness, movement of the affected limb will cause discomfort; therefore the child is positioned comfortably with the affected limb supported. A temporary splint or cast may be applied. Weight bearing is avoided in the acute phase, and moving and turning are carried out carefully to minimize pain. The child may require long-term pain medication to deal with the bone pain. Postoperatively, pain medication should be considered as with any other surgical procedure.

Antibiotic therapy requires careful observation and monitoring of the IV equipment and site. A peripherally inserted central catheter (PICC) may be inserted for long-term antibiotic therapy. Antibiotic therapy is often continued at home or through an outpatient infusion clinic.

Standard Precautions are implemented for all children with osteomyelitis. If there is an open wound, it is managed according to standard wound care precautions. If a PICC line or central venous catheter (CVC) is inserted, meticulous care should be taken to prevent catheter-related infection.

As the infection subsides, physical therapy is instituted to ensure restoration of optimum function. The child may eventually be transitioned to a regimen of oral antibiotics, and progress is followed closely for some time.

SEPTIC ARTHRITIS

Septic arthritis is a bacterial infection in the joint. It usually results from hematogenous spread or from direct extension of an adjacent cellulitis or osteomyelitis. Direct inoculation from trauma accounts for 15% to 20% of septic arthritis cases. The most common causative organism is *S. aureus.* Community-acquired MRSA is commonly a cause of septic arthritis. In addition to *S. aureus,* pathogens seen in neonates include group B streptococci, *Escherichia coli,* and *Candida albicans.* In children 2 months to 5 years old, *S. aureus, Streptococcus pyogenes, Streptococcus pneumoniae,* and *K. kingae* are the primary organisms causing infection. Children older than 5 years of age are more likely to be infected by *S. aureus* and *S. pyogenes,* and sexually active adolescents may be infected by *N. gonorrhoeae* (Gutierrez, 2005; Robinette & Shah, 2020a).

The knees, hips, ankles, and elbows are the most common joints affected. Clinical manifestations include severe joint pain, swelling, warmth of overlying tissue, and occasionally erythema. An infection involving the hip, however, is considered a surgical emergency to prevent compromised blood supply to the head of the femur (Robinette & Shah, 2020b).

The child is resistant to any joint movement. Features of systemic illness such as fever, malaise, headache, nausea, vomiting, and irritability may also be present.

Therapeutic Management and Nursing Care Management

The affected joint is aspirated and the specimen evaluated by Gram stain, cultures (including separate cultures for *H. influenzae* and *N. gonorrhoeae*), and determination of leukocyte count. In addition, perform blood cultures and obtain complete blood count with differential and ESR or CRP level. Early radiographic findings are limited to soft-tissue swelling but may reveal a foreign body, and such films always provide a baseline for comparison. Technetium scans reveal areas of increased blood flow but will not differentiate between sites. MRI and CT scans provide more detailed images of cartilage loss, joint narrowing, erosions, and ankylosis of progressive disease. Ultrasonography is helpful in the detection of joint effusions and fluid in the soft tissue and subperiosteum (Robinette & Shah, 2020b).

Treatment is IV antibiotic therapy based on Gram stain results and the clinical presentation. The benefits of serial aspirations to demonstrate sterility of synovium fluid and reduce pressure or pain are controversial. Pain management is an important aspect of nursing care, particularly with involvement of a large joint such as the hip. Surgical intervention may also be required if there was a penetrating wound or a foreign object was possibly involved. Physical therapy may be initiated for the child who is immobilized to prevent flexion contractures. Additional nursing care is the same as for osteomyelitis.

SKELETAL TUBERCULOSIS

In children, tubercular infection of the bones and joints is acquired by lymphohematogenous spread at the time of primary infection. Occasionally it is from chronic pulmonary TB. Skeletal tubercular infection is not common in the United States but should be considered in communities with high TB case rates. The condition is a late manifestation of TB and is most likely to involve the vertebrae, causing tubercular spondylitis. If the infection is progressive, it causes **Pott disease** with destruction of the vertebral bodies and results in kyphosis and spinal malalignment (Pigrau-Serrallach & Rodríguez-Pardo, 2013). Symptoms are insidious. The child may report persistent or intermittent pain. Other findings include joint swelling and stiffness; fever and weight loss are not common. Tubercular arthritis can also affect single joints (such as a knee or hip) and tends to cause severe destruction of adjacent bone. Infection in the fingers causes spina ventosa, a tuberculous dactylitis.

As with pulmonary TB, the index case should be located. A family and environmental history needs to be obtained and tuberculin skin tests (TSTs) performed. Results of TSTs are positive for most children with tuberculous arthritis; however, the results are not diagnostic, and the clinical and laboratory features do not differentiate tubercular arthritis from a nontubercular septic arthritis. Diagnosis requires isolation of *Mycobacterium tuberculosis* from the site. Patients with the susceptible organism start treatment with combined antituberculosis chemotherapy (isoniazid, rifampin, and pyrazinamide); directly observed therapy (DOT) is preferred.

Nursing Care Management

Nursing care depends on the site and extent of infection. Tuberculous spondylitis and hip infection may require immobilization, casting, and surgical fusion. Nursing care is individualized but is generally the same as for osteomyelitis and septic arthritis.

DISORDERS OF JOINTS

JUVENILE IDIOPATHIC ARTHRITIS

Juvenile idiopathic arthritis (JIA) refers to chronic childhood arthritis. A group of heterogeneous autoimmune diseases, JIA causes inflammation in the joint synovium and surrounding tissue. The cause of JIA is unknown. JIA starts before 16 years old with a peak onset between 1 and 3 years old. Twice as many girls as boys are affected. The reported incidence of chronic childhood arthritis varies from 1 to 20 cases per 100,000 children with a prevalence of 10 to 400 per 100,000 (Cassidy & Petty, 2011). Genetic factors and environmental triggers (e.g., rubella, Epstein-Barr virus, parvovirus B19) have been associated with the onset of JIA, but the etiology remains unclear.

Pathophysiology

The disease process is characterized by chronic inflammation of the synovium with joint effusion and eventual erosion, destruction, and fibrosis of the articular cartilage. Adhesions between joint surfaces and ankylosis of joints may occur if the inflammatory process persists.

Clinical Manifestations

Whether single or multiple joints are involved, swelling and loss of motion develop in the affected joint. The swollen joint may be slightly warm and mildly tender to touch, but it is not uncommon for pain not to be reported despite a large joint effusion. Loss of motion in the joint from joint inflammation and muscle spasm may be exacerbated by inactivity. Morning stiffness of the joint(s) is characteristic of JIA and may be present on arising or inactivity. Functional change may be an obvious limp or subtle limitations in joint motion, such as fisting to avoid wrist extension with pressure. Growth disturbances (either overgrowth or undergrowth) may occur, such as bony enlargement of the adjacent femoral or tibial condyles with a knee effusion or a receding chin from temporomandibular arthritis.

Classification of Juvenile Idiopathic Arthritis

JIA is not a single disease but a heterogeneous group of diseases. The universal Durban classification of JIA, developed in 1997 and revised in 1998 and 2001, lists several disease categories, each with its own set of criteria and exclusions, which continue to be revised (Petty, Southwood, Manners, et al., 2004).

- Systemic arthritis is arthritis in one or more joints associated with at least 2 weeks of quotidian fever and daily for at least 3 days and one or more of the following: rash, lymphadenopathy, hepatosplenomegaly, and serositis. [*]*Exclusions: a, b, c, d*
- Oligoarthritis is arthritis in one to four joints for the first 6 months of disease. It is subdivided to persistent oligoarthritis if it remains in four joints or fewer, or becomes extended oligoarthritis if it involves more than four joints after 6 months. [*]*Exclusions: a, b, c, d, e*
- Polyarthritis rheumatoid factor (RF) negative affects five or more joints in the first 6 months with a negative RF. [*]*Exclusions: a, b, c, e*
- Polyarthritis RF positive also affects five or more joints in the first 6 months, but these children have a positive RF. [*]*Exclusions: a, b, c, e*
- Psoriatic arthritis is arthritis with psoriasis or an associated dactylitis, nail pitting, or onycholysis or psoriasis in a first-degree relative. [*]*Exclusions: b, c, d, e*
- Enthesitis-related arthritis is arthritis or enthesitis associated with at least two of the following: sacroiliac or lumbosacral pain, human leukocyte antigen B27 (HLA-B27) antigen, arthritis in a boy older than 6 years old, acute anterior uveitis, inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis in a first-degree relative. [d]*Eclusions: a, d, e*
- Undifferentiated arthritis fits no other category above or fits more than one category.

Diagnostic Evaluation

JIA is a diagnosis of exclusion; there are no definitive tests. Classifications are based on the clinical criteria of age of onset before 16 years old, arthritis in one or more joints for 6 weeks or longer, and exclusion of other causes. Laboratory tests may provide supporting evidence of disease. The ESR/CRP may or may not be elevated. Leukocytosis is frequently present during exacerbations of systemic JIA. Antinuclear antibodies are common in JIA but are not specific for arthritis; however, they help identify children who are at greater risk for uveitis. Plain radiographs are the best initial imaging studies and may show soft-tissue swelling and joint space widening from increased synovial fluid in the joint. Later films can reveal osteoporosis, narrow joint space, erosions, subluxation, and ankylosis. A slit lamp eye examination is necessary to diagnose uveitis, inflammation in the anterior chamber of the eye, which is most common in antinuclear antibody–positive

[d]Exclusions: (a) Psoriasis or history of psoriasis in the patient or first-degree relative; (b) arthritis in an HLA-B27–positive male beginning after the sixth birthday; (c) ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or symptomatic anterior uveitis, or a history of one of these disorders in a first-degree relative; (d) the presence of immunoglobulin M rheumatoid factor (RF) on at least two occasions at least 3 months apart; (e) the presence of systemic JIA in the patient.

young girls with oligoarthritis. Routine examinations are necessary for early diagnosis and treatment to avoid or minimize sight-threatening disease (Qian & Acharya, 2010).

Therapeutic Management

There is no cure for JIA. The major goals of therapy are to control pain, preserve joint range of motion and function, minimize effects of inflammation such as joint deformity, and promote normal growth and development. Outpatient care is the mainstay of therapy; lengthy hospitalizations are infrequent in this era of managed care. The treatment plan can be exhaustive and intrusive for the child and family, including medications, physical and occupational therapy, ophthalmologic slit lamp examinations, splints, comfort measures, dietary management, school modifications, and psychosocial support.

Medications

In 2011 the American College of Rheumatology published recommendations for the treatment of JIA intended to lend guidance to the provider. Additional recommendations were added in 2013 to further address treatment of systemic JIA as well as routine screening tests for those with JIA (Ringold, Weiss, Beukelman, et al., 2013). The guidelines are divided into four groups: children with (1) four or fewer affected joints, (2) five or more affected joints, (3) systemic arthritis and active systemic features, and (4) systemic arthritis with active arthritis. Each path provides recommendations for a stepwise escalation of the medication and therapy (Beukelman, Patkar, Saag, et al., 2011). All tracks consider poor prognostic indicators, such as erosions on radiograph; arthritis of the hip, cervical spine, ankle, or wrist; and a positive RF. In addition, each track takes into account disease activity levels that include elevated acute phase reactants and global assessments of both the provider and the patient and parents.

Medications included in the guidelines include those described in the following sections.

Nonsteroidal antiinflammatory drugs. NSAIDs (e.g., naproxen, ibuprofen) are used alone or in combination with other drugs depending on the amount of disease activity and poor prognostic features. NSAIDs offer an analgesic effect but may require higher dosing for an antiinflammatory effect. Patient and parent education is important and should include potential side effects of gastrointestinal, renal, hepatic, and prolonged coagulation.

Disease-modifying antirheumatic drugs. Disease-modifying antirheumatic drugs (DMARDs) include the nonbiologic drugs methotrexate and sulfasalazine. The decision to use a DMARD at initiation of therapy or later in the escalation of therapy is guided by the amount of disease activity and poor prognostic features. Effective against arthritis and uveitis, antirheumatic low-dose methotrexate has a time-proven safety profile, but parents may be overwhelmed by the potential adverse effects of liver disease, infections, bone marrow suppression, gastrointestinal disturbance, teratogenic effects, and alarming but unconfirmed risk of cancer. Patient and parent education includes frank discussion of sexual activity and birth defects. Sexually active teenagers need effective birth control. As a precaution, pregnant caregivers or those trying to conceive need to avoid contact with methotrexate. Instructions about avoiding live immunizations and alcohol are essential during patient education. Sulfasalazine may be used in children with axial arthritis, a positive test result for HLA-B27, or symptoms of inflammatory bowel disease, given this drug's success in these select groups of patients.

Biologic disease-modifying antirheumatic drugs. Biologic DMARDs are initiated when there is significant disease activity and/or poor prognostic indicators after unsuccessful treatment with methotrexate. Tumor necrosis factor–alpha (TNF-α) inhibitors are the most frequently used biologic DMARDs and include etanercept, infliximab, and adalimumab. All three reduce the proinflammatory response that promotes arthritis. Anakinra (interleukin-1 receptor antagonist), tocilizumab (interleukin-6 receptor antagonist), and abatacept (selective T-cell costimulation blocker) are also biologics that may be selected for use in systemic JIA (tocilizumab and off-label anakinra) or in children with JIA and limited response to other biologics (tocilizumab and abatacept). Patient education focuses on the increased risk for infection, holding the scheduled dose if the child has fever or symptoms of infection, and seeking medical attention at early onset of illness. All patients starting biologic DMARDs need a negative TST prior to starting. Although biologic DMARDs have been found to be safe and effective, the potential for malignancy needs to be addressed, and patients need routine safety monitoring (Ruperto & Martini, 2011; Tarkiainen, Tynjälä, Vähäsalo, et al., 2015).

Glucocorticoids. Glucocorticoids are potent antiinflammatory agents; however, the significant adverse effects of long-term systemic steroids are undesirable, so they are used in conjunction with other medications to provide prompt antiinflammatory response with acute arthritis, then tapered and discontinued. High-dose IV steroids may be used with acutely active arthritis or systemic features (fevers, rash, and pericarditis). Intra-articular long-acting steroid injections are effective in treating individual joint effusions with minimal adverse effects and frequently provide sustained control. Glucocorticoid education is extensive and includes discussion of potential risks of infection, adrenal insufficiency, Cushingoid features, weight gain, mood or sleep changes, hypertension, diabetes, and osteoporosis and avascular necrosis. Simultaneous dietary changes (low calorie and low salt) and, if possible, an active exercise program should be considered when steroids are initiated.

Physical and Occupational Therapy

Physical therapy programs are individualized for each child and designed to reach the ultimate goal—preserving function or preventing deformity. Physical therapy is directed toward specific joints, focusing on strengthening muscles, mobilizing restricted joint motion, and preventing or correcting deformities. Occupational therapists are responsible for evaluating and improving performance of activities of daily living.

Treatment or maintenance programs vary; a child may be seen a couple of times a week or monthly, but the mainstay of any program is the child doing the daily home exercise program, which is demonstrated and revised at each therapy session.

Exercising in a pool is excellent therapy because it allows an almost weightless freedom of movement against the gentle resistance of water. If there is pain on motion, a hot pack or warm bath before therapy may help.

Providers may recommend nighttime splinting to help minimize pain and reduce flexion deformity. Joints most frequently splinted are the knees, wrists, and hands. Loss of extension in the knee, hip, and wrist causes special problems and requires vigilance to detect the earliest signs of involvement and vigorous attention to prevent deformity with specialized passive stretching, positioning, and resting splints.

Nursing Care Management

Nursing the child with JIA involves assessment of the child's general health, the status of involved joints, and the child's emotional response to all ramifications of the disease—discomfort, physical restrictions, therapies, and self-concept.

The effects of JIA are manifest in every aspect of the child's life, including physical activities, social experiences, and personality development. Nursing interventions to support the parents may foster successful adaptation for the entire family. Parental concerns about the

disease prognosis, financial and insurance issues, spouse and sibling relationships, and job and schedule conflicts must all be addressed. Referral to social workers, counselors, or support groups may be needed.

Relieve Pain

The pain of JIA is related to several aspects of the disease, including disease severity, functional status, individual pain threshold, family variables, and psychologic adjustment. The aim is to provide as much relief as possible with medication and other therapies to help children tolerate the pain and cope as effectively as possible. Nonpharmacologic modalities, such as behavioral therapy and relaxation techniques, have proved effective in modifying pain perception (see Chapter 5, Pain Management) and activities that aggravate pain. Opioid analgesics are typically avoided in juvenile arthritis; however, for children immobilized with refractory pain, short-term opioid analgesics can be part of a comprehensive plan that uses multiple pain-relief techniques (Connelly & Schanberg, 2006).

Promote General Health

The child's general health must be considered. A well-balanced diet with sufficient calories to maintain growth is essential. If the child is relatively inactive, caloric intake needs to match energy needs to avoid excessive weight gain, which places additional stress on affected joints. Sleep and rest are essential for children with JIA. Some children require rest during the day; however, daytime napping that interferes with nighttime sleepiness should be avoided. A bedtime routine that involves comfort measures can help induce sleep. A firm mattress, electric blanket, or sleeping bag helps provide warmth, comfort, and rest. Nighttime splints needed to maintain range of motion might initially be a source of bedtime conflict. The family needs to be instructed on how to use the splint appropriately; the splint should not be painful or impede sleep. Behavior modification programs that reward splint and exercise compliance may be helpful in reducing adherence barriers. Well-child care to assess growth, development, and immunization requirements needs to be coordinated between the primary care provider and the rheumatologist. Common childhood illnesses, such as upper respiratory tract infections, may cause arthritis to worsen; consequently, medical attention must be sought quickly for relatively minor illness to prevent arthritis flares. Effective communication among the family, the primary care provider, and the rheumatology team is essential for care coordination.

Children are encouraged to attend school even on days when they have some pain or discomfort. The school nurse's assistance is enlisted so that a child is permitted to take the prescribed medication at school and to arrange for rest in the nurse's office during the day. Split days or half days may help a child remain involved in school. Permitting the child to come to school late allows time to gain joint movement and reduces the time at school to avoid exhaustion. It is important that the child attend school to learn skills and engage in social interaction, especially if the JIA continues to limit physical skills. Arranging for two sets of textbooks—one for home and one for school—eliminates heavy backpacks, or rolling backpacks may be used. In addition, extra time to take tests, allowing the child to stand and stretch, participating in PE as tolerated or in a modified PE program, an elevator pass, and extra time to change classes can all reduce barriers and maximize the student's attendance and participation in school. A formal school hearing may be necessary to obtain an individualized educational program (IEP), ensured by public law, which includes intensive school modifications.

Facilitate Adherence

The child and family need to be actively involved in the treatment plan to commit to it. They need to know the purpose and correct use of any splints, exercise programs, and medications prescribed. Pill boxes can help foster adherence, although parents should continue to monitor adherence of the older child who is able to safely take medications independently. Nurses can facilitate adherence by demonstrating and providing written instructions on proper techniques for pill crushing or pill swallowing skills. Teaching parents and patients how to give subcutaneous injections lays the groundwork for future adherence by identifying and addressing potential barriers. Shots are never a pleasant activity; if available, enlist a child life specialist as a resource in providing the child with skills to cope and better understand and accept unpleasant but necessary medical treatments.

Comfort Measures and Exercise

Heat has been shown to be beneficial to children with arthritis. Moist heat is best for relieving pain and stiffness, and the most efficient and practical method is in the bathtub with warm water. In some cases, a daily whirlpool bath, paraffin bath, or hot packs may be used as needed for temporary relief of acute swelling and pain. Hot packs are easily applied using a damp hand towel wrung out after being immersed in hot water or heated in a microwave oven; after testing for heat, hot packs are applied to the area and covered with plastic to retain heat. Commercial pads that warm in only a few seconds in the microwave are also available. Painful hands or feet can be immersed in a pan of warm water or a paraffin unit.

Pool therapy is the easiest method for exercising a large number of joints. Swimming activities strengthen muscles and maintain mobility in larger joints. Very small children who are frightened of the water can carry out their exercises in the bathtub. Small children love to splash, kick, and throw things in the water. Remember, adult supervision is necessary for all water activities.

Activities of daily living provide satisfactory exercise for older children to maintain maximal mobility with minimal pain. These children are encouraged in their efforts to be independent and patiently allowed to dress and groom themselves, to assume daily tasks, and to care for their belongings. It is often difficult for children to manipulate buttons, comb or brush their hair, and turn faucets, but unless there is an acute flare with significant loss of motion and pain, parents and other caregivers should offer not assistance but extra time and encouragement to proceed independently. In turn, children should learn and understand why others do not help them. Many helpful devices, such as self-adhering fasteners, tongs for manipulating difficult items, and grab bars installed in bathrooms for safety, can be used to facilitate tasks. A raised (higher) toilet seat often makes the difference between dependent and independent toileting because weak quadriceps muscles and sore knees inhibit the ability to raise the body from a low sitting position.

A child's natural affinity for play offers many opportunities for incorporating therapeutic exercises. Throwing or kicking a ball and riding a tricycle (with the seat raised to achieve maximum leg extension) are excellent moving and stretching exercises for a young child whose activities of daily living are physically limited.

An effective approach to beginning the day's activities is to awaken children early to give them their medication and then to allow them to sleep for an hour. On arising, children take a hot bath (or shower) and perform a simple ritual of limbering-up exercises, after which they commence the activities of the day, such as going to school. Exercise, heat, and rest are spaced throughout the remainder of the day according to the child's individual needs and schedules. Parents are instructed in exercises that meet the child's needs.

The Arthritis Foundation and the American Juvenile Arthritis Alliance (an organization within the Arthritis Foundation) provide information and services for both parents and professionals, and nurses can refer families to these agencies as an added resource.

Support Child and Family

JIA affects every aspect of life for the child and family. Physical limitations may interfere with self-care, school participation, and recreational activities. The intensive treatment plan, including multiple medications, physical therapy, comfort measures, and medical appointments, is intrusive and disruptive to the parents' work schedule and the family routine. To prevent isolation and foster independence, the family is encouraged to pursue their normal activities. Unfortunately, the adaptations necessary to make that occur take resourcefulness and commitment from all family members. At diagnosis and throughout the span of JIA, it is essential to recognize signs of stress and counterproductive coping and provide the necessary support to maximize adaptation. The problems and needs of these families are discussed in Chapter 17, and readers are directed to that chapter for guidance in planning care.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a severe chronic autoimmune disease that results in inflammation and multiorgan system damage. Other forms of lupus include discoid lupus, which is limited to the skin, and neonatal lupus, which occurs when maternal autoantibodies cause a transient lupus-like syndrome in a newborn with the potential serious complication of heart block. The remaining discussion focuses on SLE.

The Lupus Foundation of America (2019) and National Kidney Foundation (2017) estimate that 5 million individuals worldwide have lupus, and 10% to 20% of these adults were diagnosed with SLE as children or adolescents. SLE in children tends to be more severe at onset and has a more aggressive clinical course than adult-onset SLE (Mina & Brunner, 2013).

SLE is more common in girls, with an approximate 4:3 female-to-male predominance before 10 years old and 4:1 in the second decade, indicating a potential hormonal trigger with maturation. There is a familial tendency, although many newly diagnosed patients are unaware of other affected family members. SLE has been reported in all cultures, but within the United States there has been a disproportionately higher incidence in African American, Asian, and Hispanic children.

The cause of SLE is not known. It appears to result from a complex interaction of genetics with an unidentified trigger that activates the disease. Suspected triggers include exposure to ultraviolet (UV) light, estrogen, pregnancy, infections, and drugs. Genetic predisposition to SLE is evidenced in an increased concordance rate in twins (tenfold), increased incidence within family members (10% to 16%), and increased frequency of certain gene alleles in population-based studies.

Clinical Manifestations and Diagnostic Evaluation

The child with SLE may have any of the clinical manifestations with mild to life-threatening severity (Box 29.10). The diagnosis is established when 4 of the 11 diagnostic criteria are met (Box 29.11). Kidney involvement heralds progressive disease and the need for rigorous therapeutic management.

Therapeutic Management

The goal of treatment is to ensure the child's health by balancing the medications necessary to avoid exacerbation and complications while preventing or minimizing treatment-associated morbidity. Therapy involves the use of specific medications and general supportive care. The drugs used to control inflammation are corticosteroids administered in doses sufficient to control inflammation and then tapered to the lowest suppressive dose or given intravenously during acute flares. Hydroxychloroquine, an antimalarial, is a useful medication for inflammatory control, rash, and arthritis. NSAIDs relieve muscle and joint inflammation, and immunosuppressive agents, such as cyclophosphamide, are administered for renal and CNS disease. Mycophenolate, azathioprine, and methotrexate are effective immunosuppressive drugs that may be used to control SLE and allow steroids to be reduced. Rituximab is a monoclonal antibody that results in decreased antibody formation and has been used off-label in pediatric patients with lupus who have not responded to standard therapy (Nwobi, Abitbol, Chandar, et al., 2008). Antihypertensives, low-dose aspirin (as a blood thinner), and calcium and vitamin D supplements are just a few of the additional remedies that may be necessary to treat or avoid complications.

General supportive care includes sufficient nutrition, sleep and rest, and exercise. Exposure to the sun and ultraviolet B (UVB) light is limited because of its association with SLE exacerbation.

BOX 29.10 Manifestations of Systemic Lupus Erythematosus

Constitutional: Fever, fatigue, weight loss, anorexia
Cutaneous: Erythematosus butterfly rash over bridge of nose and across cheeks, discoid rash, photosensitivity, mucocutaneous ulceration, alopecia, periungual telangiectasias
Musculoskeletal: Arthritis, arthralgia, myositis, myalgia, tenosynovitis
Neurologic: Headache, seizure, forgetfulness, behavior change, change in school performance, psychosis, chorea, stroke, cranial and peripheral neuropathy, pseudotumor cerebri
Pulmonary and cardiac: Pleuritis, basilar pneumonitis, atelectasis, pericarditis, myocarditis, and endocarditis
Renal: Glomerulonephritis, nephrotic syndrome, hypertension
Gastrointestinal: Abdominal pain, nausea, vomiting, blood in stool, abdominal crisis, esophageal dysfunction, colitis
Hepatic, splenic, and nodal: Hepatomegaly, splenomegaly, lymphadenopathy
Hematologic: Anemia, cytopenia
Ophthalmologic: Cotton wool spots, papilledema, retinopathy
Vascular: Raynaud phenomenon, thrombophlebitis, livedo reticularis

BOX 29.11 Classification Criteria for Systemic Lupus Erythematosus[a]

Malar rash: Fixed malar erythema
Discoid rash: Patchy erythematous lesions
Photosensitivity: Rash with sunlight exposure
Oronasal ulcers: Painless ulcers in mouth and nose
Arthritis: Swelling, tenderness, or effusion in two or more peripheral joints (nonerosive)
Serositis: Pleuritis, pericarditis
Renal disorder: Proteinuria, casts in urine
Neurologic disorder: Psychosis, seizures
Hematologic disorder: Hemolytic anemia, thrombocytopenia, leukopenia, lymphopenia
Immunologic disorder: Anti–double-stranded deoxyribonucleic acid, anti-Sm, antiphospholipid antibodies; lupus anticoagulant; false-positive result on syphilis test (rapid plasma reagin)
Antinuclear antibodies: Presence of antinuclear antibody by immunofluorescence or an equivalent assay

[a]The presence of four criteria is required for classification as systemic lupus erythematosus (SLE).

Nursing Care Management

The principal nursing goal is to help the child and family positively adjust to the disease and therapy. The child and family must learn to recognize subtle signs of disease exacerbation and potential complications of medication therapy and to communicate these concerns to their care provider. Consequently, patient and family education is an ongoing process initiated at diagnosis and tailored to the patient's individual needs. Referral to a social worker, psychologist, or support group may help the child and family make a successful adjustment. Support groups are associated with the Lupus Foundation of America and the Arthritis Foundation.

Key issues include therapy compliance; body image problems associated with rash, hair loss, and steroid therapy; school attendance; vocational activities; social relationships; sexual activity; and pregnancy (see Chapter 17 for a discussion on adjusting to a chronic illness). Specific instructions for avoiding exposure to the sun and UVB light, such as using sunscreens, wearing sun-resistant clothing, and altering outdoor activities, must be provided with great sensitivity to ensure compliance while minimizing the associated feeling of being different from peers. Patients need to be instructed to maintain regular medical supervision and seek attention quickly during illness or before elective surgical procedures, such as dental extraction, because of potential needs for increased steroids or prophylactic antibiotics. People with SLE should carry medical identification for their disease and steroid dependence.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A 6-year-old boy has experienced significant trauma in a motor vehicle crash 4 days ago. He has been in the intensive care unit and is now stabilized and being transferred to the pediatric orthopedic unit to continue recovery. He is immobilized with a fractured femur and humerus, and multiple lacerations. **Use an X for the nursing action below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Nursing Action	Indicated	Contraindicated	Non-Essential
Monitor peripheral pulses and skin temperature changes			
Use compression stockings or intermittent compression devices to decrease pooling			
Reposition every 8 hours			
Monitor intake and output closely			
Place on a hard mattress to prevent movement			
Encourage cough and deep breathing			
Complete a dietary assessment			
Monitor vital signs			

2. A 12-year-old who was in an all-terrain vehicle (ATV) accident has a long leg fiberglass cast on his left leg for a tibia-fibula fracture. He requests pain medication at 2:00 AM for pain he rates as 10/10 on the numeric scale. The nurse brings the pain medication and notes that he has removed the pillows that kept his leg elevated. He complains of pain in the left foot, and she notes that there is 3+ edema in the exposed leg and foot and she has difficulty slipping a finger under the cast; no pulse is found, and the capillary refill is difficult to visualize. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.** The nurse notes that these may be signs of a _____1_____. The nurse would immediately call the physician since permanent damage can occur within_____2_____. The nurse would _____3_____ and continue to assess for a pulse _____4_____the fracture.

Options for 1	Options for 2	Options for 3	Options for 4
bone fracture	days	keep limb at heart level	proximal to
severed nerve	hours	lower the limb	adjacent to
compartment syndrome	minutes	remove the cast	aligned with
bone contusion	seconds	turn patient on his side	alongside
bone rotation	weeks	provide pressure	distal to

3. The nurse is completing an assessment of a 2-month-old girl during a well-child visit. The infant was born breech and weighed 9 lbs. 2 oz. She is growing well and is being breast fed. She is to receive her 2-month vaccinations today. The nurse completes the assessment and finds the following on examination. Which findings would be **immediate** concern that **require follow-up**? **Select all that apply.**
   A. Back is rounded
   B. Limb may turn outward
   C. Limb may appear shorter
   D. Gluteal folds are unequal
   E. Posterior fontanel is closed
   F. Both limbs are of equal length
   G. Restricted abduction of the hip on one side

4. A 6-year-old girl is newly diagnosed with juvenile idiopathic arthritis after a 3-month history of swollen joints that are warm and painful to touch. Her symptoms also included morning stiffness. When she presented to the Emergency Department, she has bony enlargement of her left knee with an effusion. She is to be discharged today and the nurse is meeting with the parents to discuss the care she will need at home.
   Use an X for the health teaching evaluation below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).

Health Teaching	Indicated	Contraindicated	Non-Essential
"Opioid medications should be given to your child whenever she complains of pain."			
"Relaxation techniques can be effective in decreasing her pain."			
"Make sure your child takes the prescribed medications on time."			
"Keeping your child in bed when she has extremity pain will prevent swelling."			
"Swimming can help strengthen your child's muscles and maintain mobility."			
"Your child can sleep in her sister's bedroom at night if she wishes."

CONGENITAL NEUROMUSCULAR OR MUSCULAR DISORDERS

CEREBRAL PALSY

Cerebral palsy (CP) has been defined as a disorder of posture and movement from static brain injury perinatally or postnatally, which limits activity (Glader & Barkoudah, 2019; Nordqvist & Christian, 2017). In addition to motor disorders, the condition often involves disturbances of sensation, perception, communication, cognition, and behavior; secondary musculoskeletal problems; and epilepsy (Glader & Barkoudah, 2019; Nordqvist & Christian, 2017). The etiology, clinical features, and course vary and are characterized by abnormal muscle tone and coordination as the primary disturbances. CP is the most common permanent physical disability of childhood, and the incidence is reported to range from 1.5 to more than 4 per 1000 live births in various studies in the United States, affecting about 367,000 Americans (Centers for Disease Control and Prevention, 2019; Nordqvist & Christian, 2017). One systematic review and meta-analysis indicated a prevalence of 2.11 per 1000 live births, with the highest prevalence among infants weighing 1000 to 1499 g at birth; the prevalence of CP was higher among infants born before completion of 28 weeks of gestation (Oskoui, Coutinho, Dykeman, et al., 2013). Van Naarden Braun and colleagues (2016) studied spastic CP prevalence over 17 years, from 1985 to 2002, in Atlanta, Georgia, and found no significant trends by gestational age or birth weight; ethnic or racial disparities remained and warrant further investigation. In the 1960s the prevalence of CP rose approximately 20%, which most likely reflected the improved survival of extremely low birth weight (ELBW) and very low birth weight (VLBW) infants. However, in the past 2 decades there has been a decrease in the incidence of CP among ELBW and VLBW infants (Van Naarden Braun et al., 2016). The incidence is higher in males than females and more likely to occur in African Americans than in white or Hispanic children (Centers for Disease Control and Prevention, 2019).

Etiology

A variety of prenatal, perinatal, and postnatal factors contribute to the development of CP, singly or multifactorially. The human brain undergoes development during the prenatal period and up to 2 years of age. A brain insult or injury occurring during this period may result in CP.

Although the prevalent traditional hypothesis has been that CP results from perinatal problems, especially birth asphyxia, it is now believed that CP results more often from existing prenatal brain abnormalities. However, the exact cause of these abnormalities remains elusive. It has been estimated that as many as 70% to 80% of CP cases are caused by unknown prenatal factors (MacLennan, Thompson, & Gecz, 2015).

In general, infants exposed to maternal and perinatal infections are at increased risk for the development of CP as a result of the effects on the developing brain. Although CP occurs in term births, preterm birth of ELBW and VLBW infants continues to be the single most important risk factor for CP. Still, in some cases no identifiable cause is determined. Periventricular leukomalacia and intracerebral hemorrhage in low-birth-weight infants are significant risk factors in the development of CP. Perinatal ischemic stroke is also associated with a later diagnosis of CP (Golomb, Saha, Garg, et al., 2007). One study found a higher risk for CP occurring among infants born at 42 weeks of gestation or later than among those born at 37 or 38 weeks of gestation (Moster, Wilcox, Vollset, et al., 2010). Additional factors that may contribute to the development of CP postnatally include bacterial meningitis, multiple births, viral encephalitis, motor vehicle accidents, and child abuse (shaken baby syndrome [traumatic brain injury]). About 10% of children with CP acquired the condition after birth from causes such as falls, motor vehicle crashes (MVCs), and infections such as meningitis (Cerebral Palsy Guide, 2017). A significant number (4 in 10) of children with CP also have epilepsy (Centers for Disease Control and Prevention, 2019). In summary, as many as 80% of the total cases of CP may be linked to a perinatal or neonatal brain lesion or brain maldevelopment, regardless of the cause (Krageloh-Mann & Cans, 2009). A number of biochemical disorders may cause motor abnormalities often seen in CP and may be initially misdiagnosed as CP (Nehring, 2010).

Pathophysiology

It is difficult to establish a precise location of neurologic lesions on the basis of etiology or clinical signs because there is no characteristic pathologic picture. In some cases, there are gross malformations of the brain. In others, there may be evidence of vascular occlusion, atrophy, loss of neurons, and laminar degeneration that produce narrower gyri, wider sulci, and low brain weight. Anoxia appears to play the most significant role in the pathologic state of brain damage, which is often secondary to other causative mechanisms.

There are a few exceptions. In some cases, the manifestations or etiology is related to anatomic areas. For example, CP associated with preterm birth is usually spastic diplegia caused by hypoxic infarction or hemorrhage with periventricular leukomalacia in the area adjacent to the lateral ventricles. The athetoid (extrapyramidal) type of CP is most likely to be associated with birth asphyxia but can also be caused by kernicterus and metabolic genetic disorders such as mitochondrial disorders and glutaric aciduria (Johnston, 2020). Hemiplegic (hemiparetic) CP is often associated with a focal cerebral infarction (stroke) secondary to an intrauterine or perinatal thromboembolism, usually a result of maternal thrombosis or hereditary clotting disorder (Johnston, 2020). Cerebellar hypoplasia and sometimes severe neonatal hypoglycemia are related to ataxic CP. Generalized cortical and cerebral atrophy often cause severe quadriparesis with cognitive impairment and microcephaly.

Clinical Classification

A revision of the Winter classification was proposed in 2005 to reflect the child's actual clinical problems and their severity, an assessment of the child's physical and quality-of-life status across time, and long-term support needs (Nehring, 2010; Romeo, Ricci, Brogna, et al., 2016).

The proposed new definition has four major dimensions of classification (Bax, Goldstein, Rosenbaum, et al., 2005):

Motor abnormalities—Nature and typology of the motor disorder; functional motor abilities

Associated impairments—Seizures; hearing or vision impairment; attentional, behavioral, communicative, and/or cognitive deficits; oral motor and speech function

Anatomic and radiologic findings—Anatomic distribution or parts of the body affected by motor impairments or limitations; radiologic findings sometimes including white matter lesions or brain anomaly noted on computed tomography (CT) or magnetic resonance imaging (MRI)

Causation and timing—Identification of a clearly identified cause such as a postnatal event (e.g., meningitis, traumatic brain injury)

The International Classification of Functioning, Disability and Health (ICF) emphasizes participation and function, whereas the Gross Motor Function Classification System (GMFCS), Functional Mobility Scale (FMS) (Sehrawat, Marwaha, Bansal, et al., 2014), Manual Ability Classification System (MACS), and Communication Function Classification Scale (CFCS) have been widely used to assess fine motor, gross motor, and communication ability (Sun, Wang, Hou, et al., 2018). Several studies used the Hammersmith Infant Neurological Examination (HINE) as an examination tool in diagnosing CP.

CP has four primary types of movement disorders: spastic, dyskinetic, ataxic, and mixed (Box 30.1) (Nehring, 2010). The most common clinical type, spastic CP (75% to 85% reported by the Centers for Disease Control and Prevention [2019]), represents an upper motor neuron muscular weakness. The reflex arc is intact, and the characteristic physical signs are increased stretch reflexes, increased muscle tone, and (often) weakness. Early neurologic manifestations are usually generalized hypotonia or decreased tone that lasts for a few weeks or may extend for months or even as long as a year.

BOX 30.1 Clinical Classification of Cerebral Palsy

Spastic (Pyramidal)

- Characterized by persistent primitive reflexes, positive Babinski reflex, ankle clonus, exaggerated stretch reflexes, eventual development of contractures
- 70% to 80% of all cases of cerebral palsy (CP)
- **Diplegia**—All extremities affected; lower more than upper (30% to 40% of spastic CP)
- **Tetraplegia**—All four extremities involved: legs and trunk, mouth, pharynx, and tongue (10% to 15% of spastic CP)
- **Triplegia**—Three limbs involved
- **Monoplegia**—Only one limb involved
- **Hemiplegia**—Motor dysfunction on one side of the body; upper extremity more affected than lower (20% to 30% of spastic CP)
- Hypertonicity with poor control of posture, balance, and coordinated motion
- Impairment of fine and gross motor skills

Dyskinetic (Nonspastic, Extrapyramidal)

- **Athetoid**—Chorea (involuntary, irregular, jerking movements); characterized by slow, wormlike, writhing movements that usually involve the extremities, trunk, neck, facial muscles, and tongue
- **Dystonic**—Slow, twisting movements of the trunk or extremities; abnormal posture
- Involvement of the pharyngeal, laryngeal, and oral muscles causing drooling and dysarthria (imperfect speech articulation)

Ataxic (Nonspastic, Extrapyramidal)

- Wide-based gait
- Rapid, repetitive movements performed poorly
- Disintegration of movements of the upper extremities when the child reaches for objects

Mixed Type

- Combination of spastic CP and dyskinetic CP
- May be labeled *mixed* when no specific motor pattern is dominant; however, this term is losing favor to more precise descriptions of motor function and affected area of brain involved (Rosenbaum, Paneth, Leviton, et al., 2007)

Data from Nehring, W. (2010). Cerebral palsy. In P. J. Allen, J. A. Vessey, & N. A. Schapiro (Eds.), *Primary care of the child with a chronic condition* (5th ed.). St. Louis, MO: Mosby; Jones, M. W., Morgan, E., Shelton, J. E., et al. (2007). Clinical Manifestations

The alert observer may suspect CP when a child demonstrates some of the groups of manifestations in Box 30.2.

Delayed Gross Motor Development

Delayed gross motor development is a universal manifestation of CP. The child shows a delay in all motor accomplishments, and the discrepancy between motor ability and expected achievement tends to increase with successive developmental milestones as growth advances. It is especially significant if other developmental behaviors, such as language and personal-social achievement, are normal. Delayed development of the ability to balance may also slow the progression of milestones.

Abnormal Motor Performance

Neuromotor dysfunction is particularly evident in motor performance. An early sign is preferential unilateral hand use that may be apparent at approximately 6 months of age. Hand dominance does not normally develop until the preschool years. Abnormal crawling

BOX 30.2 Clinical Manifestations of Cerebral Palsy (at Time of Diagnosis)

Delayed Gross Motor Development
- A universal manifestation
- Delay in all motor accomplishments
- Increases as growth advances
- Delays more obvious as growth advances

Abnormal Motor Performance
- Very early preferential unilateral hand preference
- Abnormal and asymmetric crawl
- Standing or walking on toes
- Uncoordinated or involuntary movements
- Poor sucking
- Feeding difficulties
- Persistent tongue thrust

Alterations of Muscle Tone
- Increased or decreased resistance to passive movements
- Opisthotonic posturing (arching of back)
- Feels stiff on handling or dressing
- Difficulty in diapering
- Rigid and unbending at the hip and knee joints when pulled to sitting position (early sign)

Abnormal Postures
- Maintains hips higher than trunk in prone position with legs and arms flexed or drawn under the body
- Scissoring and extension of legs with feet plantar flexed in supine position
- Persistent infantile resting and sleeping position
- Arms abducted at shoulders
- Elbows flexed
- Hands fisted

Reflex Abnormalities
- Persistence of primitive infantile reflexes
- Obligatory tonic neck reflex at any age
- Nonpersistence beyond 6 months of age
- Persistence or hyperactivity of the Moro, plantar, and palmar grasp reflexes
- Hyperreflexia, ankle clonus, and stretch reflexes elicited in many muscle groups on fast, passive movements

Associated Disabilities
- Altered learning and reasoning
- Seizures
- Impaired behavioral and interpersonal relationships
- Sensory impairment (vision, hearing)

From Nehring, W. M. (2010). Cerebral palsy. In P. J. Allen, J. A. Vessey, & N. A. Schapiro (Eds.), *Primary care of the child with a chronic condition* (5th ed.). St. Louis, MO: Mosby. Adapted from Jones, M. W., Morgan, E., & Shelton, J. E. (2007). Primary care of the child with cerebral palsy: A review of systems (part II). *Journal of Pediatric Health Care, 21*(4), 226–237.

with propulsion by hand movements only and with lower extremities and hips hiked along, much like a "bunny hop," occurs in diplegia. Children with hemiplegia have an asymmetric crawl, using the unaffected arm and leg to propel themselves on either the buttocks or the abdomen. Spasticity may cause the child to stand or walk on the toes. Uncoordinated or involuntary movements are characteristic of dyskinetic CP, and facial grimacing and writhing movements of the tongue, fingers, and toes are signs of athetosis. Other significant signs of motor dysfunction are poor sucking and feeding difficulties, with persistent tongue thrust. Head staggering, tremor on reaching, and truncal ataxia are also common. Hand preference in the first 2 years of life is reported to be a sign of hemiplegic CP (Berker & Yalçin, 2008).

Alterations of Muscle Tone

Increased or decreased resistance to passive movements is a sign of abnormal muscle tone. The child may exhibit opisthotonic postures (exaggerated arching of the back) and may feel stiff on handling or dressing. Also, there is difficulty in diapering because of spasticity of the hip adductor muscles and lower extremities. When pulled to a sitting position, the child may extend the entire body and be rigid and unbending at the hip and knee joints. This is an early sign of spasticity.

Abnormal Posture

Children with spastic CP assume abnormal postures at rest or when their position is changed. From an early age, a child lying in a prone position will maintain the hips higher than the trunk with the legs and arms flexed or drawn under the body. In the supine position spasticity is evident by scissoring (legs in crossed position; knees, hips, and ankles stiff) and extension of the legs, with the feet plantar flexed. This posture is exaggerated when the child is suspended vertically or when others try to make the child bear weight. Depending on the degree of impairment, spasticity may be mild or severe. A persistent infantile resting and sleeping posture (i.e., arms abducted at shoulders, elbows flexed, and hands fisted) is a sign of spasticity when it remains constant after 4 to 5 months of age. The hemiparetic child may rest with the affected arm adducted and held against the torso, with the elbow pronated and slightly flexed and the hand closed.

Reflex Abnormalities

Persistence of primitive reflexes is one of the earliest clues to CP (e.g., obligatory tonic neck reflex at any age or nonobligatory persistence beyond 6 months of age, and the persistence or even hyperactivity of the Moro, plantar, and palmar grasp reflexes). Hyperreflexia, ankle clonus, and stretch reflexes can be elicited from many muscle groups on fast passive movements (e.g., resistance to passive abduction when the hips are suddenly separated [adductor catch]).

Associated Disabilities and Problems

Some of the disabilities associated with CP are visual impairment, hearing impairment, behavioral problems, communication and speech difficulties, seizures, and intellectual impairment. Additional sensory deficits such as hypersensitivity, hyposensitivity, and balance difficulties may occur in children with CP (Nehring, 2010). According to the Centers for Disease Control and Prevention (2019), about 1 in 10 children with CP are also diagnosed with autism spectrum disorder.

Intellectual impairment is a concern, although children with CP have a wide range of intelligence, and 50% to 60% are within normal limits. Speech difficulties are often interpreted as a sign of cognitive impairment. Assessing the intelligence of a child with CP is often difficult because of the motor and sensory deficits. Tests carried out periodically over time should determine the degree of intelligence. Many persons with CP who have severely limiting physical involvement actually have the least intellectual impairment. As a group, children with athetosis and ataxia are intellectually superior to those with other types of CP. The incidence of severe or profound impairment is highest in rigid and atonic CP. Improved communication devices (e.g., communication jacket, computerized communication) have revealed that some people with quadriplegic spastic CP have normal intelligence. Rick Hoyt, for example, who has quadriplegic spastic CP,

communicates with his eyes and slight head movement and a computer to spell what he wants to communicate; he graduated from University of Boston and serves as consultant for technology devices.

The manifestations of attention-deficit/hyperactivity disorder may occur in children with CP. The primary presenting symptoms are poor attention span, marked distractibility, hyperactive behavior, and defects of integration (see Chapter 16). Seizures are more likely to accompany postnatally acquired hemiplegia. They are an unusual finding in ataxia and diplegia. The most common types of seizures are generalized tonic-clonic seizures and minor motor types (Nehring, 2010). Epilepsy is reported to occur in 41% of children with CP; epilepsy was especially common in nonambulatory children (Christensen, Van Naarden Braun, Doernberg, et al., 2014).

Poor control of oral musculature may contribute to a number of problems. Abnormal posture and motor performance and alterations in muscle tone affect chewing, swallowing, and talking. Occupational and speech-language therapy interventions may be necessary to assist some children with feeding and speech. Coughing and choking, especially while eating, may predispose the child with CP to aspiration, which may not be readily apparent. Respiratory problems may result from and coexist with feeding difficulties in children with CP; respiratory symptoms observed during feedings include apnea, dyspnea, tachypnea, coughing and choking, and hypoxemia (Nehring, 2010). Many children with CP may also have gastroesophageal reflux.

Motor impairment associated with CP contributes to other problems. Children with CP who are nonambulatory have an increased risk of developing orthopedic complications such as unilateral or bilateral hip dislocations, scoliosis, and joint contractures resulting from unbalanced muscle tone. One study examined the Cobb angle for use in predicting the course of scoliosis in adolescents with CP (Oda, Takigawa, Sugimoto, et al., 2017).

A variety of factors, including decreased mobility, decreased fluid intake, a fear of toileting, poor positioning on the toilet, and lack of fiber intake, may be responsible for constipation (Nehring, 2010). Stool softeners, laxatives, and a bowel management program may be required to prevent chronic constipation.

Increased incidence of dental caries results from improper dental hygiene, congenital enamel defects (hypoplasia of primary teeth), high carbohydrate intake and retention, dietary imbalance with poor nutritional intake, inadequate fluoride, and difficulty in mouth closure and drooling. Spastic or clonic movements can cause gagging or biting down on the toothbrush, thus interfering with cleaning techniques. Oral hypersensitivity is also common, which causes the child to resist dental hygiene. Malocclusion can occur in as many as 90% of these children. Gingivitis is secondary to inadequate dental hygiene and may be further complicated by the use of antiepileptic drugs (AEDs) such as phenytoin (Nehring, 2010). Sehrawat and colleagues (2014) presented an eloquent coverage of the complexities and importance of dental care in children with CP. The CP multidisciplinary clinic within the University of Kansas Medical Center included a dental assistant at each clinic as part of the Kansas state initiative to improve oral health. The nurse may check with the state to see if it could provide this for special needs children. It was most helpful for families to receive teaching on oral health.

Skin breakdown may occur with prolonged positioning, especially with underweight children with bony prominences and those who are unable to reposition themselves or who may have insensate areas of skin.

Nystagmus and amblyopia are common and may require surgery, corrective lenses, or both. Hearing impairment is also common in children with CP. Some loss is caused by sensorineural involvement. Affected infants may spend increased amounts of time lying flat. This predisposes them to otitis media, which may result in conductive hearing loss.

Diagnostic Evaluation

Infants at risk according to known etiologic factors associated with CP warrant careful assessment during early infancy to identify the signs of muscular dysfunction as early as possible. Recent clinical practice guidelines recommend that a diagnosis of CP or of high risk of CP, can be made within the first 6 months postterm age (Spittle, Morgan, Olsen, et al., 2018). The neurologic examination and history are the primary modalities for diagnosis. Neuroimaging of the child with suspected brain abnormality and CP, is now recommended for diagnostic assessment, with MRI being a strong predictor of CP when performed at term (corrected age); general movements assessment also had a strong predictive value in children older than 2 years of age and younger than 5 years of age (Bosanquet, Copeland, Ware, et al., 2013). MRI has the capability of early identification of infants at risk for CP (George, Fiori, Fripp, et al., 2017). MRI was useful in predicting language development in people with certain brain lesions (Choi, Choi, & Park, 2017). Metabolic and genetic testing is recommended if no structural abnormality is identified by neuroimaging; laboratory tests are no longer recommended in the diagnostic process for CP.

Early recognition is made more difficult by the lack of reliable neonatal neurologic signs. However, the nurse should monitor infants with known etiologic risk factors and evaluate them closely in the first 2 years of life. Because cortical control of movement does not occur until later in infancy, motor impairment associated with voluntary control is usually not apparent until after 2 to 4 months of age at the earliest. More often the diagnosis cannot be confirmed until the age of 1 or 2 years because motor tone abnormalities may be indicative of another neuromuscular condition. In addition, some children who show signs consistent with CP before 2 years do not demonstrate such signs after 2 years (Nehring, 2010). However, there is no consensus regarding an age cutoff for the onset of symptoms.

Establishing a diagnosis may be easier with the persistence of primitive reflexes: either the asymmetric tonic neck reflex or the persistent Moro reflex (beyond 4 months of age), and the crossed extensor reflex. The tonic neck reflex normally disappears between 4 and 6 months of age. An obligatory response is considered abnormal. This is elicited by turning the infant's head to one side and holding it there for 20 seconds. When a crying infant is unable to move from the asymmetric posturing of the tonic neck reflex, it is considered obligatory and an abnormal response. The crossed extensor reflex, which normally disappears by 4 months, is elicited by applying a noxious stimulus to the sole of one foot with the knee extended. Normally the contralateral foot responds with extensor, abduction, and then adduction movements. The possibility of CP is suggested if these reflexes occur after 4 months.

A number of assessment instruments are available to evaluate muscle spasticity (Modified Ashworth Scale); functional independence in self-care, mobility, and cognition (Functional Independence Measure and WeeFIM [specific to children]); self-initiated movements over time (Gross Motor Function Measure); and capability and performance of functional activities in self-care, mobility, and social function (Pediatric Evaluation of Disability Inventory) (Krigger, 2006). Elastography is a new way to measure the flexibility of muscles, tendons, and nerves. A new technique, myotonometry, allows objective assessment of muscle spasticity by quantifying tissue displacement response to a standard measuring compression force, and it is suggested to be a sensitive method that can be used in daily clinical practice (Balci, 2018).

BOX 30.3 Therapeutic Interventions for Cerebral Palsy

Interdisciplinary developmental and physical assessment with recommendations may include the following:

Physical Therapy

Orthotic Devices

- Braces
- Splints
- Casting
- Molded orthoses

Adaptive Equipment

- Scooters, bicycles, and tricycles
- Wheelchairs
- Boards
- Standing devices

Functional (Neuromuscular) Electrical Stimulation (in Combination With Dynamic Splinting)

Occupational Therapy

Adaptive Equipment

- Utensils for functional use (e.g., eating, writing)
- Switches
- Computers

Speech-Language Therapy

- Oral-motor skills
- Adaptive communication techniques

Special Education

- Early intervention programs
- Specialized learning programs and support services in school
- Socialization to promote self-concept development

Surgical Intervention

- Orthopedic (e.g., tendon transfers, muscle lengthening, spinal deformities)
- Neurologic (e.g., neurectomies)
- Selective dorsal rhizotomy
- Feeding (e.g., gastrostomy)
- Dental

Medication Therapy

- Medications to treat the following:
  - Spasticity
  - Pain
  - Secondary conditions (e.g., seizure disorder, chronic constipation, urinary tract infections, gastroesophageal reflux)
- Primary care for health supervision and acute childhood illnesses

Behavioral Therapy

Care Coordination

- Care coordination of specialized services and community resources in collaboration with the child's family

Modified from Nehring, W. M. (2010). Cerebral palsy. In P. J. Allen, J. A. Vessey, & N. A. Schapiro (Eds.), *Primary care of the child with a chronic condition* (5th ed.). St. Louis, MO: Mosby.

A thorough knowledge of normal variations of motor development is required for detecting abnormal progress, and a careful history is necessary to detect possible etiologic factors. Observe the child's spontaneous movements and behavior, including posture; attitude; and muscle size, function, and tone. Because children with CP often have sensory deficits, it is appropriate to evaluate the child for hearing and vision deficits.

Therapeutic Management: General Concepts

The goals of therapy for children with CP are early recognition and promotion of an optimum developmental course to enable affected children to attain their potential within the limits of their dysfunction. The disorder is permanent, and therapy is chiefly symptomatic and preventive.

The beneficial influences of a habilitation program on both child and family are based on recognizing the disability as early as possible and implementing treatment. Parents are essential to a treatment program. Consider their goals and desires, their cooperation, and their confidence in all aspects of management. With early diagnosis parents can begin to provide the sensorimotor experiences essential to cognitive development because central nervous system (CNS) structures depend on stimulation and use to attain and maintain their functional integrity.

The broad aims of therapy are to (1) establish locomotion, communication, and self-help skills; (2) gain optimum appearance and integration of motor functions; (3) correct associated defects as early and effectively as possible; (4) provide educational opportunities adapted to the individual child's needs and capabilities; and (5) promote socialization experiences with other affected and unaffected children. Each child is evaluated and managed on an individual basis. The plan of therapy may involve a variety of settings, facilities, and specially trained persons. The scope of the child's needs requires multidisciplinary planning and care coordination among professionals and the child's family (Box 30.3). The outcome for the child and family with CP is normalization and promotion of self-care activities that empower the child and family to achieve maximum potential.

Mobilizing Devices

Many children with CP wear ankle–foot orthoses (AFOs) (braces) and a variety of orthotics. Orthotics are molded to fit the feet and are worn inside the shoes. Devices are often used to help prevent or reduce deformity, increase the energy efficiency of gait, and control alignment. Some of the more commonly used mobility devices include wheeled scooter boards that allow children to propel themselves while the abdomen or total body is supported and the legs are positioned with wedges to prevent scissoring. Wheeled go-carts provide good sitting balance and serve as an early "wheelchair" experience for young children. Strollers can be equipped with custom seats for dependent mobilization. Special devices for independent mobilization that may or may not allow the upper extremities to remain free are particularly valuable for children with lower extremity involvement (Fig. 30.1). A number of wheelchairs can be customized to meet the needs and preferences of older children (Fig. 30.2).

Surgery

Surgical intervention is usually reserved for the child who does not respond to more conservative measures such as orthotics, but it is also indicated for the child whose spasticity causes progressive deformities. Orthopedic surgery may be required to correct contracture or spastic deformities, to provide stability for an uncontrollable joint, to address bone malalignment (e.g., lever arm dysfunction), and to provide balanced muscle power. This includes tendon-lengthening procedures

Fig. 30.1 Child ambulating with use of assistive device.

Fig. 30.2 Bike walker used to provide mobility and to enhance leg muscle strength.

(especially heel-cord lengthening), release of spastic wrist flexor muscles, and correction of hip and adductor muscle spasticity or contracture to improve locomotion. Orthopedic specialists with special interest in CP will implement hip observation protocols for children considered at risk for hip abnormalities. Hip surveillance and surgical salvage choices are individual for each person with CP. There is not one procedure that fits all. Orthopedic surgery is generally not performed until after the child is 6 years old (Nehring, 2010). Surgery is used primarily to improve function rather than for cosmetic purposes and is followed by physical therapy. Surgery may also be performed to improve caloric intake, correct gastroesophageal reflux disease, prevent aspiration, and correct associated dental problems (Nehring, 2010).

Neurosurgical procedures are used only in selected cases. Selective dorsal rhizotomy has provided marked improvement in some children with CP (Park, Dobbs, & Cho, 2018). After selective dorsal rhizotomy, gait was improved in children with CP (Rumberg, Bakir, Taylor, et al., 2016). However, achieving the benefits from the surgery requires intensive physical therapy and family commitment. Because the procedure results in flaccid muscles, the child must relearn to sit, stand, and walk.

Medication

Intense pain may occur with muscle spasms in patients with CP. Children with CP may also experience pain as a result of painful procedures such as injection with botulinum toxin type A (Botox), surgical procedures intended to reduce contracture deformities, abdominal pain related to position and gastroesophageal reflux, and pain associated with physical therapy. Therefore pain management is an important aspect of the care of the child with CP.

Pharmacologic agents given orally (dantrolene sodium [Dantrium], baclofen [Lioresal], and diazepam [Valium]) have had little effectiveness in improving muscle coordination in children with CP. However, they are effective in decreasing overall spasticity. The most common side effects of these agents include hepatotoxicity (dantrolene), drowsiness, fatigue, and muscle weakness. Less commonly, diaphoresis and constipation may occur with oral baclofen; other possible complications include hallucinations, mood changes, seizures, nausea, and urinary incontinence. Diazepam is used frequently but should be restricted to older children and adolescents.

Botulinum toxin A is also used to reduce spasticity in targeted muscles of the upper and lower extremities (Yana, Tutuola, Westwater-Wood, et al., 2019). Botulinum toxin A is injected into a selected muscle (commonly the quadriceps, gastrocnemius, or medial hamstrings), where it acts to inhibit the release of acetylcholine into a specific muscle group, thereby preventing muscle movement. When it is administered early in the course of the illness, this may prevent affected muscle contractures, particularly in lower extremities, thus avoiding surgical procedures with possible adverse effects. The goal is to allow stretching of the muscle; as it relaxes, it permits ambulation with an AFO. The major reported adverse effects of botulinum toxin A injection include pain at the injection site and a temporary weakness (Yana et al., 2019). Prime candidates for botulinum toxin A injections are children with spasticity confined to the lower extremities. The onset of action occurs within 24 to 72 hours, with a peak effect observed at 2 weeks and a duration of action of 3 to 6 months. Decreasing spasticity with botulinum toxin A may also result in less pain from spasms (Yana et al., 2019). One case study showed improvement with spinal balance after one botulinum toxin A injection (Chaléat-Valayer, Bernard, Deceuninck, et al., 2016).

The neurosurgical and pharmacologic approach to managing the spasticity associated with CP involves the implantation of a pump to infuse baclofen directly into the intrathecal space surrounding the spinal cord to provide relief of spasticity. High doses of oral baclofen are associated with significant side effects, including drowsiness and confusion, yet are often unable to provide adequate relief of spasticity. Direct infusion of baclofen into the intrathecal space is especially helpful in improving comfort without as many side effects (Eek, Olsson, Lindh, et al., 2018).

One study combined baclofen and antibiotic in the pump to prevent infection and maintain lasting stability and benefit of the pump (Aristedis, Dimitrios, Nikolaos, et al., 2017). Patients may be screened before pump placement by the infusion of a "test dose" of intrathecal baclofen delivered via a lumbar puncture. Close monitoring for side effects (e.g., hypotonia, somnolence, seizures, nausea, vomiting, headache, catheter- or pump-related problems) and relief of spasticity occurs for several hours after the infusion. If a positive effect occurs, the patient is considered a candidate for pump placement.

The pump is placed in the subcutaneous space of the midabdomen; it is about the size of a hockey puck. An intrathecal catheter is tunneled from the lumbar area to the abdomen and connected to the pump. The pump is filled with baclofen and programmed to provide a set dose using a telemetry wand and a computer. The patient remains hospitalized for several days to adjust the dosage and ensure proper

healing. Outpatient visits to refill the pump and make dosage adjustments occur about every 4 to 6 weeks, depending on the patient's response to the treatment. Benefits of intrathecal baclofen include fewer systemic side effects, dosage titration for maximizing effects, and reversibility of therapy with removal of the pump if so desired. Abrupt withdrawal of intrathecal baclofen, especially at high doses, may result in adverse effects such as rebound spasticity, pruritus, hyperthermia, rhabdomyolysis, disseminated intravascular coagulation, multiorgan failure, and death; in some cases intrathecal baclofen withdrawal may mimic sepsis. Treatment of withdrawal centers on reestablishing the medication dosage, with improvements observed within 1 to 2 hours. Hospitalization and surgery may be required for withdrawal as a result of pump or catheter failure.

AEDs such as carbamazepine (Tegretol), divalproex (valproate sodium and valproic acid [Depakote]), oxcarbazepine (Trileptal), and lamotrigine (Lamictal) are prescribed routinely for children who have seizures. Gabapentin (Neurontin) has been used in adults with spinal cord injury (SCI) to decrease spasticity with success. Yuan-Kim Liow and colleagues (2016) found that gabapentin improved quality of life, pain, and dystonia in children with CP. The α_2-adrenergic agonists clonidine (Catapres) and tizanidine (Zanaflex) have been used to decrease spasticity in adults with SCI and multiple sclerosis; however, their use in children does not appear to have gained widespread acceptance in the United States. Oral tizanidine given in conjunction with botulinum type A has been reported to be more effective than oral baclofen and botulinum type A in one study of children with CP (Dai, Wasay, & Awan, 2008). Monitor all medications for maintenance of therapeutic levels and avoidance of subtherapeutic or toxic levels (see Quality Patient Outcomes box).

QUALITY PATIENT OUTCOMES: Seizures
- No physical injury as a result of seizure activity
- Prevention of seizure activity

Children with CP have been treated with a number of complementary and alternative medicine strategies, including Chinese herbs, acupuncture, growth hormone therapy, aquatic exercise, equine-assisted therapy, and hyperbaric oxygen (Nehring, 2010). Gasalberti (2006) reported some alternative therapies being used in children with disabilities that the practitioner may overlook during a health history but that may be beneficial to such children. These include pet therapy, massage, hippotherapy (horse riding), music, and color-light therapy. Other alternative therapies that may be used by families with children with disabilities include vitamins, prayer, meditation, hypnosis, and guided imagery.

Technical Aids

A wide variety of technical aids are available to improve the functioning of children with CP. These include electromechanical toys that use the concept of biofeedback and operate from a head unit. The toy is manipulated only when the head and trunk are in correct alignment. Computerized toys and games can also enhance eye-hand coordination.

Microcomputers combined with voice synthesizers help children with speech difficulties to "speak." Smart phones and tablets with speech applications are appropriate for some children. These and other devices print messages onto screen monitors and paper. These devices have made it apparent that some children have been erroneously considered to be cognitively impaired. Microcomputers have also increased the possibilities for increased mobility via wheelchairs and specially designed mobilization devices.

Many other electronic devices allow independent functioning. Computerized games have been studied to help with fine motor skills in school-age children (Kanitkar, Szturm, Parmar, et al., 2017). Robots were studied to help improve movement in children with CP; there is a need for more cost-effective robots to further evaluate effectiveness (Michmizos & Krebs, 2017). Combined brain stimulation and robotics improved upper limb functioning in adults with CP; more study is needed with children (Friel, Lee, Soles, et al., 2017).

Sensors can be activated and deactivated using a head-stick, a voluntary muscle such as the tongue, or any other voluntary muscle movement over which the child has control. The application of this technology makes it possible for older persons with CP to eventually function in their own apartments and can be extended into the workplace.

Associated Problems

Children with CP often have sensory deficits, which require the attention of appropriate specialists. Speech-language therapy involves the services of a speech-language pathologist (SLP) who may also assist with feeding problems (see Chapter 20). Dental care is especially important for children with CP and often is overlooked. Regular visits to the dentist and dental prophylaxis, including brushing, fluoride, and flossing (after several teeth are present), should begin as soon as the teeth erupt. This is especially important for children given phenytoin, who often develop gum hyperplasia. Additional problems common among children with CP include constipation caused by neurologic deficits and lack of exercise; poor bladder control and urinary retention; chronic respiratory tract infections and aspiration pneumonia, which occur as a result of gastroesophageal reflux, abnormal muscle tone, immobility, and altered positioning; and skin problems as a result of altered positioning, poor nutrition, and immobility. Hip dislocation occurs often in children with CP. Latex allergy has also been reported in children with CP (Nehring, 2010).

Therapeutic Management: Therapies, Education, Recreation

Physical Therapy

Physical therapy is one of the most commonly used treatment modalities in children with CP. In general, physical therapy is directed toward good skeletal alignment for the child with spasticity; training in purposeful acts, even in the face of involuntary motion, for the child with athetosis; and gait training and maximum development of proprioceptive sense for the child with ataxia.

An active therapy program involves the family, the physical therapist (PT), the occupational therapist (OT), and other members of the health care team. Developing a treatment program that can be carried out at home is of utmost importance. The major approach uses traditional types of therapeutic exercises that consist of stretching; passive, active, and resistive movements applied to specific muscle groups or joints to maintain or increase range of motion; strength; or endurance. Neuromuscular electrical stimulation combined with dynamic splinting may benefit some children (Wright, Durham, Ewins, et al., 2012). No therapeutic approach is able to achieve spectacular changes in the ultimate outcome of motor disability. Early efforts focus on alleviating abnormal postures by positioning and range-of-motion exercises. Passive range-of-motion exercises, stretching, and elongation exercises are valuable at any age, even when the child is too young to cooperate. Some active extension can be performed when the child is old enough to cooperate, with passive motion applied to complete joint

extension. Prevention of contracture deformity is a prime function of physical therapy. Seating, mobility, strength, and endurance are other key goals.

Functional and Adaptive Training (Occupational Therapy)

Training in manual skills and activities of daily living (ADLs) proceeds along developmental lines and according to the child's functional level. Sitting, balancing, crawling, and walking are encouraged at appropriate ages and are accompanied by stimulation of protective extension and equilibrium reactions. Hand activities are begun early to improve motor function and provide the child with sensory experiences and information about the environment. As the child progresses from simple feeding and self-care activities, training is extended to include other tasks (e.g., cooking or use of keyboard or computer mouse) that are within the child's developmental and functional capabilities.

Incorporating play into the therapeutic program often requires great ingenuity and inventiveness from those involved in the child's care. Objects and toys are chosen to provide needed sensory input using a variety of shapes, forms, and textures. Nurses can help parents integrate therapy into play activities in natural ways.

Children with CP may need considerable help (and patience) in learning to feed and dress themselves and care for personal hygiene needs. A feeding program may be developed by an OT in conjunction with an SLP. Children should be fed in the normal eating position. When they have difficulty sucking and swallowing, it is tempting to hold them in a semireclining posture to make use of gravity flow. However, this method does not promote active swallowing, and the neck hyperextension may even interfere with swallowing. A more flexed sitting position, with the arms brought forward to decrease the tendency toward back and neck extension, is more natural during bottle- or spoon-feeding and encourages active swallowing.

Because jaw control is compromised, more normal control can be achieved if the feeder provides stability for the oral mechanism from the side or front of the face. When directed from the front, the middle finger of the nonfeeding hand is placed posterior to the bony portion of the chin, the thumb is placed below the bottom lip, and the index finger is placed parallel to the child's mandible (Fig. 30.3). Manual jaw control from the side assists with head control, correction of neck and trunk hyperextension, and jaw stabilization. The middle finger of the nonfeeding hand is placed posterior to the bony portion of the chin, the index finger is placed on the chin below the lower lip, and the thumb is placed obliquely across the cheek to provide lateral jaw stability (Fig. 30.4).

In all ADLs it is important to capitalize on the child's assets and compensate for liabilities. The level of expected independence is related to both gross and fine motor manipulation. Even when complete independence in a specific activity is not realistic, the child should learn any part of the task that he or she can master. However, motor function is not the sole purpose of learning to be as independent as possible. Any accomplishment promotes self-reliance and self-esteem for healthier personality development.

Speech Therapy

Speech training under the supervision of an SLP begins early, before the child learns poor habits of communication. Parents and others can help by following the directions of the speech therapist and by talking to the child slowly while using pictures or handling objects about which the adult is speaking. Feeding techniques such as forcing the child to use the lips and tongue in eating facilitate speech. An example of this technique is placing food at the side of the tongue, first one side and then the other, and making the child use the lips to take food from a spoon rather than placing it directly on the tongue. If severe dysarthria prevents articulate speech and the child has reasonable intelligence, the child learns nonverbal communication (e.g., sign language) (see Chapter 18).

Fig. 30.3 Manual jaw control provided anteriorly.

Fig. 30.4 Manual jaw control provided from the side.

Education

As in all aspects of care, educational requirements are determined by the child's needs and potential. This includes the severity of the child's disease and the presence and degree of associated conditions that affect learning and participation, such as learning impairment, abnormal actions or behaviors, impaired vision or hearing, and seizures. Children with mild to moderate cognitive involvement are generally able to participate, for varying amounts of time, in regular classes. Resource rooms are available in most schools to provide more individualized attention to a child's particular needs. Integration of these children into regular classrooms should be the initial goal. Teachers' assistants often work one-on-one with children in both settings. A training program may be appropriate for those children who are unable to benefit from formal education. Prevocational and vocational counseling and guidance are arranged at adolescence. Education is geared toward the child's assets at any phase or in any setting. Nurses should be aware of early intervention programs and provisions for special education and related

services for children and should support parents in their efforts to obtain appropriate educational services for the child. Bourke-Taylor and colleagues (2017) emphasized the importance of collaboration among team members of school-age children with CP in schools, in the community, in health care, and across the life span for best outcomes.

Recreation

Recreational activities are also a necessary part of growing up. Recreational outlets and after-school activities should be an option for the child who is unable to participate in regular athletic and other peer activities. Some can compete in athletic and artistic endeavors, and many games and pastimes are suited to their capabilities. Sports, physical fitness, and recreation programs are encouraged for children with CP, and young children should be exposed to all physical activities available to children without disabilities. Individual sports such as the martial arts (e.g., Tae Kwon Do) in which groups are small and the emphasis is on discipline and balance are also enjoyable to many children with CP. Many states mandate adaptive physical education classes.

Numerous developmental centers have facilities for indoor and outdoor activities designed to appeal to children of all ages. If these are not available, they should be developed. However, such programs require adequate supervision to avoid any harmful effects. Recreational activities serve to stimulate children's interest and curiosity, help them adjust to their disability, improve their functional abilities, and build self-esteem. Competitive sports are also becoming increasingly available to children with disabilities and offer an added dimension to physical activities. For more information, access the United Cerebral Palsy website (http://www.ucp.org) and go to the Sports and Leisure link. Any accomplishment that helps children approach a normal way of life enhances their self-concept.

Prognosis

The prognosis for the child with CP depends largely on the type and severity of the condition. Children with mild to moderate involvement (85%) have the capability of achieving ambulation between the ages of 2 and 7 years (Berker & Yalçin, 2008). If the child does not achieve independent ambulation by this time, chances are poor for ambulation and independence. Approximately 30% to 50% of individuals with CP have significant cognitive impairments, and an even higher percentage have mild cognitive and learning deficits (National Institute of Neurological Disorders and Stroke, 2013). Children with profound cognitive impairment have a higher mortality rate, and less than one-half of those children reach adulthood (O'Shea, 2008). However, many children with severe spastic tetraplegic CP have normal intelligence. Growth is affected in children with spastic tetraplegia, and many children remain below the 5th percentile for age and sex.

As children with CP become adults, about 30% remain in the home and are cared for by a parent or caregiver; 50% of individuals with spastic tetraplegia live in independent settings and function at appropriate social levels considering their disability (Green & Hurvitz, 2007). Vocational rehabilitation and higher education are possible for adults with CP. Children with severe CP mobility impairment and feeding problems often succumb to respiratory tract infection in childhood. The few survival rate studies on children or adults with CP show that survival is influenced by existing comorbidities (Nehring, 2010). In general, the more medically fragile children are least likely to survive to adulthood (Westbom, Bergstrand, Wagner, et al., 2011) (see Quality Patient Outcomes box).

QUALITY PATIENT OUTCOMES: Pain

- Acceptable pain threshold experienced as defined by patient or caregiver, or a pain score of 4 or less on Wong-Baker FACES Pain Rating Scale.
- The occurrence of pain in people with cerebral palsy (CP) was measured and found to be similar to previous reports. More attention to the report and treatment of pain needs to be given (Westbom, Rimstedt, & Nordmark, 2017).
- Early detection, prevention, and treatment of pain in children with CP have been studied by several (Adolfsson, Johnson, & Nilsson, 2017).

Nursing Care Management

Assessment

Nursing assessment includes risk identification of infants with etiologic factors that are associated with CP. Ongoing assessment of infants for abnormal muscle tone, inability to achieve developmental milestones, and persistence of neonatal reflexes alert the nurse to investigate further.

Reinforce Therapeutic Plan and Assist in Normalization

Because children are being treated at an earlier age, parents are participating at an earlier stage in treatment programs for their disabled child. They learn the proper handling and home care of young children with CP and need carefully programmed steps so that their expanded parental role can be melded into the established relationship. Close work with other multidisciplinary team members is essential. Nurses reinforce the therapeutic plan and assist the family in devising and modifying equipment and activities to continue the therapy program in the home (see also Chapter 17).

Some children have difficulty keeping their head upright. Because of this, they can neither explore much of their environment nor process the information. Parents need to be complimented on their efforts to provide a stimulating environment for these children. These infants are at risk for delayed development in holding up their heads, righting their shoulders and trunks for stable posture, sitting, pulling, standing, and crawling. Most parents of children with impaired movements benefit from support and practical suggestions for feeding, moving, holding, and encouraging the infant to explore hands and feet and to play. Helping parents incorporate therapeutic suggestions into typical daily activities is an important normalizing strategy.

Although practical advice is important, the nurse, OT, or PT should offer suggestions at a pace that can be absorbed by the parents. Encourage the parents to define their concerns, acknowledge the concerns as genuine, and ask the parents what approaches they have tried and for how long. In this way the nurse is able to find out what works, what does not work, and what the parents would like to try next. Give the parents positive feedback for their observations of the infant, the progress they note, and how they differentiate the child's needs.

Address Health Maintenance Needs

Because children with CP expend so much energy in their efforts to accomplish ADLs, more frequent rest periods should be arranged to avoid the fatigue that may aggravate their limited capabilities. Meeting the child's nutritional needs may be a challenge because of gastroesophageal reflux, feeding and swallowing difficulties, chronic constipation and subsequent anorexia, and absence or diminished ability to independently feed himself or herself (Trivic & Hojsak, 2019). As a result of being ELBW or VLBW in combination with these feeding problems, children with CP are at risk for failure to thrive, and the nurse must ensure an adequate caloric intake. Children with spasticity expend more energy and often require more energy intake than

same-age counterparts to maintain adequate growth. Nutritional supplements such as high-calorie milk products (e.g., Pediasure) may be necessary to provide adequate caloric intake after the child has reached 1 year of age. Additional nutritional concerns include providing adequate intake of fruits and fiber to enhance gastrointestinal (GI) motility, routinely monitoring the child's growth on a standardized growth chart, and avoiding overfeeding and obesity (Trivic & Hojsak, 2019).

Routine assessment of skin status is imperative in children with CP who are limited in movement or who must remain in assistive devices such as a wheelchair for a prolonged period. The overall nutritional status may also be a risk factor for skin breakdown. Care must be taken to ensure that adequate objective skin assessments are routinely performed. If skin breakdown does occur, consult a skin and wound specialist for treatment and further prevention.

Gastrostomy feedings may be necessary to supplement regular feedings and ensure adequate weight gain, particularly in children at risk for growth failure and chronic malnutrition, those with severe CP and subsequent oral feeding difficulties, and children whose well-being is affected by illness and decreased fluid or medication intake (Trivic & Hojsak, 2019). Oral feedings may be continued to maintain oral motor skills. Weight gain is perceived as an important measure of adequate oral feeding efficiency along with follow-up and body composition assessments (Trivic & Hojsak, 2019).

Parents may need assistance and advice with medication administration through a gastrostomy tube to prevent clogging. Pills may be crushed and mixed with small amounts of water but not with other liquids, such as formula or elixir medications, because these may act together to form a sludge that can interfere with gastrostomy tube function. When crushed pills or tablets are administered, flush the feeding tube with more water after instilling the dissolved pill in water. The pharmacist can provide information on crushed pills and tablets and elixirs, which should not be mixed together when administered via gastrostomy or nasogastric tube. A skin-level gastrostomy is particularly suited for the child with CP (see also Chapter 20, Gastrostomy Feeding).

Safety precautions are implemented, such as having children wear protective helmets if they are subject to falls or capable of injuring their heads on hard objects. Because the child with CP is at risk for altered proprioception and subsequent falls, parents should adapt the home and play environment to the child's particular needs to prevent bodily harm. Transportation of the child with motor problems and restricted mobility may be especially challenging for the family and child. Attention must be given to the child's safety when riding in a motor vehicle; a federally approved safety restraint should be used at all times. Lovette (2008) recommends that children with CP ride in a rear-facing position for as long as possible because of their poor head, neck, and trunk control. This author also provides a list of options for special car restraint systems for children with CP, including several restraints that are suitable for children with a hip spica cast.

Appropriate immunizations should be administered to prevent childhood illnesses and protect against respiratory tract infections such as influenza. Depending on the level of involvement, dental problems may be more common in children with CP, which creates a need for meticulous attention to all aspects of dental care.

Support the Family

The nursing interventions that are probably most valuable to the family are support and help in coping with the emotional aspects of the chronic disorder, many of which are discussed in Chapter 19. Initially the parents need information and support in understanding the implications of the diagnosis and all the feelings it engenders. Later they need clarification regarding what they can expect from the child and from health care professionals. Educating families in the principles of family-centered care and parent-professional collaboration is essential. The family also may require help to modify the home environment for care of the child. Transportation to the practitioner's office and other health care agencies often requires special considerations.

Care management for the child and family with CP is an important nursing role. In many cases the family assumes complete care of the child and becomes quite adept at caring for her or his individual needs. The home health nurse or case manager has an important role in the support and encouragement of families who assume the primary care of a child with CP. Having a child with CP implies numerous problems of daily management, with changes in family life, and the nurse needs to stress principles of normalization (see Chapter 17, Normalization and Transition).

Parents can also find help and support from parent groups, where they can share experiences, accomplishments, problems, and concerns while deriving comfort and practical information. For example, parents can understand from others what it is like to have a child with CP. United Cerebral Palsy has branches in most communities and provides a variety of services for children and families. A number of excellent books are available to guide parents and nurses who work with children with CP. Many of the books are written by people with CP who have triumphed (e.g., *My Left Foot,* a movie and book).

Care of the Hospitalized Child

CP is not a condition that requires hospitalization; therefore when children with CP are hospitalized, they are usually admitted for an associated illness or for corrective surgery. To facilitate the care and management of hospitalized children with CP, the therapy program should be continued (insofar as their condition allows) while they are hospitalized. This should be incorporated into the multidisciplinary care plan, with every effort expended to make certain the ground that has been so laboriously gained is not lost. Encouraging the parent to room-in and actively participate in the child's care facilitates a continuation of the home therapy program and helps the child adjust to an unfamiliar environment. However, it is equally important to remember that a hospitalization may be the first time a parent can defer care to a nurse and not be the primary caregiver. This respite may be crucial to the parent's well-being. Respect the parent's preference in this regard.

DEFECTS OF NEURAL TUBE CLOSURE

Abnormalities that derive from the embryonic neural tube (**neural tube defects [NTDs]**) constitute the largest group of congenital anomalies with multifactorial inheritance. Normally the spinal cord and cauda equina are encased in a protective sheath of bone and meninges (Fig. 30.5A). Failure of neural tube closure produces defects of varying degrees (Box 30.4). They may involve the entire length of the neural tube or may be restricted to a small area.

ETIOLOGY

Two of the defects, anencephaly and spina bifida (SB), occur in association with each other more often than would be expected by chance, suggesting a common origin. The CNS defects may alternate in siblings, which also tends to support the theory of a common origin. In the United States, approximately 1645 infants with spina bifida are born each year (Centers for Disease Control and Prevention: National Center on Birth Defects and Developmental Disabilities, 2019). The incidence of SB is higher in girls than in boys, and it is more likely to occur in Hispanic (3.8 per 10,000 births) women than in Caucasian

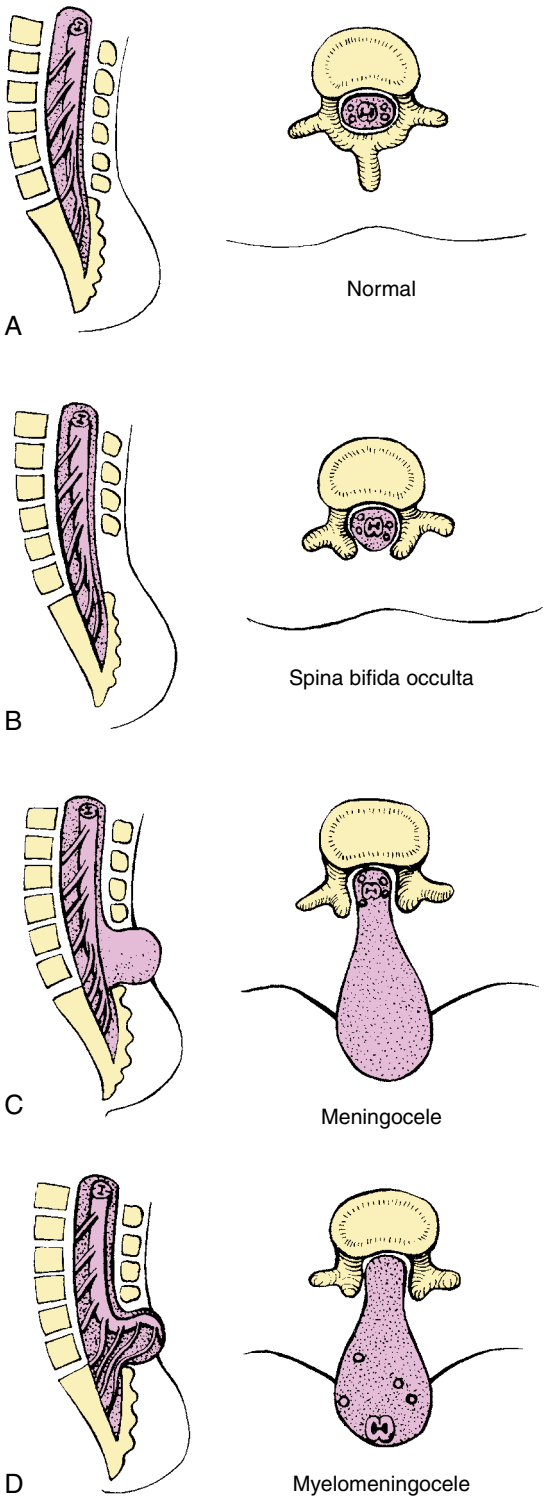

Fig. 30.5 Midline defects of the osseous spine with varying degrees or neural herniations. **A,** Normal. **B,** Spina bifida occulta. **C,** Meningocele. **D,** Myelomeningocele.

(3.09 per 10,000) or African American (2.73 per 10,000) women (Centers for Disease Control and Prevention: National Center on Birth Defects and Developmental Disabilities, 2019).

In the United States, rates of NTDs declined by as much as 23% between 1995 and 2000. NTD rates decreased an additional 6.9% between 2000 and 2005, primarily among African American mothers.

BOX 30.4 Neural Tube Defects

Cranioschisis—A skull defect through which various tissues protrude

Exencephaly—Brain totally exposed or extruded through an associated skull defect; fetus usually aborted

Anencephaly—Congenital malformation in which both cerebral hemispheres are absent

Encephalocele—Herniation of brain and meninges through a defect in the skull producing a fluid-filled sac

Rachischisis or spina bifida—Fissure in the spinal column that leaves the meninges and spinal cord exposed

Meningocele—Hernial protrusion of a saclike cyst of meninges filled with spinal fluid (see Fig. 30.5C)

Myelomeningocele (meningomyelocele)—Hernial protrusion of a saclike cyst containing meninges, spinal fluid, and a portion of the spinal cord with its nerves (see Fig. 30.5D)

One concern is that NTD rates have not decreased significantly among Hispanic and non-Hispanic Caucasian mothers since 1999 (Centers for Disease Control and Prevention, 2009). The decline in NTDs in the late 1990s has been attributed in large part to the addition of folic acid to cereal grain products (Williams, Mai, Mulinare, et al., 2015). Population-based studies have also witnessed a substantial decrease in NTDs since food fortification with folic acid and folic acid supplementation recommendations were made (Williams et al., 2015). Increased use of prenatal diagnostic techniques and termination of pregnancies have also affected the overall incidence of NTDs.

The National Spina Bifida Patient Registry is a data collection program funded by the Centers for Disease Control and Prevention. It was started in 2008 to provide a framework to standardize and improve treatment of children, adolescents, and adults older than 21 years of age. Detailed questionnaires from the participating 10 specialized, multidisciplinary spina bifida clinics provide data, which are sent to a Centers for Disease Control and Prevention database for analysis. This process helps identify the most beneficial care for patients.

Most authorities believe that the primary defect in NTDs is a failure of neural tube closure during the embryo's early development (between the third and fourth week). However, evidence also implicates a multifactorial origin, including drugs, radiation, maternal malnutrition, chemicals, and possibly a genetic mutation in folate pathways in some cases, which may result in abnormal development (Kinsman & Johnston, 2020).

Additional factors predisposing the infant to NTDs include maternal obesity, previous NTD pregnancy, Hispanic ancestry, low folic acid intake, gestational diabetes, hot tub or sauna use, low maternal vitamin B_{12} status, and the use of antiepileptic drugs (e.g., valproic acid) in pregnancy (Agopian, Tinker, Lupo, et al., 2013). The degree of neurologic dysfunction depends on where the sac protrudes through the vertebrae, the anatomic level of the defect, and the amount of nerve tissue involved (see Fig. 30.5). Most myelomeningoceles involve the lumbar or lumbosacral area.

The American Academy of Pediatrics, Committee on Genetics (2007) recommends daily intake of folic acid for all women of childbearing age. The recommended 0.4-mg daily dose is supplied safely in many multivitamin preparations. Because the greatest risk factor is a previous pregnancy affected by NTDs, women in this category should increase their daily folic acid dose to 4 mg, under a practitioner's supervision, beginning at least 1 month before they plan a pregnancy and through the first trimester because the neural tube closes about 1 month after conception. In 2009 the US Preventive Services Task Force published a statement indicating that there is ample evidence

to support the recommendations for folic acid supplementation to decrease the incidence of NTDs (Williams et al., 2015). In 1998 the US Food and Drug Administration authorized the fortification of cereal grains (including cornmeal, grits, and wheat flour) with folic acid. It remains important for all women of childbearing age to take a multivitamin with 0.4 mg folic acid daily (American Academy of Pediatrics, Committee on Genetics, 2007). Sexually active females should be counseled on the risks of inadequate folate intake (Burke, Liptak, & Council on Children with Disabilities, 2011).

The following discussion of NTDs is limited to the two most common types: anencephaly, a defect incompatible with life, and SB, in particular myelomeningocele, an abnormality that causes significant disability.

ANENCEPHALY

Anencephaly, the most serious NTD, is a congenital malformation in which both cerebral hemispheres are absent. If the child with exencephaly (where brain protrudes from the skull), survives, degeneration of the brain to a spongiform mass occurs, with no bony covering. The condition is incompatible with life, and many affected infants are stillborn. For those who survive, no specific treatment is available. The infants have a portion of the brainstem and are able to maintain vital functions (such as temperature regulation and cardiac and respiratory function) for a few hours to several weeks but eventually die of respiratory failure.

Traditionally these infants have been provided comfort measures, but with no effort at resuscitation. Ethical and moral questions arise regarding treatment and withdrawal of support systems (e.g., feedings) if the newborn survives the first few days of life, as well as regarding use of the organs for donor transplants. During this time the family requires emotional support and counseling to cope with the birth of an infant with a fatal defect. Referral to neonatal palliative care or hospice should be made as soon as possible.

SPINA BIFIDA AND MYELODYSPLASIA

Myelodysplasia refers broadly to any malformation of the spinal canal and cord. Midline defects involving failure of the osseous (bony) spine to close are called **spina bifida**, the most common defect of the CNS. SB is categorized into two types: SB occulta and SB cystica.

SB occulta refers to a defect that is not visible externally. It occurs most commonly in the lumbosacral area (L5 and S1) (see Fig. 30.5B). Routine radiographic examinations indicate that the disorder may occur in as many as 10% to 30% of the general population. However, it may not be apparent unless there are associated cutaneous manifestations or neuromuscular disturbances. Superficial cutaneous indications include a skin depression or dimple (which may also mark the outlet of a dermal sinus tract that extends to the subarachnoid space); port-wine angiomatous nevi; dark tufts of hair; and soft, subcutaneous lipomas. These signs may be absent, appear singly, or be present in combination.

If associated neurologic involvement is present, the defect is known as occult spinal dysraphism. Fibrous bands and adhesions, an intraspinal **lipoma** (fatty tumor) or subcutaneous lipoma (lipomyelomeningocele), a dermoid or epidermoid cyst, diastematomyelia (spinal cord split in two), or a tethered cord can distort the spinal cord or roots. The usual cause is abnormal adhesion, or tethering, to a bony or fixed structure, resulting in traction on the spinal cord and cauda equina.

Neuromuscular disturbances usually consist of progressive or static changes in gait with foot weakness, foot deformity, or bowel and bladder sphincter disturbances. Some manifestations may not be evident until the child walks or is toilet trained.

Plain radiography is used to disclose the precise bony defect in the symptomatic lesion and to establish the diagnosis in the suspected, nonsymptomatic occult variety. MRI is the most sensitive tool for evaluating the defect. CT, ultrasonography, and myelography are also used to differentiate between SB occulta and other spinal disorders.

SB cystica refers to a visible defect with an external saclike protrusion. The two major forms of SB cystica are meningocele, which encases meninges and spinal fluid but no neural elements, and myelomeningocele (or meningomyelocele), which contains meninges, spinal fluid, and nerves. Neurologic deficit is not associated with meningocele but occurs in varying, often serious, degrees in myelomeningocele.

MYELOMENINGOCELE (MENINGOMYELOCELE)

Myelomeningocele (MMC) develops during the first 28 days of pregnancy when the neural tube fails to close and fuse at some point along its length. It may be detected prenatally or at birth, accounts for 90% of spinal cord lesions, and may be located at any point along the spinal column. Usually the sac is encased in a fine membrane that is prone to tears through which cerebrospinal fluid (CSF) leaks. In other instances the sac may be covered by dura, meninges, or skin, in which case there is rapid and spontaneous epithelialization. The largest number (75%) of myelomeningoceles occur in the lumbar or lumbosacral area (see Fig. 30.5). The location and magnitude of the defect determine the nature and extent of neurologic impairment. When the defect is below the second lumbar vertebra, the nerves of the cauda equina are involved, giving rise to symptoms such as flaccid, areflexic partial paralysis of the lower extremities and varying degrees of sensory deficit. Unlike an SCI, the degree of deficit is not necessarily uniform on both sides but may vary between extremities, depending on the compromise to specific nerves from malformation or tethering.

The anomaly most frequently associated with myelomeningocele is **hydrocephalus**; approximately 80% to 85% of children with SB develop hydrocephalus (Burke et al., 2011; Kinsman & Johnston, 2020). Although present at birth, hydrocephalus may not be apparent until shortly thereafter, or after the primary closure of the opening on the back. Careful monitoring of head circumference, fontanel tension, and ventricular size by head ultrasonography can indicate its presence. Hydrocephalus can occur because the NTD itself disrupts the flow of CSF. In many cases Chiari malformation (type II) is responsible. Type II **Chiari malformation** (a downward herniation of the brain into the brainstem) is present, though asymptomatic, in many children with SB. It can, however, adversely affect respiratory function, causing episodic apnea. Other clinical symptoms of problematic Chiari malformation include stridor, hoarse cry from vocal cord paralysis, feeding difficulties, aspiration pneumonia, and, in older children, upper extremity spasticity. The appearance of such symptoms should not be taken for granted; immediate referral is required to prevent further neurologic deterioration.

Pathophysiology

The pathophysiology of SB is best understood when related to the normal formative stages of the nervous system. At approximately 20 days of gestation, a decided depression, the neural groove, appears in the dorsal ectoderm of the embryo. During the fourth week of gestation, the groove deepens rapidly, and its elevated margins develop laterally and fuse dorsally to form the neural tube. Neural tube formation begins in the cervical region near the center of the embryo and advances in both directions—caudally and cephalically—until by the end of the fourth week of gestation, the ends of the neural tube, the anterior and posterior neuropores, close.

Most experts believe that the primary defect in neural tube malformations is a failure of neural tube closure. However, some evidence indicates that the defects are a result of splitting of the already closed neural tube as a result of an abnormal increase in CSF pressure during the first trimester.

There is evidence of a multifactorial etiology, including drugs, radiation, maternal malnutrition, chemicals, and possibly a genetic mutation in folate pathways in some cases, which may result in abnormal development. There is also evidence of a genetic component in the development of SB; myelomeningocele may occur in association with syndromes such as trisomy 18, PHAVER (limb **p**terygia, congenital **h**eart **a**nomalies, **v**ertebral defects, **e**ar anomalies, and **r**adial defects) syndrome, and Meckel-Gruber syndrome (Shaer, Chescheir, & Schulkin, 2007). The genetic predisposition is supported by evidence of the risk for recurrence after one affected child (3% to 4%) and a 10% risk for recurrence with two previously affected children (Kinsman & Johnston, 2020).

The degree of neurologic dysfunction depends on where the sac protrudes through the vertebrae, the anatomic level of the defect, and the amount of nerve tissue involved. One classification designates the level of functional mobility in relationship to the anatomic level of the defect. For example, children with a high lumbar-thoracic defect may be able to walk short distances using long leg braces and by early adolescence must use a wheelchair for mobility; children with a low lumbar defect can walk with short leg braces and forearm crutches (Liptak & Dosa, 2010). This classification system, however, does not describe genitourinary and bowel function. About 80% of patients with myelomeningocele develop a type II Chiari malformation (Kinsman & Johnston, 2020). There is some evidence that prolonged exposure of the MMC sac to amniotic fluid predisposes to the development of hindbrain herniation and Chiari II malformation (Adzick, 2013).

Clinical Manifestations

The manifestations of SB vary widely according to the degree of the spinal defect. The defect is readily apparent on inspection. The degree of neurologic dysfunction is directly related to the anatomic level of the defect and thus the nerves involved. Sensory disturbances usually parallel motor dysfunction. The upper level of sensory and motor impairment can be determined by observation of the infant's response to a pinprick over the legs and trunk. The infant responds to the sensory stimulus with limb movement, arousal, and crying. When withdrawal activity is used to determine the lowest level of spinal cord function, the response to pinprick should begin above the lesion.

Defective nerve supply to the bladder affects both sphincter and detrusor tone, which often causes constant dribbling of urine or produces overflow incontinence. This can often be mistaken for normal voiding patterns in the newborn. Some infants with SB, however, are able to void in a stream and achieve complete bladder emptying with each void.

Frequently the infant has poor anal sphincter tone and poor anal skin reflex, which result in lack of bowel control and sometimes rectal prolapse. Avoid taking rectal temperatures in affected infants. Because bowel sphincter function is frequently affected, the thermometer can cause irritation and rectal prolapse. If the defect is below the third sacral vertebra, the infant has no motor impairment but may have saddle anesthesia with bladder and anal sphincter paralysis.

Sometimes the denervation to the muscles of the lower extremities produces joint deformities in utero. These are primarily flexion or extension contractures, talipes valgus or varus contractures, kyphosis, lumbosacral scoliosis, and hip dislocations. The extent and severity of these associated orthopedic deformities again depend on the degree of nerve involvement. Most flexion deformities result from the pull of stronger, fully innervated muscles acting without the counterpull of their nonfunctioning paralyzed antagonists. Box 30.5 provides a summary of clinical manifestations of SB cystica and occulta.

BOX 30.5 Clinical Manifestations of Spina Bifida

Spina Bifida Cystica

- Sensory disturbances usually parallel to motor dysfunction
- Below second lumbar vertebra:
  - Flaccid, partial paralysis of lower extremities
  - Varying degrees of sensory deficit
  - Overflow incontinence with constant dribbling of urine
  - Lack of bowel control
  - Rectal prolapse (sometimes)
- Below third sacral vertebra:
  - No motor impairment
  - Bladder and anal sphincter paralysis
- Joint deformities (sometimes produced in utero):
  - Talipes valgus or varus (foot) contractures
  - Kyphosis
  - Lumbosacral scoliosis
  - Hip dislocation

Spina Bifida Occulta

- Frequently no observable manifestations
- May be associated with one or more cutaneous manifestations:
  - Skin depression or dimple
  - Port-wine angiomatous nevi
  - Dark tufts of hair
  - Soft, subcutaneous lipomas
- May be neuromuscular disturbances:
  - Progressive disturbance of gait with foot weakness
  - Bowel and bladder sphincter disturbances

Diagnostic Evaluation

The diagnosis of SB is made on the basis of clinical manifestations (see Box 30.5) and examination of the meningeal sac (Fig. 30.6A). Diagnostic measures used to evaluate the brain and spinal cord include MRI, ultrasonography, and CT. A neurologic evaluation will determine the extent of involvement of bowel and bladder function, as well as lower extremity neuromuscular involvement. Flaccid paralysis of the lower extremities is a common finding with absent deep tendon reflexes.

Prenatal Detection

It is possible to determine the presence of some major open NTDs prenatally. Ultrasonographic scanning of the uterus and elevated maternal concentrations of alpha-fetoprotein (AFP, or MS-AFP), a fetal-specific gamma-1-globulin, in amniotic fluid may indicate anencephaly or myelomeningocele. The optimum time for performing these diagnostic tests is between 16 and 18 weeks of gestation before AFP concentrations normally diminish and in sufficient time to permit a therapeutic abortion. It is recommended that such diagnostic procedures and genetic counseling be considered for all mothers who have borne an affected child, and testing is offered to all pregnant women (American College of Obstetrics and Gynecology, 2016). Chorionic villus sampling is also a method for prenatal diagnosis of NTDs; however, it carries certain risks (skeletal limb depletion) and is not recommended before 10 weeks of gestation (Simpson, Richards, & Otaño, 2012).

Therapeutic Management

Management of the child who has a myelomeningocele requires a multidisciplinary team approach involving the specialties of neurology, neurosurgery, pediatrics, urology, orthopedics, rehabilitation, physical therapy, occupational therapy, and social services, as well as intensive nursing care in a variety of specialty areas. The collaborative efforts of these specialists focus on the following:

- The myelomeningocele and the problems associated with the defect—hydrocephalus, paralysis, orthopedic deformities (e.g., developmental dysplasia of the hip, clubfoot), and genitourinary abnormalities
- Possible acquired problems that may or may not be associated, such as Chiari II malformation, meningitis, seizures, hypoxia, tethered cord, and hemorrhage
- Other abnormalities, such as cardiac or GI malformations

Many hospitals have specialty clinics staffed by multidisciplinary teams to provide the complex follow-up care needed for children and families with myelodysplasia.

In 2008 the Centers for Disease Control and Prevention started a National Spina Bifida Patient Registry, based on results from a survey from spina bifida clinics across the United States. The Registry was initiated to provide a more organized approach to the care of all individuals with spina bifida. It seeks to improve and align the quality of care received at spina bifida clinics nationwide. The registry works to develop standards and best practices for patients with spina bifida. The data collected from the Registry clinics is sent to the Centers for Disease Control and Prevention to be analyzed so that it can be disseminated to other physicians and clinics. The Registry also hopes to gain insight into some of the secondary conditions of spina bifida, such as paralysis, neurogenic bladder and bowel, and hydrocephalus (Moldenhauer & Adzick, 2017).

Many authorities believe that early closure, within the first 24 to 72 hours, offers the most favorable outcome. Surgical closure within the first 24 hours is recommended if the sac is leaking CSF (Kinsman & Johnston, 2020). Surgical closure within 24 hours also results in improved bladder capacities and lower detrusor leak point pressures. Increased incidence of febrile urinary tract infections (UTIs), vesicoureteral reflux, and hydronephrosis have been shown when closure is delayed past 72 hours (Tarcan, Onol, Ilker, et al., 2006).

A variety of neurosurgical and plastic surgical procedures are used for skin closure without disturbing the neural elements or removing any portion of the sac. The objective is satisfactory skin coverage of the lesion and meticulous closure. Wide excision of the large membranous covering may damage functioning neural tissue.

Prenatal surgical closure of the myelomeningocele sac through fetal surgery has been evaluated in relation to prevention of injury to the exposed spinal cord tissue and the improvement of neurologic and urologic outcomes in the affected child. The Management of Myelomeningocele Study (MOMS), a clinical trial supported by the National Institutes of Health, found that prenatal surgery for myelomeningocele reduced the need for shunting (for hydrocephalus), evaluated at 12 months, and decreased the incidence of hindbrain herniation. In addition, there was an improvement in mental and motor function scores at 30 months in the children who had prenatal surgery (compared with children who had postnatal surgery) (Lapa, 2019). However, the surgery is not without risks to the fetus and mother, and premature delivery is common. Outcome data for urologic and bowel function, motor function, cognition, and spina bifida–associated outcomes are being gathered in the MOMS2 study, which ended in 2013 (Moldenhauer, Soni, Rintoul, et al., 2015).

Initial Care

Care of the newborn involves preventing infection; performing a neurologic assessment, including observation for associated anomalies; and dealing with the impact of the anomaly on the family. Although meningoceles are repaired early, especially if the sac is in danger of rupturing, the philosophy regarding skin closure of myelomeningocele varies. Most authorities believe that early closure, within the first 24 to 72 hours, offers the most favorable outcome. Surgical closure within the first 24 hours is recommended if the sac is leaking CSF (Kinsman & Johnston, 2020). Early closure, preferably in the first 12 to 18 hours, not only prevents local infection and trauma to the exposed tissues but also avoids stretching other nerve roots (which may occur as the meningeal sac expands during the first hours after birth), thus preventing

further motor impairment. Broad-spectrum antibiotics are initiated, and neurotoxic substances such as povidone-iodine are avoided at the malformation.

Associated problems are assessed and managed by appropriate surgical and supportive measures. Shunt procedures provide relief from imminent or progressive hydrocephalus (see Chapter 27). When diagnosed, ventriculitis, meningitis, and UTI are treated with vigorous antibiotic therapy and supportive measures. Surgical intervention for Chiari II malformation is indicated only when the child is symptomatic (i.e., high-pitched crowing cry, stridor, respiratory difficulties, apnea, failure to thrive, gastroesophageal reflux, oral-motor difficulties, upper extremity spasticity).

Improved surgical techniques do not alter the major physical disability and deformity or chronic UTIs that affect the quality of life for these children. Superimposed on these physical problems are the disorder's effects on family life and finances and on school and hospital services.

Musculoskeletal Considerations

According to most orthopedists, musculoskeletal problems that will affect later locomotion should be evaluated early and treatment, where indicated, instituted without delay. Neurologic assessment determines the neurosegmental level of the lesion, spasticity and progressive paralysis, potential for deformity, and functional expectations. Orthopedic and musculoskeletal management includes preventing joint contractures, correcting the existing deformity, preventing or minimizing effects of motor and sensory deficits, preventing skin breakdown, and obtaining the best possible function of affected lower extremities. Common musculoskeletal problems requiring attention in SB include deformities of the knees, hips, feet, and spine; fractures and insensate skin further complicate orthopedic care. Other problems that may occur later include kyphosis and scoliosis (Lazzaretti & Pearson, 2010; Liptak & Dosa, 2010). An overwhelming majority of infants born with myelomeningocele will have clubfoot (Moldenhauer & Adzick, 2017). Because children with MMC often have decreased sensitivity in lower extremities, preventive skin care is important. A high percentage (60%) of children seen in a wound clinic for skin breakdown had myelomeningocele at birth (Samaniego, 2003). The most common wound sites were the foot and ankle, with the buttocks being the second most common site. Pressure wounds are more common in patients who use wheelchairs for mobility (Ottolini, Harris, Amling, et al., 2013).

The status of the neurologic deficit remains the most important factor in determining the child's ultimate functional abilities; however, many children with lumbar and sacral myelomeningocele are able to achieve functional ambulation (Kinsman & Johnston, 2020). With technologic advances, a variety of lightweight orthoses, including braces, special "walking" devices, and custom-built wheelchairs, are available to provide mobility to children with spinal cord lesions. Early in infancy, intervention with passive range-of-motion exercises, positioning, and stretching exercises may help decrease the incidence of muscle contractures. Corrective surgical procedures, when indicated, are best initiated at an early age so that the child will not lag significantly behind age-mates in developmental progress. The degree of lower extremity function guides decisions about whether orthopedic surgery will be needed.

Physical therapy and musculoskeletal management of children with myelomeningocele are continual processes to achieve optimum function and ambulation when possible. Problems such as type II Chiari malformation, hydrocephalus, and a tethered spinal cord can complicate expectations. A common complication is tethered cord syndrome in which there is a presumed traction injury to the distal spinal cord with subtle and progressive loss of neural function; this may occur any time but is more common during periods of rapid growth and can be precipitated by ventricular shunt failure (Burke et al., 2011).

Management of Genitourinary Function

Myelomeningocele is one of the most common causes of neuropathic (neurogenic) bladder dysfunction among children. Neurologic deficits can affect the innervation of the bladder, impairing the ability to store and empty urine. As many as 90% of children with SB will experience some form of voiding dysfunction. A child with a neuropathic bladder will require care across the life span. The goals of urologic treatment should be individualized to the child's developmental stage. In infants the goal of treatment is to preserve renal function. In older children the goal is to preserve renal function and achieve optimum urinary continence. Urinary incontinence is a chronic, often debilitating problem for the child. In addition, the neuropathic bladder may produce **urinary system distress**, characterized by symptomatic urinary tract infections, ureterohydronephrosis, vesicoureteral reflux, or renal insufficiency. The characteristics of bladder dysfunction in children vary according to the level of the neurologic lesion and the influence of bony growth and development of the spine. In addition, the presence of type II Chiari malformation and subsequent hydrocephalus has the potential to affect bladder function, although spinal influences predominate.

During infancy, urinary incontinence is normally physiologic, but urinary system distress may occur. Ongoing urologic monitoring is essential. Evidence is growing that early intervention, based on evaluation during the neonatal period and before complications occur, improves bladder function, reduces the subsequent risk of urinary system distress, and reduces the need for reconstructive surgery of the lower urinary tract. Ultrasonography of the bladder and ureters and routine urinalysis (and urine cultures when indicated) are used to detect urinary system distress before renal function is compromised. In addition, urodynamic testing is used to identify bladder dysfunction that predisposes the child to urinary system distress (Gray & Moore, 2009; Snodgrass & Gargollo, 2010). These conditions include high-pressure detrusor hyperreflexia (reflex contractions of the detrusor muscle) with vesicosphincter dyssynergia (incoordination of detrusor and sphincter muscles), low bladder wall compliance (poor distensibility of the bladder wall causing increased intravesical pressures during urine filling and storage), or detrusor areflexia (absence of detrusor contractions caused by the spinal defect).

Infants may have one of several predominant neuropathic bladder disorders. Detrusor contractions associated with vesicosphincter dyssynergia are particularly common. Some infants are able to empty the bladder efficiently despite incoordination between the sphincter mechanism and detrusor, but the majority experience chronic residual urine, UTIs, or more serious types of urinary system distress. A minority of infants have poor detrusor contraction strength or detrusor areflexia. This condition is particularly damaging to the urinary system when it coexists with low bladder wall compliance and an elevated detrusor leak point pressure. Low bladder wall compliance occurs when collagen or fibrosis causes stiffening of the bladder wall. This stiffened bladder wall raises intravesical pressures, obstructing the bladder, ureters, and, ultimately, the nephron. The impact of low bladder wall compliance is directly related to the influence of the bladder outlet. Among children with myelodysplasia, the urethral muscles are typically weakened, and collagen replaces much of the muscle tissue. As a result, the sphincter is fixed, so it neither closes efficiently to prevent urinary leakage nor opens well to allow urinary flow with a detrusor contraction. When the magnitude of the pressure required to drive urine across the abnormal sphincter is greater than 40 cm H_2O (the detrusor leak point pressure)

and the compliance of the bladder wall is low (<10 cm H_2O), the risk of urinary system distress is high.

In contrast, a small number of infants experience effective detrusor contractions without vesicosphincter dyssynergia. Effective bladder evacuation is likely among this group, and the incidence of urinary system distress during the first year of life is low.

As the child grows, detrusor hyperreflexia is often replaced by deficient detrusor contraction strength and **stress urinary incontinence (SUI)** (leakage produced by physical exertion). The bladder wall is often poorly compliant (producing chronically elevated intravesical pressures), and the bladder outlet, while incompetent, obstructs the outflow of urine. When the detrusor leak point pressure exceeds 40 cm H_2O, the child is predisposed to chronic urinary leakage and urinary distress symptoms, including recurrent UTIs and reflux. When the detrusor leak point pressure is lower than 40 cm H_2O, urinary leakage is more severe, although the risk of urinary system distress is lessened. Thus the child with more severe urinary incontinence is less predisposed than the "drier" child to serious UTIs.

Infants with myelomeningocele and a neurogenic bladder who are not at risk for urinary system distress are managed by diaper containment and watchful waiting. The infant empties the bladder into a diaper, the urine is routinely monitored for infection, and the upper urinary tracts are monitored for evidence of urinary system distress (dilation of the ureters, renal pelves, or collecting systems) via serial ultrasonography.

In contrast, children with evidence of urinary system distress, or those considered at risk based on early urodynamic testing, undergo **clean intermittent catheterization (CIC)**, typically in combination with an antispasmodic medication such as oxybutynin or propantheline (Elzeneini, Waly, Marshall, et al., 2019; Gray & Moore, 2009). Anticholinergic medications are prescribed because they reduce detrusor muscle tone and reduce bladder pressures both during urine filling and storage and during micturition. CIC is not intended to prevent spontaneous voiding. Instead, it ensures routine, regular bladder evacuation, further preventing deleterious elevation of intravesical pressures. Usually the parents learn to catheterize the infant every 4 hours during the day and once each night. Follow-up evaluation, consisting of serial ultrasonography and urinalysis, is completed every 3 to 6 months as indicated.

Infants with significant urinary system distress and neuropathic bladder dysfunction at birth sometimes require temporary urinary diversion to ensure adequate urine outflow and prevent further damage to the upper urinary tracts. A vesicostomy is a relatively simple procedure wherein the anterior bladder wall is brought to the abdominal wall, creating a small stoma for urinary drainage. Urine is contained via a diaper, but double diapering or use of a larger diaper that can be placed higher on the abdomen is necessary for adequate urine containment. Meticulous skin care is necessary because the perineal skin is exposed to continuous urinary leakage.

Among older children the quest for continence typically begins with a CIC program. The parents learn the procedure and teach the child to self-catheterize as soon as possible, usually by 6 years of age (Gray & Moore, 2009). The child with detrusor hyperreflexia and dyssynergia often responds well to antispasmodic medications and CIC. In contrast, the child with poor bladder wall compliance and SUI often requires a combination of antispasmodic medications to reduce intravesical filling pressures and a sympathetic agonist (such as imipramine, pseudoephedrine, or phenylpropanolamine) to enhance sphincter competence. Unfortunately, the combination of medications and CIC is typically only partially effective, and more aggressive interventions are often required to render the neuropathic bladder both continent and free from its predisposition toward producing urinary system distress. It is important that a careful history is taken by the provider to identify other problems that may be contributing to persistent incontinence. Factors that can affect bladder continence include caffeinated drinks, constipation, or lack of access to bathrooms (Metcalfe, 2017).

When the child cannot attain continence by conservative measures, surgery is considered. Augmentation enterocystoplasty (or gastrocystoplasty) is a surgical procedure that increases bladder capacity, reverses or halts the negative effects of the poorly compliant bladder wall, and reduces harmfully high bladder pressures caused by detrusor hyperreflexia with vesicosphincter dyssynergia. A detubularized segment of large or small bowel or a wedge of the fundus of the stomach has been used to successfully augment bladder capacity. The choice of segment varies according to the surgeon's preference and the status of the patient's urinary and GI systems. Large and small bowel segments produce significant volumes of mucus that may clog catheters used for CIC. Augmentation with the stomach produces less mucus, and its acidic secretions may reduce the urinary system's predisposition to infection. The bladder must be irrigated to decrease mucus within the bladder; this also decreases the possible complications of infection, stones, and bladder perforation.

Even though augmentation of the bladder may improve or resolve urinary leakage related to detrusor hyperreflexia or urinary system distress caused by low bladder wall compliance, the SUI produced by the abnormal sphincter mechanism typically persists. Several surgical procedures help correct this intrinsic sphincter deficiency. The Mitrofanoff procedure uses the appendix to provide an alternative route for intermittent catheterization. The appendix is removed from the colon and used to create a continent conduit between the abdominal wall and the bladder. The resulting stoma is relatively small and produces minimum mucus. The ureter may be used as an alternative to the appendix for some children. If the appendix is insufficient, a segment of tapered intestine, ileum, or colon may be used to create a conduit (Monti tube) (Gray & Moore, 2009). CIC through the easily accessible abdominal route fosters greater independence in children, especially in those unable to transfer from wheelchair to toilet to perform CIC.

When intrinsic sphincter deficiency produces only mild stress urinary leakage, the construction of a Mitrofanoff route alone may be sufficient to achieve continence between catheterization episodes. However, when SUI is more severe, a suburethral sling or suburethral collagen injection is used to alleviate intrinsic sphincter deficiency.

The suburethral sling is a slip of fascia or synthetic material that is placed below the proximal third of the urethra. The sling may be placed in a fashion that uses only slight tension to obstruct the urethra and prevent SUI. The sling may be used for both boys and girls, and the procedure can be completed at the same time as the augmentation enterocystoplasty is constructed. After augmentation enterocystoplasty and placement of a suburethral sling, the patient can expect to evacuate the bladder by CIC of the appendiceal Mitrofanoff route (appendicovesicostomy) or the urethra if a Mitrofanoff route has not been constructed.

Suburethral injection of glutaraldehyde cross-linked (GAX) collagen also may be used to alleviate or prevent SUI caused by intrinsic sphincter deficiency. Collagen is used to bulk or expand the urethral tissue, promoting coaptation (approximation) of the mucosa. The collagen implant complements the urethra's ability to form a watertight seal, rather than obstructing the urethral lumen. Collagen may be injected using different approaches. Transurethral collagen is injected through the working channel of a cystoscope. Transperineal collagen is directed underneath the urethra using a needle inserted through the perineal skin. In this case the location of the urethra is confirmed by simultaneous cystoscopic visualization of the urethra. The antegrade

approach requires creation of a suprapubic cystostomy tract. A flexible cystoscope is then inserted through the cystostomy tract, and collagen is injected into the proximal urethra. Multiple injections may be required to achieve optimum continence. Subsequent injections may be required when the collagen is dissipated or resorbed by the body over a period of years. Botulinum toxin (Botox) can also be injected into the detrusor muscle to increase bladder capacity and decrease intravesicular pressures, but this measure is only temporary (Ingham, Angotti, Lewis, et al., 2019).

The artificial urinary sphincter provides another alternative for the management of intrinsic sphincter deficiency in the child with myelomeningocele. The device consists of a urethral cuff, abdominal reservoir, and control pump. In the activated position, the cuff is filled, and the pressure of this cuff closes the urethral lumen. During micturition, the control pump is used to baffle fluid from the urethral cuff to the abdominal reservoir, opening the urethra for micturition or catheterization. However, because of the significant risk for infection, need for revision with growth, and mechanical failure, the popularity of the artificial urinary sphincter has declined.

Because of advances in neurogenic bladder management, adolescents and young adults with myelomeningocele and neurogenic bladder have been followed for up to 30 years without evidence of deterioration in renal function. Nevertheless, urinary and fecal incontinence are common, and these conditions lead to significant and sometimes devastating problems with growth and developmental tasks, including establishing independence and social and intimate relationships. This observation underscores the need to aggressively manage both continence and the threat of urinary system distress from an early age and to establish an expectation of social continence critical to providing these patients with the skills they need to thrive as adolescents and adults. Newborns with SB and normal urodynamics require close follow-up care during the first several years of life to prevent deterioration in urodynamic status as a result of neurologic deterioration.

Bowel Control

Some degree of fecal continence can be achieved in most children with myelomeningocele with diet modification, regular toilet habits, and prevention of constipation and impaction. It is frequently a lengthy process. Dietary fiber supplements (recommended: age of child in years + 5 g/day), laxatives, suppositories, or enemas aid in producing regular evacuation. Older children and adolescents seeking more independence may attain bowel continence and higher quality of life after undergoing an **antegrade continence enema** (ACE) procedure (Ayub, Zeidan, Larson, et al., 2019). In a procedure similar to the Mitrofanoff, the appendix or ileum is used to create a catheterizable channel with attachment of the proximal end to the colon. The distal end of the channel exits through a small abdominal stoma. Every 1 or 2 days, a catheter is passed through the stoma, allowing enema solution to be instilled directly into the colon. After administration of the enema solution, the child sits on the toilet for 30 to 60 minutes as stool is flushed out through the rectum. The frequency of enemas and volume of solution used to completely evacuate the bowel vary among individuals.

Prognosis

The early prognosis for the child with myelomeningocele depends on the neurologic deficit present at birth, including motor ability, bladder innervation, and associated neurologic anomalies. Early surgical repair of the spinal defect, antibiotic therapy to reduce the incidence of meningitis and ventriculitis, prevention of urinary system dysfunction, and early detection and correction of hydrocephalus have significantly increased the survival rate and quality of life in such children. Mortality rates are reported to be 10% to 15%, with many deaths occurring before the age of 4 years (Kinsman & Johnston, 2020). Many young adults with SB achieve partial independent living and gainful employment. Reports of survival rates vary, and many include adults who were born before medical advances and surgical techniques seen in the past 25 years. Coordinated care for adults with SB is essential; however, multidisciplinary adult care is often inadequate (Lazzaretti & Pearson, 2010). One of the factors associated with early death among adults with MMC is hydrocephalus and shunt failure (Mourtzinos & Stoffel, 2010). This chronic condition has an array of associated complications, including hydrocephalus and shunt malfunctions, tethered cord syndrome, scoliosis, Chiari II development, bowel and bladder management issues, latex allergy, and epilepsy. However, based on current medical knowledge and ethical considerations, aggressive, early management is favored for the child with myelomeningocele.

Prevention

The Centers for Disease Control and Prevention (2009) continues to affirm that 50% to 70% of NTDs can be prevented by daily consumption of 0.4 mg of folic acid by women of childbearing age. The data indicate that serum folate concentrations among women of childbearing age decreased 16% from 2003 to 2004 in all ethnic groups studied. Lowest serum folate levels were seen in non-Hispanic whites in 2003 to 2004; however, overall serum folate levels remained below recommended levels in non-Hispanic African Americans during all three periods studied (Centers for Disease Control and Prevention, 2007). These results indicate that nurses and other health care workers have an important task in disseminating information that may decrease the incidence of birth defects in children by promoting maternal consumption of folic acid.

To ensure adequate daily intake of the recommended amount of folic acid, women must take a folic acid supplement, eat a fortified breakfast cereal containing 100% of the recommended dietary allowance of folic acid (e.g., Kellogg's Product 19, General Mills Total, Multigrain Cheerios Plus), or increase their consumption of fortified foods (e.g., cereal, bread, rice, grits, pasta) and foods naturally rich in folate (e.g., green leafy vegetables, citrus fruits). For women who have had a previous pregnancy affected by NTDs, folic acid intake is increased to 4 mg/day under the supervision of a health care practitioner beginning 1 month before a planned pregnancy and continuing through the first trimester. Supplementation of 4 mg of folate should not be given solely in multivitamin preparations because of the risk for overdose of other vitamins. Drugs that affect folic acid metabolism and increase the risk for myelomeningocele should be avoided before pregnancy (if plans are to become pregnant in the near future) and during pregnancy; these include trimethoprim and the AEDs carbamazepine, phenytoin, phenobarbital, valproic acid, and primidone (Kinsman & Johnston, 2020).

Nursing Care Management

The basic needs of the infant with a myelomeningocele are essentially the same as for any newborn infant (see Chapter 8). Special needs related to the defect and potential complications are discussed in the following section. As the child matures, the problems increase and involve all aspects of daily living; therefore care is directly related to the child's habilitation at each stage of development.

Assessment

At the time of delivery an examination is performed to assess the intactness of the membranous cyst. During transport to the nursery, make every effort to prevent trauma to this protective covering. In addition to the routine assessment of the newborn (see Chapter 7), assess the

infant for the level of neurologic involvement. Note movement of extremities or skin response, especially an anal reflex that might provide clues to the degree of motor or sensory impairment.

Care of the Myelomeningocele Sac

The infant is usually placed in an incubator or radiant warmer so that temperature can be maintained without clothing or covers that might irritate the CNS lesion. When an overhead warmer is used, the dressings over the defect require more frequent moistening because of the dehydrating effect of the radiant heat. Before surgical closure, the myelomeningocele is kept from drying by the application of a sterile, moist, nonadherent dressing. The moistening solution is usually sterile normal saline. Dressings are changed frequently (every 2 to 4 hours), and the sac is closely inspected for leaks, abrasions, irritation, and signs of infection. The sac must be carefully cleansed if it becomes soiled or contaminated. Sometimes the sac ruptures during delivery or transport, and any opening in the sac greatly increases the risk of infection to the CNS (see Fig. 30.6B).

Positioning

One of the most important and challenging aspects of early care of the infant with myelomeningocele is positioning. Before surgery the infant remains in the prone position to minimize tension on the sac and the risk of trauma. The prone position allows for optimum positioning of the legs, especially in cases of associated hip dysplasia. Various aids, including diaper rolls, foam pads, and specially designed frames and appliances, are available to maintain the desired position.

The prone position affects other aspects of the infant's care. For example, in this position the infant is more difficult to keep clean, pressure areas are a constant threat, and feeding becomes a problem. The infant's head is turned to one side for feeding. Fortunately, most defects are repaired early, and the infant can be held for feeding and routine care soon after surgery. Physical therapy consultation may be necessary for difficult positioning problems. Speech-language pathologist consultation may be needed for difficulty with oral-motor skills that may indicate complications caused by a Chiari malformation.

General Care

Diapering the infant may be contraindicated until the defect has been repaired and healing is well advanced or epithelialization has taken place. The padding beneath the diaper area is changed as needed to keep the skin dry and free of irritation. When the nurse detects urinary retention (the bladder is still an abdominal organ in early infancy), CIC is used. Because the bowel sphincter is frequently affected, there may be continual passage of stool, often misinterpreted as diarrhea, which is a constant irritant to the skin and a source of infection to the spinal lesion.

Areas of sensory and motor impairment are subject to skin breakdown and therefore require meticulous care. The infant may be placed on a pressure-reducing mattress or a mattress to prevent pressure on the knees and ankles (see Chapter 20, Skin Care and General Hygiene).

Gentle range-of-motion exercises are carried out to prevent contractures, and stretching of contractures is performed when indicated. However, these exercises may be restricted to the foot, ankle, and knee joint. When the hip joints are unstable, stretching against tight hip flexors or adductor muscles, which act much like bowstrings, may aggravate a tendency toward subluxation. A physical therapy consultation is often necessary to develop a multidisciplinary plan to prevent long-term complications.

Some infants with unrepaired myelomeningocele are unable to be held in the arms and cuddled as unaffected infants are, so their need for tactile stimulation is met by caressing, stroking, and other comfort measures. To facilitate handling and reduce parental anxiety, the infant can recline on a pillow placed in the parent's lap.

Ophthalmic complications may occur in children with SB and hydrocephalus. The appearance of a squint, other ocular motility, or papilledema usually denotes hydrocephalus and is reported. Ophthalmologic follow-up care, particularly in children with shunts, is generally included in the multidisciplinary care plan.

Postoperative Care

Postoperative care for the infant with myelomeningocele involves the same basic care as for any postsurgical infant: monitoring vital signs, weight, and intake and output; maintaining body temperature; assessing and relieving pain; providing nourishment; and observing for signs of infection. The wound is managed according to the surgeon's directions, and general care is continued as preoperatively.

The prone position is maintained after operative closure, although many neurosurgeons allow a side-lying or partial side-lying position unless it aggravates a coexisting hip dysplasia or permits undesirable hip flexion. This offers an opportunity for position changes, which reduces the risk of pressure sores and facilitates feeding. Once the effects of anesthesia have subsided and the infant is alert, feedings may resume unless there are other anomalies or associated complications.

Nursing assessments are carried out for implementation of comfort measures in the postoperative period. The infant can be held upright against the body, taking care to avoid pressure on the operative site. In the case of an unusually large defect, skin grafting may be required for wound closure; the infant must then be kept prone postoperatively with as little movement as possible to prevent tension on the skin graft.

The nurse can assist in determining the extent of neuromuscular involvement. Note movement of the extremities or skin response, especially an anal reflex, that might provide clues to the degree of motor or sensory status. Measure head circumference daily (see Chapter 4) and examine the fontanels for signs of tension or bulging. The nurse is also alert to early signs of infection, such as elevated or decreased temperature (axillary), irritability, and lethargy, and to signs of increased intracranial pressure. Urinary catheterization may be needed for urine retention. Although it may not have been a problem preoperatively, swelling around the operative site may cause transient urine retention, which resolves in 2 to 5 days.

Family Support and Home Care

As soon as the parents are able to cope with the infant's condition, encourage them to become involved in care. They need to learn how to continue at home the care that has been initiated in the hospital: positioning, feeding, skin care, and range-of-motion exercises when appropriate. Parents also need to learn CIC technique when prescribed. The family needs to know the signs of complications and how to reach assistance when needed.

As the child grows and develops, parents need guidance to encourage and stimulate the infant to accomplish age-appropriate developmental tasks within the limits imposed by the disabilities. Upper limb movement can be stimulated early by placing the infant on the floor in a prone position with toys within reach. Activities that encourage body consciousness, such as rolling over and pulling to a sitting position, are encouraged at the appropriate times. Creeping and crawling help the child explore the environment. The parents may need help to modify appliances and activities normally expected of a growing child. A standing table, frame, or parapodium is helpful for a variety of activities, and it is best for the child to begin supported weight bearing and standing as close as possible to the expected time for standing to occur.

It is important for the family to understand the nature of sensory deficit in a child with a spinal defect. The child will be insensitive to

pressure or other sources of tissue injury. Therefore the family must be alert to hot or cold items that could cause thermal injury to tissues and remember to inspect the skin regularly for signs of pressure, especially over bony prominences. Because of sensory impairment, the child is unaware of bladder discomfort, and signs of UTIs may go unnoticed. Urinary tract infection is often considered when the child becomes ill.

The long-range planning with and support of the parents and newborn begin in the hospital and extend throughout childhood and even into young adulthood. The life expectancy of children with SB extends well into adulthood; therefore planning should involve long-term goals and plans for optimum function as an adult. Long-range planning goals should include a discussion of achievement of functional mobility, urinary continence, and as much bowel continence as physically possible. Discussion about aspects of adulthood such as having a mate, sexual relationships, and bearing and rearing children is important and should not be overlooked (Rowe & Jadhav, 2008). The unique service needs of adolescents with SB as they attempt to gain independence from family and establish a life of their own have not been adequately addressed in the literature (Sawyer & Macnee, 2010). Betz and colleagues (2010) interviewed young people with SB making the transition to adulthood. Some common themes that emerged among these young people were challenges in preparation for self-management, limited social relationships, awareness of their cognitive challenges, and the cost of independence. Advances in neurology, orthopedics, and urology have enabled adolescents to progress into adulthood with fewer deficits than observed in previous decades; one key factor is the recognition of subtle signs of neurologic deterioration and rapid intervention (Rowe & Jadhav, 2008).

Changes in functional ability, particularly in the lower extremities, bowel, or bladder, may indicate the presence of a tethered cord, one that is bound low or restricted in an abnormal position by scar tissue. These symptoms usually occur after a growth spurt and can best be detected with MRI. Tethering can be repaired surgically but, unfortunately, may recur.

Habilitation involves solving not only problems of self-help and locomotion but also the most distressing problem of incontinence, which threatens the child's social acceptability. Assistance in preparing the child and the school regarding the special needs of children with disabilities helps the parents provide a better initial adjustment to broader social experiences. A Life Course Model has been developed for patients, families, caregivers, teachers, and clinicians to facilitate, through a developmental approach, the care of the child and young person with SB; this program has been made into a web-based tool that can be used to assist in the transition to adulthood (Dicianno, Fairman, Juengst, et al., 2010). Additional information on this program is available through the Spina Bifida Association's website (https://www.spinabifidaassociation.org/).

Latex Allergy

Latex allergy, or latex hypersensitivity, was identified as a serious health hazard when a report linked intraoperative anaphylaxis with latex in children with SB. Latex, a natural product derived from the rubber tree, is used in combination with other chemicals to give elasticity, strength, and durability to many products. Children with SB are at high risk for developing latex allergy because of repeated exposure to latex products during surgery and procedures. Therefore such children should not be exposed to latex products from birth onward to minimize the occurrence of latex hypersensitivity. Allergic reactions range from urticaria, wheezing, watery eyes, and rashes to anaphylactic shock. More severe reactions tend to occur when latex comes in contact with mucous membranes, wet skin, the bloodstream, or an airway. There also can be cross-reactions to a number of foods (e.g., banana, avocado, kiwi, chestnut).

Allergic reactions to latex protein can also occur when the substance is transferred to food by food handlers wearing latex gloves, prompting several states to pass legislation that prohibits the use of latex gloves in food service. In addition to patients with SB, high-risk populations include patients with urogenital anomalies or multiple surgeries, as well as health care workers.

The most important goals are prevention of latex sensitivity and identification of children with a known hypersensitivity (see Nursing Care Guidelines box). High-risk and latex-allergic individuals must be managed in a **latex-free environment**. Take care that they do not come in direct or secondary contact with products or equipment containing latex at *any time* during medical treatment. Allergy testing can identify latex sensitivity with varying success. Skin prick testing and provocation testing carry the risk for allergic reaction or anaphylaxis. Several commercially available assays can be useful in confirming latex sensitivity. To date, none of these tests demonstrates complete diagnostic reliability, and they should not be the sole determinant of the presence or absence of an allergic response to latex.

NURSING CARE GUIDELINES

Identifying Latex Allergy

- Does your child have any symptoms, such as sneezing, coughing, rashes, or wheezing, when handling rubber products (e.g., balloons, tennis or Koosh balls, adhesive bandage strips) or when in contact with rubber hospital products, such as gloves or catheters?
- Has your child ever had an allergic reaction during surgery?
- Does your child have a history of rashes, asthma, or allergic reactions to medication or foods, especially milk, kiwi, bananas, or chestnuts?
- How would you identify or recognize an allergic reaction in your child?
- What would you do if an allergic reaction occurred?
- Has anyone ever discussed latex or rubber allergy or sensitivity with you?
- Has the child had any allergy testing?
- When did the child last come in contact with any type of rubber product? Were you present?

Because children who have SB are prone to develop sensitivity to latex, reducing exposure from birth on may decrease the chance of allergy development. Nonlatex products lists are available to parents and health care workers; these products may be substituted for those containing latex. In the health care arena, it is important to use products with the lowest potential risk for sensitizing patients and staff members.

The identification of those sensitive to latex is best accomplished through careful screening of all patients. During the health interview with the parent or child, ask *all* patients, not only those at risk, about sensitivity to latex. Be certain that this is a routine part of all preoperative and preprocedural histories. Stress the importance of the allergy history to all personnel (e.g., phlebotomists, respiratory therapists) (see Nursing Care Guidelines box for questions related to latex allergy). Children with latex hypersensitivity should carry some form of allergy identification, such as a MedicAlert bracelet. Education programs on latex hypersensitivity are aimed at those who care for high-risk groups, such as children with SB, and may include relatives, school nurses, teachers, child care workers, and babysitters. In addition to educating caregivers about the child's exposure to medical products that contain latex, nurses need to inform them of common nonmedical latex objects such as water toys, pacifiers, and plastic storage bags. Items brought to the hospital, such as floral bouquets, should also be

screened for latex toys and balloons. Parents should also receive literature explaining signs and symptoms of latex hypersensitivity and appropriate emergency treatment (see Chapter 23, Anaphylaxis).

SPINAL MUSCULAR ATROPHY TYPE 1 (WERDNIG-HOFFMANN DISEASE)

Spinal muscular atrophy (SMA) type 1 (Werdnig-Hoffmann disease) is a disorder characterized by progressive weakness and wasting of skeletal muscles caused by degeneration of anterior horn cells. It is inherited as an autosomal recessive trait and is the most common paralytic form of the **floppy infant syndrome (congenital hypotonia)**. The sites of the pathologic condition are the anterior horn cells of the spinal cord and the motor nuclei of the brainstem, but the primary effect is atrophy of skeletal muscles.

Clinical Manifestations

The age of onset is variable, but the earlier the onset, the more disseminated and severe the motor weakness. The disorder may be manifested early—often at birth—and almost always before 2 years of age; death may occur as a result of respiratory failure by age 2 years (Arnold, Kassar, & Kissel, 2019).

The manifestations (Box 30.6) and prognosis are categorized according to the age of onset, severity of weakness, and clinical course; some children may fluctuate between exhibiting symptoms of types 1 and 2 or types 2 and 3 in regard to clinical function (Haliloglu, 2020). Some experts also categorize SMA according to the highest level of motor function; type 1 includes "nonsitters," type 2 includes "sitters," and type 3 includes "walkers" (Arnold et al., 2019). A severe rare fetal form of SMA, classified as type 0, is reported to be quite lethal in the perinatal period; motor neuron degeneration may be noted as early as midgestation in type 0 (Haliloglu, 2020). Type 4 may present between 20 and 30 years of age and may be referred to as proximal adult-type SMA (Arnold et al., 2019).

Diagnostic Evaluation

The diagnosis is based on the molecular genetic marker for the *SMN* (survival motor neuron) gene, which is located on chromosome *5q13*. Prenatal diagnosis may be made by genetic analysis of circulating fetal cells in maternal blood or circulating fetal cells in amniotic fluid. The risk for subsequent affected offspring in carriers of the mutant gene or in families with known cases of SMA may also be evaluated genetically. Further diagnostic studies include muscle electromyography (EMG), which demonstrates a denervation pattern, and muscle biopsy; however, the genetic analysis has become the gold standard for diagnosis of the condition (Haliloglu, 2020).

Therapeutic Management

There is no cure for the disease, and treatment is symptomatic and supportive, primarily preventing joint contractures and treating orthopedic problems, the most serious of which is scoliosis. Hip subluxation and dislocation may also occur. Many children benefit from powered wheelchairs, lifts, special pressure-adjustable mattresses, and accessible environmental controls. Muscle and joint contractures require careful attention and care to prevent further complications. Nutritional growth failure may occur in infants and toddlers as a result of poor feeding; supplemental gastrostomy feedings may be required to maintain adequate nutritional status and maintain weight gain. The use of lower extremity orthoses may assist with ambulation, but eventually the child may be confined to a wheelchair as muscle atrophy progresses. Restrictive lung disease is the most serious complication of SMA (Arnold et al., 2019). Upper respiratory tract infections often

BOX 30.6 Clinical Manifestations of Spinal Muscular Atrophy

Type 1 (Werdnig-Hoffmann Disease)

- Clinical manifestations within first few weeks or months of life
- Onset within 6 months of life
- Inactivity the most prominent feature
- Infant lying in a frog-leg position with legs externally rotated, abducted, and flexed at knees
- Generalized weakness
- Absent deep tendon reflexes
- Limited movements of shoulder and arm muscles
- Active movement usually limited to fingers and toes
- Diaphragmatic breathing with sternal retractions (diaphragmatic paralysis may occur)
- Abnormal tongue movements (at rest)
- Weak cry and cough
- Poor suck reflex
- Fatigues quickly during feedings (if breastfed, may lose weight before noticeable)
- Failure to thrive (nutritional)
- Alert facies
- Normal sensation and intellect
- Affected infants not able to sit alone, roll over, or walk
- Early death possible from respiratory failure or infection

Type 2 (Intermediate Spinal Muscular Atrophy)

- Onset before age 18 months
  - **Early**—Weakness confined to arms and legs
  - **Later**—Becomes generalized
- Legs usually involved to greater extent than arms
- Prominent pectus excavatum
- Movements absent during complete relaxation or sleep
- Some infants able to sit if placed in position, but few can ambulate
- For most, life span varies from 7 months to 7 years, although many have normal life expectancy

Type 3 (Kugelberg-Welander Syndrome; Mild Spinal Muscular Atrophy)

- Onset of symptoms after 18 months of age
- Normal head control and ability to sit unassisted by 6 to 8 months of age
- Thigh and hip muscles weak
- Scoliosis common
- Failure to walk a common presentation
- In those who manage to walk:
  - Waddling gait
  - Genu recurvatum
  - Protuberant abdomen
  - Ambulation becoming increasingly difficult
  - Confined to a wheelchair by second decade
- Deep tendon reflexes may be present early but disappear

Type IV (Adult Spinal Muscular Atrophy)

- Rare, adult-onset spinal muscular atrophy usually in second or third decade of life; muscle weakness is first symptom

Note: These classifications are general, but some research suggests that there may be variations in life span and other characteristics (Iannaccone & Burghes, 2002; Lunn & Wang, 2008; Russman, 1996; Russman, Iannaccone, Buncher, et al., 1992).

occur and are treated with antibiotic therapy; they are the cause of death in many children. Rapid eye movement (REM)–related sleep-disordered breathing is common in children with SMA type 1; this progresses to sleep-disordered breathing during REM and non-REM sleep followed by respiratory failure, which often requires nocturnal noninvasive mechanical ventilation (Arnold et al., 2019). Noninvasive ventilation methods such as bilevel positive airway pressure (BiPAP) have decreased the morbidity and increased the survival rate of children with SMA types 1 and 2. Children with SMA type 1 who undergo tracheotomy and invasive ventilation often remain ventilator dependent for the rest of their lives; some families choose to withdraw support when invasive ventilation becomes necessary (Mercuri, Bertini, & Iannaccone, 2012). Palliative care is an important aspect of care for families of children with SMA type 1. A decreased ability to cough and clear secretions may be managed with airway clearance therapies such as the cough-assist machine and manual cough assistance. Guidelines for the standardization of respiratory care for patients with SMA have been published elsewhere (Schroth, 2009).

In addition to noninvasive respiratory support, some infants and children may benefit from tracheostomy and mechanical ventilation. If untreated, some infants may die of respiratory complications in infancy.

Associated medical conditions in survivors include gastroesophageal reflux, scoliosis, early-onset puberty, hip dysplasia, and recurrent oral candidiasis (Bach, 2007). A referral to pediatric palliative care may help the families of children with SMA make decisions about the benefits and burdens of treatment options.

A new therapy to treat SMA has recently been approved by the US Food and Drug Administration. Spinraza (nusinersen) is an antisense oligonucleotide (ASO) that consists of small strings of synthetic nucleotides that selectively bind ribonucleic acid (RNA). It was designed to treat infants with SMA. In recent studies, treated infants experienced a statistically significant improvement in motor milestones compared with those not treated. The medication is given by intrathecal injection. This allows it to be delivered directly to the CSF around the spinal cord, where motor neurons degenerate in SMA patients due to insufficient levels of survival motor neuron (SMN) protein. Spinraza is designed to alter the splicing of *SMN2* to increase the production of full-length SMN protein. Although not a cure, it is showing promise of improving motor skills in infants with SMA (Meylemans & De Bleecker, 2019).

Nursing Care Management

An infant or a small child with progressive muscle weakness requires nursing care similar to that of an immobilized patient. However, the underlying goal of treatment should be to assist the child and family in dealing with the illness while progressing toward a life of normalization within the child's capabilities. Special attention should be directed to preventing muscle and joint contractures, promoting independence in performance of ADLs, and becoming incorporated into the mainstream of school when possible. In addition, parents need support and resources to be able to provide for the child and remain an intact family. Because children with neuromuscular disease have abnormal breathing patterns that often contribute to early death, it is important to assess adequate oxygenation, especially during the sleep phase when shallow breathing occurs and hypoxemia may develop. Home pulse oximetry may be used to assess the child during sleep and provide noninvasive mechanical ventilation as necessary (Young, Lowe, & Fitzgerald, 2007) (see Duchenne Muscular Dystrophy, later in the chapter, for respiratory management). Supportive care also includes management of orthoses and other orthopedic equipment as required. Because children with SMA are intellectually normal, verbal, tactile, and auditory stimulation are important aspects of developmental care. Supporting them so that they can see the activities around them and transporting them in appropriate equipment (e.g., wagon, power wheelchair) for a change of environment provide stimulation and a broader scope of contacts.

Children who are able to sit require proper support and attention to alignment to prevent deformities and other complications. Children who survive beyond infancy need attention to educational needs and opportunities for social interaction with other children. The parents of a child who is chronically ill require much support and encouragement (see Chapter 19). Parents who have not sought genetic counseling should be encouraged to do so to evaluate further risk potential.

JUVENILE SPINAL MUSCULAR ATROPHY (KUGELBERG-WELANDER DISEASE)

Spinal muscular atrophy type 3 (Kugelberg-Welander disease) is a result of anterior horn cell and motor nerve degeneration. The disease is characterized by a pattern of muscular weakness similar to that of infantile SMA (see Box 30.6). Several modes of inheritance have been reported for the disease: autosomal recessive, autosomal dominant, and X-linked recessive.

The onset occurs from younger than 1 year of age into adulthood, with symptoms resembling group 3 infantile SMA. Proximal muscle weakness (especially of the lower limbs) and muscular atrophy are the predominant features. The disease runs a slowly progressive course. Some children lose the ability to walk 8 to 9 years after the onset of symptoms, but many can still walk after 30 years or more. One source notes that approximately one-half of all children with SMA type 3 lose ambulation by age 14 years and may require a wheelchair when falls are more frequent (Mercuri et al., 2012). Many affected persons have a normal life expectancy.

Therapeutic and Nursing Care Management

Promising results from ongoing clinical trials suggest that treatments that increase SMN protein might provide clinical benefit to patients with spinal muscular atrophy (Sumner & Crawford, 2018). However, the management is primarily symptomatic and supportive and is related to maintaining mobility for as long as possible, preventing complications such as skin breakdown, optimizing and maintaining respiratory function, and providing support to the child and family. The discussion of family support in the section on Duchenne muscular dystrophy (later in the chapter) is also applicable to families of children with SMA.

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS), also known as *infectious polyneuritis,* is an uncommon acute demyelinating polyneuropathy with a progressive, usually ascending flaccid paralysis. The hallmark of GBS is acute peripheral motor weakness. The paralysis usually occurs approximately 10 days after a nonspecific viral infection; GBS has also been reported after administration of certain vaccines (e.g., rabies, influenza, polio, meningococcal) (Haliloglu, 2020). Several subtypes of GBS include acute inflammatory demyelinating neuropathy, acute motor axonal neuropathy, acute motor sensory axonal neuropathy, and Miller Fisher syndrome. Children are less often affected than adults; among children, those between ages 4 and 10 years have higher susceptibility. The male-to-female ratio is reported to be 1.5 to 1. Two peak periods with an increased incidence of GBS have been identified: late adolescence and young adulthood.

Chronic inflammatory demyelinating polyradiculoneuropathies (CIDPs) are chronic types of GBS that recur intermittently or do not improve over a period of months to years (Ryan, 2020). The following discussion focuses on GBS.

Congenital GBS is rare, yet may occur in the neonatal period, and consists of hypotonia, weakness, and decreased or absent reflexes.

Maternal neuromuscular disease may or may not be present. Diagnosis is established by the same criteria as in older children, but the symptoms gradually subside over the first few months of life and disappear by 12 months (Ryan, 2020).

Pathophysiology

Guillain-Barré syndrome is an immune-mediated disease often associated with a number of viral or bacterial infections or the administration of certain vaccines. It has been associated with infectious mononucleosis, measles, mumps, *Campylobacter jejuni* (gastroenteritis), cytomegalovirus, *Borrelia burgdorferi* (Lyme disease), Epstein-Barr virus, *Helicobacter pylori,* and *Mycoplasma* and *Pneumocystis* infections. Onset of GBS symptoms usually occurs within 10 days of the primary infection. Pathologic changes in spinal and cranial nerves consist of inflammation and edema with rapid, segmented demyelination and compression of nerve roots within the dural sheath. Nerve conduction is impaired, producing ascending partial or complete paralysis of muscles innervated by the involved nerves. GBS has three phases:

1. Acute—Phase starts when symptoms begin and continues until new symptoms stop appearing or deterioration ceases; it may last as long as 4 weeks.
2. Plateau—Symptoms remain constant without further deterioration; it may last from days to weeks.
3. Recovery—Patient begins to improve and progress to optimal recovery; it usually lasts a few weeks to months, depending on the deficits incurred by the illness.

Clinical Manifestations

A mild influenza-like illness or sore throat usually precedes the paralytic manifestations of GBS. The onset can be rapid, reaching peak activity within 24 hours, or there may be a gradual progression of symptoms over days or weeks. Neurologic symptoms initially involve muscle tenderness that sometimes is accompanied by paresthesia and cramps. Proximal muscle weakness progressing to paralysis usually occurs before distal weakness, and there is a tendency toward symmetric involvement. In most patients paralysis ascends from the lower extremities, often involving the muscles of the trunk and upper extremities and those supplied by cranial nerves. The seventh cranial (facial) nerve is often affected.

Tendon reflexes are depressed or absent, and paralysis is flaccid. Paralysis may involve facial, extraocular, labial, lingual, pharyngeal, and laryngeal muscles. Evidence of intercostal and phrenic nerve involvement includes breathlessness in vocalizations and shallow, irregular respirations. There may be variable degrees of sensory impairment. Most patients complain of muscle tenderness or sensitivity to slight pressure. Lower limb pain and back pain are common in children with GBS. Urinary incontinence or retention and constipation are often present. Abdominal pain and fatigue have also been reported in children with GBS (Lyons, 2008).

Autonomic nervous system disturbances may occur in children and adolescents with severe muscle involvement and respiratory muscle paralysis. These include orthostatic hypotension; hypertension; and vagal responses such as bradycardia, asystole, and heart block (Piccione, Salame, & Katirji, 2014).

Diagnostic Evaluation

Diagnosis is based on the paralytic manifestations, CSF analysis, and EMG. Motor nerve conduction velocities are greatly reduced. Sensory nerve conduction time is often slowed. CSF analysis reveals an elevated protein concentration, fewer than 10 WBCs/mm^3, and normal glucose level (Ryan, 2020). Other laboratory studies are usually noncontributory. The symmetric nature of the paralysis helps differentiate this disorder from spinal paralytic poliomyelitis, which usually affects sporadic muscles.

Therapeutic Management

Treatment of GBS is primarily supportive. In the acute phase, patients are hospitalized because respiratory and pharyngeal involvement may require assisted ventilation, sometimes with a temporary tracheostomy. Treatment modalities include aggressive ventilatory support in the event of respiratory compromise, intravenous (IV) administration of immunoglobulin (IVIG), and sometimes steroids; plasmapheresis and immunosuppressive drugs may also be used. Plasmapheresis has been shown to decrease the length of recovery in patients with severe GBS; however, it is expensive, and side effects include hypotension, fever, bleeding disorders, chills, urticaria, and bradycardia. Further evidence reports equal benefits to treatment of GBS with IVIG administration or plasmapheresis; both sped up recovery time in studies reviewed (Liu, Dong, & Ubogu, 2018). However, there is evidence of significant improvement in children with high-dose IVIG therapy (vs. supportive treatment alone) (Liu et al., 2018). IVIG is now recommended as the primary treatment of GBS when administered within 2 weeks of disease onset (Piccione et al., 2014). Corticosteroids alone do not decrease the symptoms or shorten the duration of the disease.

Additional medications that may be administered during the acute phase include a low-molecular-weight heparin to prevent deep vein thrombosis (DVT), a mild laxative or stool softener to prevent constipation, pain medication such as acetaminophen, and a histamine-antagonist to prevent stress ulcer formation. Chronic neuropathic pain after GBS may be treated with gabapentin, which is reported to be more effective than carbamazepine (Ryan, 2020).

Rehabilitation after the acute phase may involve physical therapy, occupational therapy, and speech therapy. Additional consideration should be given to problems of general weakness and retraining for toileting and feeding (Lyons, 2008).

Prognosis

Better outcomes are associated with younger age, no requirement for mechanical respiratory assistance, slower progression of disease, normal peripheral nerve function on EMG, and treatment with either IVIG or plasmapheresis. Recovery usually begins within 2 to 3 weeks, and most patients regain full muscle strength. The recovery of muscle strength progresses in the reverse order of onset of paralysis, with lower extremity strength being the last to recover. Poor prognosis with subsequent residual effects in children is reportedly associated with cranial nerve involvement, extensive disability at time of presentation, and intubation.

Most deaths associated with GBS are caused by respiratory failure; therefore early diagnosis and access to respiratory support are especially important. The rate of recovery is usually related to the degree of involvement and may extend from a few weeks to months. The greater the degree of paralysis, the longer the recovery phase.

Nursing Care Management

Nursing care is primarily supportive and is the same as that required for children with immobilization and respiratory compromise. The emphasis of care is on close observation to assess the extent of paralysis and on prevention of complications, including aspiration, ventilator-associated pneumonia (VAP), atelectasis, DVT, pressure ulcer, fear and anxiety, autonomic dysfunction, and pain.

During the acute phase of the disease, the nurse should carefully observe the child's condition for possible difficulty in swallowing and respiratory involvement. The child's respiratory function is closely monitored, and oxygen source, appropriate-size insufflation bag and

mask, endotracheal intubation and suctioning equipment, tracheotomy tray, and vasopressor drugs are kept available. Vital signs are monitored frequently, as are neurologic signs and level of consciousness. For children who develop respiratory impairment, the care is the same as that for any child with respiratory distress requiring mechanical ventilation.

Respiratory care, if intubation is required, requires close monitoring of oxygenation status (usually by pulse oximetry and sometimes arterial blood gases), maintenance of an open airway with suctioning, and postural changes to prevent pneumonia. Consideration should be given to preventing opportunistic infections such as VAP; meticulous oral care and hypopharynx suctioning, elevating the head of the bed 30 degrees, and strict asepsis with suctioning equipment (including catheters, a Yankauer device, or both) should be implemented to prevent VAP. Children with oral and pharyngeal involvement may be fed via a nasogastric or gastrostomy tube to ensure adequate feeding. It is also important to consider the possibility of stress ulcers in such patients and to administer a proton pump inhibitor. Immobilization, which occurs with GBS, decreases GI function; therefore problems such as decreased gastric emptying, constipation, and feeding residuals require nursing assessment and appropriate collaborative interventions. Temporary urinary catheterization may be required; urinary retention is common, and appropriate assessment of urinary output is vital. Sensory impairment and paralysis in the lower extremities make the child susceptible to skin breakdown, and attention should be given to meticulous skin care. Passive range-of-motion exercises and application of orthoses to prevent muscle contracture are important when paralysis is present. Prevention of DVT is accomplished with pneumatic compression (antiembolism) devices, administration of a low-molecular-weight heparin, and early mobilization and ambulation. Autonomic dysfunction may be life threatening; thus close monitoring of vital signs in the acute phase is essential.

A key to recovery in the child with GBS is the prevention of muscle and joint contractures, so passive range-of-motion exercises must be carried out routinely to maintain vital function. Although the child may have a generalized paralysis, cognitive function remains intact; therefore it is important for nursing care to involve communication with the child or adolescent regarding procedures and treatments that may be frightening, especially if mechanical ventilation is required. Encourage parents to talk to the child and make eye and physical contact and to reassure the child during this phase of the illness.

Pain management is crucial in the care of children with GBS. Although neuromuscular impairment may make pain perception more difficult to evaluate accurately, objective pain scales should be used. Gabapentin and carbamazepine may be used to manage neuropathic pain in patients with GBS.

Physical therapy may be limited to passive range-of-motion exercises during the evolving phase of the disease. Later, as the disease stabilizes and recovery begins, an active physical therapy program is implemented to prevent contracture deformities and facilitate muscle recovery. This may include active exercise, gait training, and bracing.

Throughout the course of the illness, child and parent support are paramount. The usual rapidity of the paralysis and the long recovery period greatly tax the emotional reserves of all family members. The parents and child benefit from repeated reassurance that recovery is occurring and from realistic information on the possibility of permanent disability. In the event of a residual disability, the family needs assistance in accepting and adjusting to the loss of function (see Chapter 17). The GBS/CIDP Foundation International is a nonprofit organization devoted to support, education, and research. It provides families with support from recovered persons, publishes informational literature and a newsletter, and maintains a list of health care practitioners experienced with the disease.

TETANUS

Tetanus, or lockjaw, is an acute, preventable, and sometimes fatal disease caused by an exotoxin produced by the anaerobic, spore-forming, gram-positive bacillus *Clostridium tetani*. It is characterized by painful muscular rigidity primarily involving the masseter and neck muscles. The development of tetanus has four requirements: (1) presence of tetanus spores or vegetative forms of the bacillus, (2) injury to the tissues, (3) wound conditions that encourage multiplication of the organism, and (4) a susceptible host.

Tetanus spores are found in soil, dust, and the intestinal tracts of humans and animals, especially herbivorous animals. The organisms are more prevalent in rural areas but are readily carried to urban areas by wind. They enter the body by way of wounds, particularly a puncture wound, burn, or crushed area. In the newborn, infection may occur through the umbilical cord, usually in situations in which infants are delivered in contaminated surroundings and the mother has not been properly immunized against tetanus. The disease has the greatest incidence during months in which persons are more involved in outdoor activities.

Prevention

Primary prevention is key and occurs through immunization and boosters and good wound care. Once an injury has occurred, further preventive measures are based on the child's immune status and the nature of the injury. Specific prophylactic therapy after trauma is administration of either tetanus toxoid or tetanus antitoxin. A dose of tetanus toxoid is not necessary for clean, minor wounds in children who have completed the immunization series (see Chapter 10) or who have received a booster within the previous 10 years. Protective levels of antibody are maintained for at least 10 years. Therefore antitoxin is not indicated for the fully immunized child. Children with more serious wounds (e.g., contaminated, puncture, crush, or burn wounds) are given a tetanus toxoid booster prophylactically as soon as possible after injury.

The unprotected or inadequately immunized child who sustains a "tetanus-prone" wound (including wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite) should receive tetanus immunoglobulin (TIG). Concurrent administration of both TIG and tetanus toxoid at separate sites is recommended both to provide protection and to initiate the active immune process (Kimberlin, Brady, Jackson, et al., 2018). Completion of active immunization is carried out according to the usual pattern. Proper surgical cleansing and debridement of contaminated wounds reduce the chance of infection.

Pathophysiology

When prevention efforts are not effective and conditions are favorable, the organisms multiply and form two exotoxins: (1) tetanospasmin, a potent toxin that affects the CNS to produce the clinical manifestations of the disease, and (2) tetanolysin, which appears to have no significance. The ideal conditions for growth of the organisms are devitalized tissues without access to air (e.g., puncture wounds); wounds that have not been washed or kept clean; and those that have crusted over, trapping pus beneath. The exotoxin appears to reach the CNS by way of either the neuron axons or the vascular system. The toxin becomes fixed on nerve cells of the brainstem and the anterior horn of the spinal cord. The toxin acts at the neuromuscular junction to produce muscular stiffness and to lower the threshold for reflex excitability.

The incubation period is 3 days to 3 weeks and averages 8 days. Most cases occur within 14 days; in neonates it is usually 5 to 14 days.

Shorter incubation periods have been associated with more heavily contaminated wounds, more severe disease, and a worse prognosis (Kimberlin et al., 2018).

Clinical Manifestations

There are several forms of the disease. Local tetanus is a less common but severe form characterized by persistent rigidity of muscles near the inoculation site, which may persist for weeks or months. Some cases resolve without sequelae. Neonatal tetanus results from contamination of the umbilical cord, which is rare in the United States but is common and often fatal in developing countries. The first symptom is difficulty in sucking, progressing to total inability to suck, excessive crying, irritability, and nuchal rigidity.

Generalized tetanus is the most common and dangerous form of the disease. The manner of onset varies, but the initial symptoms are usually a progressive stiffness and tenderness of the muscles in the neck and jaw. The characteristic difficulty in opening the mouth (**trismus**), which is caused by sustained contraction of the jaw-closing muscles, is evident early and gives the disease its common name, lockjaw. Spasm of facial muscles produces the so-called sardonic smile (**risus sardonicus**). Progressive involvement of the trunk muscles causes **opisthotonos** and a boardlike rigidity of abdominal and limb muscles. The patient has difficulty swallowing and is highly sensitive to external stimuli. The slightest noise, a gentle touch, or bright light triggers convulsive muscular contractions that last seconds to minutes. The paroxysmal contractions recur with increased frequency until they become almost continuous.

Mentation is unaffected; the patient remains alert, and pain and distress are reflected in a rapid pulse, sweating, and an anxious expression. Laryngospasm and tetany of respiratory muscles and accumulated secretions predispose the child to respiratory arrest, atelectasis, and pneumonia. Fever is usually absent or mild and generally indicates a poor prognosis. As the child recovers from the disease, the paroxysms become less frequent and gradually subside. Survival beyond 4 days usually indicates recovery, but complete recovery may take weeks.

Therapeutic Management

The unprotected or inadequately immunized child who sustains a "tetanus-prone" wound (as described earlier) should receive TIG. Concurrent administration of both TIG and tetanus toxoid at separate sites is recommended both to provide protection and to initiate the active immune process (Kimberlin et al., 2018). After the individual has received primary tetanus immunization, antitoxin is believed to provide protection for at least 10 years and for a longer period after booster immunization (Kimberlin et al., 2018) (see also Chapter 6, Immunizations).

Antibiotic treatment with penicillin G (or erythromycin or tetracycline in older children with allergy to penicillin) is important in the management of tetanus as an adjunct against clostridia; metronidazole is a viable alternative (Schleiss, 2020).

Aggressive supportive care is necessary to treat tetanus in the acute phase. The acutely ill child is best treated in an intensive care facility, where close and constant observation and equipment for monitoring and respiratory support are readily available.

General supportive care is indicated, including maintaining adequate airway and fluid and electrolyte balance, providing pain management, and ensuring adequate caloric intake. Indwelling oral or nasogastric feedings may be required to maintain adequate fluid and caloric intake; continued laryngospasm may necessitate total parenteral nutrition or gastrostomy feeding. Severe or recurrent laryngospasm or excessive secretions may require advanced airway management such as endotracheal intubation; in some cases a tracheotomy may be performed to provide an adequate airway.

TIG therapy to neutralize toxins is the most specific therapy for tetanus. In countries where TIG is not available, equine tetanus antitoxin (not available in the United States) should be administered. Antibiotics are administered to control the proliferation of the vegetative forms of the organism at the site of infection. When the child recovers, active immunization should take place because contraction of the disease does not confer a permanent immunity. Standard Precautions for the child with tetanus are recommended; isolation is not recommended.

Local care of the wound by surgical debridement and cleansing with an antiseptic solution helps reduce the number of proliferating organisms at the site of injury. The cleansing should be repeated several times during the first 48 hours. Deep, infected lacerations are usually exposed and debrided. Infiltration of the wound with TIG is no longer considered necessary (Kimberlin et al., 2018).

Diazepam is the drug of choice for seizure control and muscle relaxation (Schleiss, 2020), but lorazepam (Ativan) may be used in some cases. Other AEDs may be administered as well. Intrathecal baclofen, magnesium sulfate, dantrolene sodium, and midazolam may also be used in the management of tetanus; intrathecal baclofen may cause apnea and should be used only in the intensive care setting (Schleiss, 2020). Patients with severe tetanus and those who do not respond to other muscle relaxants may require the administration of a neuromuscular blocking agent, such as rocuronium or vecuronium. Because of their paralytic effect on respiratory muscles, use of these drugs requires mechanical ventilation with endotracheal intubation or tracheotomy and constant cardiopulmonary monitoring. Endotracheal tube insertion or tracheotomy is often indicated and should be performed before severe respiratory distress develops. Despite the absence of pain manifestation with these drugs, it is important to administer adequate analgesia. The administration of corticosteroids has met with success in some cases.

Nursing Care Management

The care of the child with tetanus requires supportive management with particular attention to airway and breathing. Respiratory status is carefully evaluated for any signs of distress, and appropriate emergency equipment is kept available at all times. The location, extent, and severity of muscle spasms are important nursing observations. Muscle relaxants, opioids, and sedatives that may be prescribed can also cause respiratory depression; therefore the child should be assessed for excessive CNS depression. Attention to hydration and nutrition involves monitoring an IV infusion, monitoring nasogastric or gastrostomy feedings, and suctioning oropharyngeal secretions when indicated.

In caring for a child with tetanus during the acute phase, every effort should be made to control or eliminate stimulation from sound, light, and touch. Although a darkened room is ideal, sufficient light is essential so that the child can be carefully observed; light appears to be less irritating than vibratory or auditory stimuli. The infant or child is handled as little as possible, and extra effort is expended to avoid any sudden or loud noise to prevent seizures.

If a potent muscle relaxant such as vecuronium is used, the total paralysis makes oral communication impossible. The drug is not a sedative, however, and anxiety should be considered in children who are intubated. Therefore all of the child's needs must be anticipated and procedures carefully explained beforehand. Additional care is focused on preventing the complications associated with prolonged immobility, including decreased bowel and bladder tone and subsequent constipation, anorexia, DVT, pneumonia, and skin breakdown.

BOTULISM

Botulism is serious food poisoning that results from ingestion of the preformed toxin produced by the anaerobic bacillus *Clostridium botulinum.* Botulism toxin exerts its effect by inhibiting the release of acetylcholine at the neuromuscular junction, thereby impairing motor activity of the muscles innervated by the affected nerves. The disease has a wide variation in severity, from constipation to progressive sequential loss of neurologic function and respiratory failure. Human botulism is caused by neurotoxins A, B, E, and rarely F (Kimberlin et al., 2018). Types A and B are the most common causes of infant botulism.

Several forms of botulism are recognized: foodborne, infant, wound, human made (for bioterrorism), and botulism from undetermined causes. This chapter covers only the first three forms.

Foodborne Botulism

This classic form of the disease usually occurs in adults but may occur in children and adolescents. The most common source of the toxin is improperly sterilized home-canned foods. CNS symptoms appear abruptly approximately 12 to 36 hours after ingestion of contaminated food and may or may not be preceded by acute digestive disturbance. Early symptoms include blurred vision, diplopia, weakness, dizziness, difficulty talking and speaking, vomiting, and dysphagia. These are followed by descending paralysis and dyspnea. Progressive respiratory paralysis is life threatening.

Infant Botulism

Infant botulism, unlike the disease in older persons, is caused by ingestion of spores or vegetative cells of *C. botulinum* and the subsequent release of the toxin from organisms colonizing the GI tract. *C. botulinum* types A and B are the most common causative strains of infant botulism. This form of botulism has become more prevalent than any other form. Many cases of infant botulism occur in breastfed infants who are being introduced to nonhuman milk substances (Kimberlin et al., 2018). Cases of infant botulism are still being reported in Europe, where honey is commonly given to infants. There appears to be no common food or drug source of the organisms; however, the *C. botulinum* organisms have been found in honey. Botulism may occur in infants from 1 week to 12 months of age, with peak incidence between 2 and 4 months of age.

The severity of the disease varies widely, from mild constipation to progressive sequential loss of neurologic function and respiratory failure. The affected infant is usually well before the onset of symptoms. Constipation is a common presenting symptom, and almost all infants exhibit generalized weakness and a decrease in spontaneous movements. Deep tendon reflexes are usually diminished or absent. Cranial nerve deficits are common, as evidenced by loss of head control, difficulty in feeding, weak cry, and reduced gag reflex. SMA type 1 and metabolic disorders are often mistaken for infant botulism in the initial diagnostic phase because of the similarities in clinical manifestations of hypotonia, lethargy, and poor feeding (Norton & Schleiss, 2020). Presenting clinical signs also often mimic those of sepsis in young infants. Botulism toxin exerts its effect by inhibiting the release of acetylcholine at the myoneural junction, thereby impairing motor activity of muscles innervated by affected nerves.

Diagnosis and Therapeutic Management

The diagnosis is made on the basis of the clinical history, physical examination, and laboratory detection of the organism in the patient's stool and, less commonly, blood. However, isolation of the organism may take several days; therefore suspicion of botulism by clinical presentation should require emergency treatment (Norton & Schleiss, 2020). EMG may be helpful in establishing the diagnosis; however, results may be normal early in the course of the illness.

Treatment consists of immediate administration of botulism immune globulin intravenously (BIG-IV) (Norton & Schleiss, 2020) without delaying for laboratory diagnosis. Early administration of BIG-IV neutralizes the toxin and stops the progression of the disease. The human-derived botulism antitoxin (BIG-IV) has been evaluated and is now available nationwide for use only in infant botulism. Infants treated with BIG-IV usually have a shortened hospital stay from approximately 6 days to 2 weeks, reportedly as a result of decreased requirements for mechanical ventilation and intensive care (Norton & Schleiss, 2020). Approximately 50% of affected infants require intubation and mechanical ventilation; therefore respiratory support is crucial, as is nutritional support because these infants are unable to feed. Trivalent equine botulinum antitoxin and bivalent antitoxin, used in adults and older children, are not administered to infants. Antibiotic therapy is not part of the management because the botulinum toxin is an intracellular molecule and antibiotics would not be effective; aminoglycosides in particular should not be administered because they may potentiate the blocking effects of the neurotoxin (Norton & Schleiss, 2020).

The prognosis is generally good if the patient is adequately treated, although recovery may be slow, requiring a few weeks after severe illness. Untreated patients may require a longer hospitalization.

! NURSING ALERT

Although the precise source of *Clostridium botulinum* spores has not been identified as originating from honey in many cases of infant botulism in the United States, it is still recommended that honey not be given to infants younger than 12 months because the spores have been found in honey.

Nursing Care Management

Nursing responsibilities include observing, recognizing, and reporting signs of poor feeding, constipation, and muscle impairment in the infant with botulism and providing intensive nursing care when an infant is hospitalized (see Nursing Care Management for the infant with SMA, earlier in the chapter, and Chapter 8, Care of High-Risk Newborns). Parental support and reassurance are important. Most infants recover when the disorder is recognized and BIG-IV therapy is implemented. Nursing care of the infant on mechanical ventilation requires observation of oxygenation status and vigilance for any complications (see Chapter 26). Parents should be aware that, during recovery, infants fatigue easily when muscular action is sustained. This has important implications for timing the resumption of feedings because of the risk of aspiration. They should also be advised that normal bowel activity may not return for several weeks. Therefore a stool softener can be beneficial.

One cultural consideration that requires further parent education and anticipatory guidance is the use of honey pacifiers among mothers with small infants; there is evidence that honey pacifiers are still commonly used among many mothers to soothe their infants (Benjamins, Gourishankar, Yataco-Marquez, et al., 2013).

SPINAL CORD INJURIES

SCIs with major neurologic involvement are not a common cause of physical disability in children. Pediatric SCI incidence is estimated at 14 per million, with the adolescent age-group predominating (Piatt & Imperato, 2018). However, many children with these injuries are

admitted to major medical centers, and because of the increased survival rate resulting from improved management, nurses have an important role in the care of children with SCI.

The principles of management and nursing care of the child with a spinal cord lesion apply regardless of cause. In addition to care related to the immobilized child, as discussed in Chapter 17, children with damage to the spinal cord present additional problems—specifically, complications related to the neuropathology of the central and autonomic nervous systems. The extent of paralysis is determined by both neurologic and clinical assessment. Although most children with SCI are paraplegic, some are tetraplegic (quadriplegic). Some children with tetraplegia are able to move only their face and neck muscles, whereas others are able to lift and bend their arms but are unable to perform fine hand movements. Almost every physiologic system is disrupted in a child with high-level tetraplegia. Not only are the central and peripheral nerves impaired, but there is also autonomic nervous system dysfunction. Vital structures such as blood vessels, lungs, bladder, and bowel are affected. Therefore an understanding of neuromuscular physiology is essential to effectively care for the child with damage or injury to the spinal cord.

Essential Neuromuscular Physiology

The spinal cord extends from the medulla oblongata to the lower border of the first lumbar vertebra and contains millions of nerve fibers. However, because of its protected location, a considerable amount of direct trauma is required to cause injury. Posteriorly the cord is protected by the spinous processes, which are stabilized by related ligaments and muscles. It is further protected by the spinal fluid, which surrounds it and absorbs some of the shock.

Spinal Nerves

The 31 nerves of the spinal cord are divided into five segments. The cervical cord segments lie within the first seven vertebrae. The remaining cord segments—thoracic (12), lumbar (5), sacral (5), and coccygeal (1)—extend from the first thoracic vertebra to the lower level of the first lumbar vertebra. Therefore the cord constituents do not anatomically match by number the 33 associated vertebrae. However, nerves that arise from the spinal cord exit from the spinal column at the numerically corresponding vertebrae. In describing injuries to the spinal cord, the highest point at which there is normal function is referred to in relation to the vertebra; for example, an intact cord at the sixth cervical vertebra is designated a C6 injury.

Certain areas of the curved vertebral column are less stable and more prone to damage from severe flexion and twisting. These sites are the cervical area and the junction of the thoracic and lumbar regions. The cervical vertebrae are fractured most often, and this high level of injury causes extensive paralysis and many associated neurologic problems. Also, traumatic tearing or embolic occlusion of the arteries supplying these areas can markedly jeopardize the cord tissue. Impaired blood supply often produces severe neurologic deficit, which can extend to complete loss of cord function at the level of injury.

Cell bodies of interneurons and motor neurons within the spinal cord are identified as H-shaped gray matter surrounded by columns of white myelinated nerve fibers. Each column serves as a route for a specific type of impulse, such as touch, vibration, pain, and temperature. Nerve pathways in the spinal cord transmit sensory and motor impulses between peripheral receptors and the brain, conduct impulses through the reflex arc, and convey sympathetic and parasympathetic nerve impulses from the brain to peripheral structures.

Sensory transmission begins when peripheral receptors pick up a wide variety of stimuli and transfer the impulses, by means of peripheral nerves, to the spinal nerves, where they make ganglionic connections and enter the cord posteriorly. At this point the impulses travel in two directions: across the interneuron connection and then to the motor neurons (reflex arc) or up the spinal cord to predetermined areas of the brain. Motor impulses are transmitted from the cerebral cortex to the medulla (where nerve tracts cross) and proceed down descending motor pathways to the desired level within the spinal cord. Here they connect with the anterior horn cells and are transmitted to the muscle fibers by means of the lower motor neurons to complete a meaningful movement.

A network of nerves that serves the major muscle groups constitutes a plexus. Total involvement of any one of these plexuses seriously impairs function to the areas it innervates.

Upper Versus Lower Motor Neurons

Upper motor neurons extend from cerebral centers to cells in the spinal column; lower motor neurons consist of anterior horn cells and spinal and peripheral nerves. Motor fibers of the reflex arc are lower motor neurons. This is an important point because relative dominance of the CNS over reflex arcs suppresses some reflex responses. When the higher centers no longer exert an influence in SCI, spastic responses are observed in muscles innervated by the intact lower motor neurons. Most SCIs involve upper motor neurons; children born with spinal cord defects have primarily lower motor neuron deficits.

Effect on Sensory and Motor Tracts

Voluntary muscle control is lost after complete transection of the cord. In partial transection, function is altered to varying degrees depending on the areas innervated by involved nerves. The crossing of motor tracts at various levels makes it possible for an injured person to have motor paralysis in one leg but retain pain and temperature sensation in that leg, while the opposite leg retains its motor function but loses pain and temperature sensation.

Although a transected cord injury leads to sensory loss, it is not uncommon for the injured person to experience pain. For example, smooth or skeletal muscle spasms, destruction of the myelin sheath (impulses cross to adjacent nerves), and scar formation or irritation of nerve endings may cause pain. Pain suffered by a person with tetraplegia or paraplegia is often intensified because of loss of sensation in other parts. Severe and prolonged pain should be medically evaluated for a treatable pathologic condition.

Effect on Autonomic System

Sympathetic and parasympathetic systems receive both excitatory and inhibitory stimuli from autonomic centers in the cerebral cortex, limbic system, and hypothalamus. The stimuli are transmitted by means of a feedback mechanism within the ascending fibers of the cord that normally controls descending input. Axons of the many CNS neurons synapse with autonomic preganglionic fibers and thus are able to alter their patterned responses.

Etiology

The most common cause of serious spinal cord damage in children is trauma involving MVCs (including automobile/bicycle, all-terrain vehicles, and snowmobiles), sports injuries (especially from diving, trampoline activities, gymnastics, and football), birth trauma, and nonaccidental trauma. MVCs accounted for 31.9% of SCIs in children and 50% in adolescents, and falls accounted for 18.3% in children and 10% in adolescents (Piatt & Imperato, 2018). In the United States football injuries accounted for a high percentage of sport-related injuries in adolescents, whereas in Canada such injuries were associated with ice hockey (Mathison, Kadom, & Krug, 2008).

The increased use of recreational activities involving motorized vehicles such as jet water skis, all-terrain vehicles, and motorcycles has also increased the incidence of SCIs in children. Congenital defects of the spine such as myelomeningocele also may in some cases produce the effects of SCI (see discussion earlier in the chapter).

Transverse myelitis (inflammation of the spinal cord) may be caused by illness and has also been reported to develop from inadvertent intra-arterial administration of long-acting penicillin injected into the buttocks. Damage can be extensive enough to result in paraplegia or even lower limb amputation.

In MVCs, most SCIs in children are a result of indirect trauma caused by sudden hyperflexion or hyperextension of the neck, often combined with a rotational force. Trauma to the spinal cord without evidence of vertebral fracture or dislocation (**SCI without radiographic abnormality**, or SCIWORA) is particularly likely to occur in an MVC when proper safety restraints are not used. An unrestrained child becomes a projectile during sudden deceleration and is subject to injury from contact with various objects inside and outside the vehicle. Individuals who use only a lap seat belt restraint are at greater risk for SCI than those who use a combination lap and shoulder restraint. High cervical spine injuries have been reported in children younger than 2 years who are improperly restrained in forward-facing car seats. Infants who are improperly restrained in an infant car seat may experience cervical trauma in a car crash. Small children may also be severely injured by deploying front seat air bags.

Falling from heights occurs less often in children than in adults, but vertebral compression from blows to the head or buttocks can occur in water sports (diving and surfing), falls from horses, or other athletic activities. Birth injuries may occur in breech births from traction force on the spinal cord during birth of the head and shoulders. When shaken, infants commonly sustain cervical cord damage, as well as subdural hematoma and retinal hemorrhage; cognitive impairment and death may occur subsequent to the traumatic event. Infants have weak neck muscles, and during vigorous shaking their large and heavy heads rapidly wobble back and forth. A significant number of adolescents receive SCIs secondary to gunshot wounds, stabbings, and other violent inflicted injuries.

Because of the marked mobility of the neck, fracture or **subluxation** (partial dislocation) is the most common immediate cause of SCI, particularly in the lower cervical region. Although unusual in adults, SCI without fracture is common in children, whose spines are suppler, weaker, and more mobile than those of adults. Therefore the force is more easily dissipated over a larger number of segments. In infants and small children younger than 5 years, upper cervical spine fractures and spinal compression are more common, but adolescents tend to have lower cervical and thoracolumbar fracture dislocations (Proctor, 2020). Children who suffer SCI before puberty are reported to experience a higher incidence of musculoskeletal complications such as scoliosis and hip dislocation (Vogel, Betz, & Mulcahey, 2012).

Pathophysiology

The severity of the force, the mechanisms of the injury, and the degree of the individual's muscular relaxation at the time of the injury greatly influence the extent of the trauma. SCIs are classified as either *complete* or *incomplete*. In a complete injury, there is no motor or sensory function more than three segments below the neurologic level of the injury (Alizadeh, Dyck, & Karimi-Abdolrezaee, 2019). Incomplete lesions have several typical characteristics (Mathison et al., 2008):

- Central cord syndrome—Central gray matter destruction and preservation of peripheral tracts; tetraplegia with sacral sparing common; some motor recovery gained
- Anterior cord syndrome—Complete motor and sensory loss with trunk and lower extremity proprioception and sensation of pressure
- Posterior cord syndrome—Loss of sensation, pain, and proprioception with normal cord function, including motor function; able to move extremities but have difficulty controlling such movements
- Brown-Séquard syndrome—Unilateral cord lesion with a motor deficit on the opposite side of the body from the primary insult; absence of pain and temperature sensation on the opposite side from the injury
- Spinal cord concussion—Transient loss of neural function below the level of the acute spinal cord lesion, resulting in flaccid paralysis and loss of tendon, autonomic, and cutaneous reflex activity; may last hours to weeks

The American Spinal Injury Association (Alizadeh et al., 2019) International Standards for Neurological Classification of Spinal Cord Injury worksheet was recently revised and published in the cited reference. The American Spinal Injury Association Impairment Scale combines motor and sensory function and is used to determine the severity of impairment from the injury (complete or incomplete). It may also be used to measure neurologic changes and functional goals for rehabilitation (Alizadeh et al., 2019).

The injury sustained can affect any of the spinal nerves, and the higher the injury, the more extensive the damage. The child can be left with complete or partial paralysis of the lower extremities (**paraplegia**) or with damage at a higher level and without functional use of any of the four extremities (**tetraplegia**). A high cervical cord injury that affects the phrenic nerve paralyzes the diaphragm and leaves the child dependent on mechanical ventilation.

A mild but equally frightening form of cord trauma is **spinal cord compression**, a temporary neural dysfunction without visible damage to the cord. Complete tetraplegia can result but initially may not be differentiated from serious cord injury.

Clinical Manifestations

It is often difficult to determine the extent and severity of damage at first. Immediate loss of function is caused by both anatomic and impaired physiologic function, and improved function may not be evident for weeks or even months. Manifestation of the initial response to acute SCI is flaccid paralysis below the level of the damage. This stage is often referred to as **spinal shock syndrome** and is caused by the sudden disruption of central and autonomic pathways. Local effects of cord edema and ischemia produce a physiologic transection with or without an anatomic severance. Most children with an SCI experience some spinal shock. Manifestations include the absence of reflexes at or below the cord lesion, with flaccidity or limpness of the involved muscles, loss of sensation and motor function, and autonomic dysfunction (i.e., symptoms of hypotension, low or high body temperature, loss of bladder and bowel control, and autonomic dysreflexia). It is estimated that 25% to 50% of children with SCI will have a delay in the onset of neurologic abnormalities ranging from 30 minutes to 4 days (Vogel et al., 2012).

Autonomic paralysis also affects thermoregulatory functions. Afferent impulses from temperature receptors in the skin are not integrated; therefore the patient is subject to temperature increases or decreases in response to alterations in environmental temperature. Hyperthermia can result from excessive ambient temperature, such as too many covers.

Except in the situations previously mentioned, flaccid paralysis is replaced by spinal reflex activity and increasing spasticity or, in incomplete lesions, greater or lesser degree of neurologic recovery.

The paralytic nature of autonomic function is replaced by **autonomic dysreflexia**, especially when the lesions are above the midthoracic level. This autonomic phenomenon is caused by visceral distention or irritation, particularly of the bowel or bladder. Sensory impulses are triggered and travel to the cord lesion, where they are blocked, which causes activation of sympathetic reflex action with disturbed central inhibitory control. Excessive sympathetic activity is manifested by a flushing face, sweating forehead, pupillary constriction, marked hypertension, headache, and bradycardia. The precipitating stimulus may be merely a full bladder or rectum, or other internal or external sensory input. It can be a catastrophic event unless the irritation is relieved.

Additional clinical findings of SCI may include numbness, tingling, or burning; priapism; weakness; and loss of bowel and bladder control (Hayes & Arriola, 2005).

Neurogenic shock occurs as a result of a disruption in the descending sympathetic pathways with loss of vasomotor tone and sympathetic innervations to the cardiovascular system (Hagen, 2015). Hypotension, bradycardia, and peripheral vasodilation occur as a result of neurogenic shock.

Children with suspected SCI may have suffered multiple injuries (e.g., MVC); therefore multiple clinical manifestations that may mask those of an SCI may occur.

In the final stage, neurologic signs are stabilized in terms of loss and recovery of function. The major emphasis is on rehabilitation. A problem unique to injury in childhood is progressive spinal deformity usually not seen in adults or in adolescents near the end of the growth period. Scoliosis develops in most children with high thoracic and cervical lesions and is almost certain to occur in children with tetraplegia whose injury occurred in infancy or early childhood.

Diagnostic Evaluation

A history of the injury provides valuable clues regarding the possible type of damage incurred and directions for further assessment without the risk of additional damage. A complete neurologic examination determines whether damage was incurred and, if so, the level and extent of any nerve impairment. A neurologic unit of the CNS is considered normal if reflex arcs are functioning, sensory tracts are intact when each dermatome is examined separately, and voluntary motor response demonstrates an ability to move a body part against gravity on command.

Testing a reflex arc is accomplished by stimulating the peripheral receptors at a specific site, such as eliciting the patellar reflex. Symmetric testing is performed to determine unilateral or bilateral neurologic deficit. A sufficient number of reflexes are examined to test motor function thoroughly. The blunt end of a safety pin is used to assess pressure sensitivity, and the sharp point is used to elicit pain. Hot and cold water, a tuning fork, and cotton may also be used to determine specific sensory loss (e.g., temperature, vibration, light touch).

The American Spinal Injury Association dermatome classification worksheet is used to determine the extent of neurologic damage. Body surface zones, or **dermatomes**, accurately correspond to the spinal cord segment receiving the sensory input from the peripheral nerves in that zone. Systematically pinpricking the body surface in each zone determines intactness of sensory pathways. The examiner tests for each specific sensory fiber in the dermatome areas in which neurologic deficit is suspected.

Matching cord level to vertebra is more difficult in infants and young children than it is in older children and adults because the sacral and several lower lumbar cord segments lie at a lower position, especially during the first 2 years of life. The spinal anatomy approaches adult configuration by the time the child reaches age 7 or 8 years; by late adolescence the conus medullaris has usually reached the level of L1.

Motor system evaluation includes observing gait if the child is able to walk; noting balance maintenance with the child's eyes open and closed; and noting the ability to lift, flex, and extend the arms and legs. Testing muscle strength with and without resistance and against gravity provides clues to the specific nature and degree of motor dysfunction. The number of muscles in any muscle group that remain completely intact in the upper extremities makes a marked difference in the individual's ability to provide self-care, especially at high injury levels. Hip movement is necessary for ambulation with braces and crutches.

The degree to which supportive aids are needed for ambulation is determined by the strength, stability, and movement of the pelvis, trunk, hip flexor muscles, and quadriceps muscles. A general guideline for determining the capacity for self-help is that a person with paraplegia who has function down to and including the quadriceps muscle or muscle function below the L3 level will have little difficulty in learning to walk with or without braces and crutches. It is especially vital that children with lumbar levels of injury be taught to walk functionally so that they are weight bearing at least part of the time; this minimizes the risk of osteoporosis and hypercalcemia.

If a CNS pathologic disorder is detected, a body system assessment is performed to determine the degree of autonomic impairment. Because the cord and CNS directly influence the function of the autonomic nerves, the specific sympathetically related organ systems are examined for skeletal muscle and vascular tone and body temperature regulation. For example, bladder and GI functions have sympathetic and parasympathetic innervation and local reflexes.

CT and MRI scans are important for localizing the lesion, but the nature of the spine in childhood often creates difficulty in interpretation. Guidelines for diagnostic imaging of children with suspected SCI have been published elsewhere (Rozelle, Arabi, Dhall, et al., 2013). Small children often have no radiographic evidence of vertebral or spinal injury despite significant injuries ranging from complete transection with major hemorrhage to minor hemorrhage, edema, or normal neural findings. This condition, SCIWORA, is reported to occur in 17% to 20% of cervical spine injuries in toddlers ages 0 to 3 years and accounts for only 5% of cervical spine injuries in teenagers (Farrell, Hannon, & Lee, 2017). The younger the child, the more likely it is for SCIWORA to occur; it is seen in up to 72% of children 5 years old and younger (Schottler, Vogel, & Sturm, 2012). SCIWORA is also a common finding in very young children who are victims of abuse (primarily shaken baby syndrome) because of the elasticity and incomplete ossification of the vertebrae. SCIWORA is more common in children under the age of 8 years, and injury to the cervical spine is common. Diagnostic scans must be taken carefully and with sufficient help to prevent further damage to the spine.

Therapeutic Management

Initial care begins at the scene of the accident with proper immobilization of the cervical, thoracic, and lumbar spine. Immobilization should take into account the age and size of the child; smaller children have a larger head, which may make effective immobilization on a rigid board difficult (Rozelle et al., 2013). Because of the complexity of these injuries, it is usually recommended that these persons be transported to a spinal injury center for care by specially trained health care personnel as soon as possible after the injury for appropriate diagnostic evaluation and intervention.

The initial management of the child with a suspected SCI should begin with an assessment of the ABCs: **a**irway, **b**reathing, and

circulation. The airway should be opened using the jaw-thrust technique to minimize damage to the cervical spine. The child is monitored for cardiovascular instability, and measures are taken to support systemic blood pressure and maintain optimal cardiac output. Because MVCs and other trauma in children may involve internal organ damage and potential bleeding, abdominal distention and other signs are acted on immediately to prevent further systemic shock. After the child is stabilized and transported to a regional trauma center, a thorough evaluation of neurologic status and any other associated trauma is carried out by the multidisciplinary team. In the emergency department, spinal immobilization should be maintained until a thorough neurologic assessment is completed and SCI is ruled out; in children, this typically involves a CT scan and possibly an MRI. Additional interventions are discussed in the Nursing Care Management section. Assessment of neurologic status using the Glasgow Coma Scale (see Chapter 27) is important; a helpful assessment is represented in the mnemonic AVPU: ***a***lert; responds to ***v***erbal stimuli; responds to ***p***ainful stimuli; and ***u***nresponsive. A secondary assessment tool in the emergency department follows the mnemonic AMPLE: ***a***llergies, ***m***edications, ***p***ast medical history, ***l***ast meal or fluids, and ***e***nvironment and events leading to the incident (Avarello & Cantor, 2007).

The American Association of Neurological Surgeons and the Congress of Neurological Surgeons have published management guidelines and standards of care for adult and pediatric patients with SCIs. Recently, evidence-based guidelines for the management of SCI in children were published (Rozelle et al., 2013).

IV methylprednisone may be started within the first 12 hours after the injury to decrease inflammation and minimize further injury; however, its use in small children is controversial. Studies of methylprednisone administration in adults with SCI have shown mixed results, with experts recommending against its use in acute SCI (Hurlbert, Hadley, Walters, et al., 2013).

In children with upper motor neuron involvement, the spasticity that develops may require administration of an antispasmodic medication such as diazepam. Baclofen is considered the drug of choice for reducing muscle spasticity (Vogel et al., 2012). Gabapentin may be used to treat neuropathic pain (Hauer & Houtrow, 2017). Botulinum toxin type A and α_2-adrenergic agonists may be used in older children with SCI to decrease muscle spasticity.

A number of progressive rehabilitation modalities that have the potential for increasing the quality of life for children with SCI have been developed in recent years. One treatment is functional electrical stimulation (FES), also referred to as *functional neuromuscular stimulation* or *neuromuscular electrical stimulation*. With this treatment, an electrical stimulator is surgically implanted under the skin in the abdomen and electrode leads are tunneled to paralyzed leg muscles, enabling the child to sit, stand, and walk with the aid of crutches, a walker, or other orthoses. The stimulator can also be used to elicit a voluntary grasp and release with the hand. Before the latter can be accomplished, a number of surgical tendon transfers may be required for elbow extension, wrist extension, and finger and thumb flexion. In addition, FES has therapeutic benefits, which include increased muscle strength, improved gait function, and increased cardiovascular fitness (Ho, Triolo, Elias, et al., 2014). Tendon transfers have been shown to be successful in enhancing hand and arm function, increasing pinch force, and facilitating independence in ADLs (van Zyl, Hill, Cooper, et al., 2019). Restoration of hand and arm function enables children with SCI to perform self-catheterization and achieve greater independence in personal hygiene.

Exercise is considered an integral part of SCI rehabilitation; exercise may enhance neuroplasticity and decrease further muscle atrophy. Examples of exercise modalities in SCI patients include upper body strength training and hand cycling (Hosalkar, Pandya, Hsu, et al., 2009).

Administration of pharmacologic agents such as clonidine hydrochloride may improve ambulation in patients with partial SCIs, and exercise therapy through interactive locomotor training has helped some individuals with SCI regain ambulatory function.

A number of orthoses or ambulation aids such as crutches may still be necessary to achieve upright mobility, yet as robotic technology advances, so do the chances for improved mobilization in children with SCI. Mechanical or robotic orthoses may be used in conjunction with FES to enable ambulation in persons with SCI (To, Kirsch, Kobetic, et al., 2005). Gait training may be achieved with a number of different modalities, including a stationary cycle; however, no specific method has proved superior to the others. FES has also been effective in reducing complications from bladder and bowel incontinence and in assisting males in achieving penile erection. Ambulation is an important part of rehabilitation in SCI; retrospective studies found that ambulation was dependent on age at injury and extent of neurologic injury (as measured by American Spinal Injury Association motor scales). Age (younger) and lesser neurologic impairment are key predictors for ambulation (Vogel et al., 2012). A knee-ankle-foot orthosis and reciprocating-gait orthosis may also be used to assist with early rehabilitation and ambulation (Vogel et al., 2012). Additional detailed information on ambulation and orthotics for children have been published elsewhere (Calhoun, Schottler, & Vogel, 2013).

Surgical interventions for SCI include early cord decompression (decompression laminectomy) and cervical or thoracic fusion. Crutchfield, Vinke, or Gardner-Wells tongs and skeletal traction may be used for early cervical vertebral stabilization. A halo vest or Minerva jacket may be suited for ambulation after the acute phase. After cervical spinal fusion, a hard cervical collar or sterno-occipital-mandibular immobilizer brace may be worn until the fusion is solidified. When SCI occurs in young children and preteens, scoliosis develops over time and often requires surgical consideration (Parent, Mac-Thiong, Roy-Beaudry, et al., 2011).

Prognosis

The ultimate outlook for spinal cord function after injury depends on the completeness of the cord transection, site of injury, complicating damage to the neuronal tissue, and success of treatment regimens aimed at recovery of lost muscle movement and ability. Healing of the injury and the return of neurologic function are related to two factors:

1. Although individual nerve fibers do regenerate, they do not necessarily reconnect or make synaptic connections with the distal portion of the severed fibers; the chance of numerous fibers reconnecting is highly unlikely.
2. The damage resulting from cord ischemia produces necrosis in the gray and white matter of the cord tissue, which does not regenerate if the axon cylinder is not intact.

In children the prognosis for recovery is considered better than in adults because children have rapid healing of bone and ligaments and increased potential for nervous system regeneration. Paraplegia is more common in children under age 12 years, whereas older children and adolescents tend to have incomplete injuries (Mathison et al., 2008). Shavelle and colleagues (2007) reported an increased likelihood of mortality among children younger than 16 years of age who suffered an SCI in comparison to adults with similar injuries. Children with incomplete injuries (and who are not ventilator dependent) had a projected 83% chance of normal life expectancy, whereas those with high-level cervical injuries who are not ventilator dependent had a 50% chance of having a normal life expectancy. One study found that adults who had an SCI as children (younger than 18 years of age at time of

incident) had comparable or greater degrees of education in comparison to the general population of the same age (Vogel, Chlan, Zebracki, et al., 2011). The same study found lower employment rates for adults with pediatric-onset SCI, lower rates of independent living and independent driving, and lower rates of marriage in this select population.

In general, recovery of motor function in children with thoracic lesions is variable. Cervical injuries are also variable in the extent of damage. Incomplete lesions produce hemiplegia, whereas complete transection implies some involvement of all extremities—from partial use of the upper extremities to complete paralysis, including the need for some type of assisted ventilation. Lumbar injury may involve partial or complete loss of function in the lower extremities and bladder. With rapidly advancing surgical technology, use of microcomputers in medicine, and newer treatment modalities such as FES, there are increasing hope and evidence that functional mobility and independence can be restored in children with SCI (see Quality Patient Outcomes box).

QUALITY PATIENT OUTCOMES: Neurologic Impairment
- Neurologic status maintained or improved
- No further injuries

Nursing Care Management

The nursing care of the child affected by SCI is complex and challenging. A multidisciplinary SCI team is equipped to manage the acute phase of the injury, and some members, including the nurse, may follow the patient to eventual recovery. Nursing management is concerned with ensuring adequate initial stabilization of the entire spinal column with a rigid cervical collar with supportive blocks on a rigid backboard. The traumatic event causing the injury may or may not be recalled if the child lost consciousness; such events are extremely frightening to the child. The young child may also be frightened by the immobilization process and the inability to move extremities; therefore it is important to reassure and comfort the child during this process.

During the acute phase of the injury it is imperative that airway patency be ensured, complications prevented, and function maintained. Evaluate the extent of the neurologic damage early to establish a baseline for neurologic function. Continual assessment of sensory and motor function should occur to prevent further deterioration of neurologic status as a result of spinal cord edema. The American Spinal Injury Association Impairment Scale can be used to assess neurologic function on a routine basis during the patient's recovery. Once the patient is admitted, further evaluation of his or her ability to perform ADLs and need for assistance during recovery can be made with the Functional Independence Measure scale.

Nursing care during the acute phase should also focus on frequent monitoring of neurologic signs to determine any changes in neurologic function that require further intervention (e.g., level of consciousness using the Glasgow Coma Scale). In addition to airway maintenance, the nurse monitors for changes in hemodynamic status that may require immediate medical attention. Neurogenic shock consists of hypotension, bradycardia, and vasodilation. Inotropic medications may be required to maintain adequate perfusion. Renal function is closely monitored by measuring urinary output and fluids administered. The child with a head injury may experience elevated intracranial pressure; therefore changes in neurologic status are reported to the practitioner. Fluid restriction may be required if intracranial pressure is elevated, so fluid intake should be closely monitored.

The nursing care of the child with an SCI is, in most respects, the same as that of any immobilized child (see Chapter 29, The Immobilized Child). Additional aspects of care that should be addressed on an individual basis include hypercalcemia in adolescent boys, DVT, latex sensitization, pain, hypothermia and hyperthermia, spasticity, autonomic dysreflexia, and sleep-disordered breathing (Vogel et al., 2012).

Respiratory Care

The child with a high-level cervical injury (C3 and above) requires continuous ventilatory assistance. In most instances a tracheostomy is the method of choice for greater ease in clearing secretions and for less trauma to tissues during long-term ventilatory dependence. Patient-triggered synchronous intermittent mandatory ventilation (SIMV–assist/control mode) may be required to maintain adequate oxygenation. In an acute care center, respiratory therapy personnel are often responsible for establishing and maintaining the equipment, but the nurse must understand how it works and recognize mechanical malfunction and deviations from the prescribed rate and volume. In case of malfunction, the nurse must be prepared to maintain respirations manually with a self-inflating bag-valve-mask device. In many home care situations the family is responsible for the care of ventilatory assistance devices; therefore adequate family training and availability of the nurse (or durable medical equipment representative) for questions related to the equipment and evaluation of the child's breathing are essential. For some children, breathing pacemaker devices (phrenic nerve stimulators) are implanted to stimulate the phrenic nerve and produce diaphragmatic contractions and lung expansion without assisted ventilation.

Children with lesions below the C4 level are seldom ventilator dependent, but pulmonary vital capacity is significantly reduced. Position them for optimum chest expansion, and use a variety of breathing exercises and assistive devices to stimulate deep breathing. Chest physiotherapy is performed as needed to mobilize secretions, and flow-by oxygen may be needed occasionally. Regular monitoring of breath sounds to assess for adequate ventilation in all lung fields is part of routine care.

The cough reflex may be markedly diminished, which, combined with weak intercostal muscles, may mean that the child has difficulty with secretions. Increasing the elastic qualities of the lung by breathing exercises, mechanical cough assist techniques, and incentive spirometry helps the child achieve a productive cough. (See the discussion of airway management and airway clearance devices under Duchenne Muscular Dystrophy: Therapeutic Management later in the chapter.)

Cardiovascular Care

Children with SCI may experience cardiovascular instability as a result of loss of vagal tone, vagal stimulation during procedures such as oral suctioning or insertion of a nasogastric tube, turning, and endotracheal suctioning. Close monitoring of heart rate and blood pressure is essential to detect any signs of decreased cardiac output. Pneumothorax may occur, resulting in a mediastinal shift and decreased cardiac output. Autonomic dysreflexia may occur and result in decreased cardiac output (see discussion later in the chapter).

The child with loss of muscle tone and prolonged immobility may be at high risk for the development of DVT. In addition, major reparative surgery for associated injuries and spinal decompression place the child at risk for thrombus formation. DVT is prevented with the use of pneumatic compression devices and low-molecular-weight heparin during the acute phase of care. Fluid and electrolyte balance may be impaired as a result of trauma and associated injuries or decreased fluid intake during the recovery period. Fluid intake should be closely monitored, especially with regard to the development of pulmonary edema and intracranial pressure. The child may require nasogastric tube feedings due to anorexia and immobility.

Temperature Regulation

Temperature is often poorly regulated in children with SCI; therefore body temperature must be monitored closely for fluctuations. In small children hypothermia may occur relative to large body surface and inability to mount an appropriate metabolic response to the initial injury, so close attention should be given to preserving body temperature. Response to environmental temperature changes may be slow or absent, and the ability to dissipate heat through the process of shivering may be compromised.

During the spinal shock stage, the dilated capillaries conducting body heat to the subcutaneous tissues cause heat loss. Without the capacity to sweat, the body retains heat in hot weather. An elevated temperature that cannot be corrected by environmental measures should be evaluated to rule out urinary or upper respiratory tract infection. However, excessive perspiration observed in sentient areas usually indicates an elevated ambient temperature.

Skin Care

Children with SCI have unique needs in relation to skin care. Because of decreased sensation and impaired mobility, they depend on others to assess and assist in the management of intact skin. Skin care practices are the same as those for any child who is immobilized. A skin score scale such as the Braden Q Scale can objectively evaluate risks for skin breakdown and skin conditions (Noonan, Quigley, & Curley, 2011). Keep an alternating-pressure mattress or other pressure relief or reduction device underneath the child, and inspect the skin thoroughly at least twice a day for signs of pressure, especially over bony prominences. Prevention of skin breakdown is much easier than treatment. A number of factors contribute to the risk of skin breakdown in these children: decreased sensation, inadequate nutrition, muscle spasticity, impaired peripheral circulation, diaphoresis, mechanical shearing from assistive devices, and improper positioning (see Chapter 20, Maintaining Healthy Skin).

The areas most likely to be affected are the sacrum, scapulae, heels, and occiput when the child is supine; the trochanters and the lateral aspect of the ankles, heels, and knees when the child is in a side-lying position; and the ischial tuberosities when the child is sitting. The pressure wound may begin in deeper tissues and be visible on the surface only at a later stage. Therefore areas that feel firm, irregular, or warm or that appear to be only slightly reddened require careful evaluation. Keeping the skin clean and dry is particularly important in these children, especially those who are incontinent of urine or stool or those who have significant diaphoresis. When there is any evidence of skin breakdown, treatment to prevent further breakdown is implemented promptly. When orthotic devices such as AFOs and braces are used, skin care and vigilance for pressure areas are also important in the prevention of pressure ulcers. Prolonged use of wheelchairs without special sacral protection may also lead to skin ulceration.

The child who is heavily sedated or who is being given muscle paralytics should receive appropriate eye care to prevent corneal damage (e.g., artificial tears, ointment, impermeable eye shield). Additional nursing care may involve the administration of histamine blockers and proton pump inhibitors to prevent stress ulcers by reducing the secretion of hydrochloric acid.

Physical Therapy

An important consideration for the child with SCI is achievement of mobility and ambulation. A developmental approach should be considered in the rehabilitation phase (Calhoun et al., 2013). Range-of-motion, passive, and active exercises are carried out under the guidance of a physical therapist.

Unless there are contraindications, exercises during the period of immobilization are aimed at maintaining and increasing the strength of the child's intact musculature. Upper extremity strengthening is especially important to the paraplegic child, who must rely on these muscle groups for turning, transferring, dressing, parallel bar walking, gait training, and other activities. Children are usually eager to use their muscles and respond to interesting and innovative activities.

Neurogenic Bladder

When the bladder is denervated, as in the acute stage of spinal shock syndrome or after lower motor neuron damage, the bladder wall is flaccid. Lack of muscle tone inhibits the bladder's ability to respond to changes in passive pressure, causing overdistention. Therefore it is important to prevent distention by periodic emptying, even though there may be dribbling between emptying.

In contrast, an upper motor neuron lesion causes increased bladder tone and contractions that often include the urinary sphincter. Thus although the bladder empties periodically by reflex action, complete emptying is prevented, resulting in urinary retention and ureteral reflux. Administration of an anticholinergic drug such as dicyclomine (Bentyl) relaxes bladder musculature and promotes increased bladder capacity and more adequate emptying. Intervals of urination depend on many factors, including patterns of fluid intake and perspiration.

In school-age children and adolescents, achieving bladder and bowel continence is a significant developmental issue related to self-esteem and perception of self in relation to peers. Therefore it is imperative to consider options that best meet the child's physiologic and emotional needs.

Surgical options for children with neurogenic bladder include the creation of a urinary stoma, made possible by removing the appendix and creating a urinary diversion from the bladder to the exterior, usually the umbilicus, thus making self-catheterization more private, especially with the recovery of hand and elbow movement (with tendon transfers). Other options include surgical bladder augmentation to increase capacity and FES to restore micturition on command without a urinary catheter (Merenda & Hickey, 2005). There are promising recent research efforts to augment the bladder using tissue engineering technology (Osorio, Reyes, & Massagli, 2014).

Emptying the bladder by CIC is also an option for children with SCI; older children who are functionally capable can learn to perform self-catheterization. Encourage the child to adhere to a schedule for CIC and to maintain a regular pattern of fluid intake throughout the day; they should avoid large intakes of fluid without considering the need for more frequent CIC. Caffeinated beverages and other caffeinated foods are used sparingly to avoid bladder overdistention with increased urine formation (Francis, 2007). Latex catheters should be avoided to prevent the development of latex allergy (if it is not already present). Bladder-training programs usually begin with intermittent bladder emptying at regular intervals that are gradually increased. The Credé method (applying suprapubic pressure) for emptying the bladder may be used by some individuals with SCI, but this may result in high intravesical pressures, causing further bladder complications (Francis, 2007).

Urinary tract infections are common due to urinary stasis. A regular schedule of CIC may help prevent such infections. Encourage the child to increase fluid intake by approximately 240 ml/day and use CIC every 3 to 4 hours.

Maintenance of bladder dynamics and control of UTIs are of utmost importance. Pyelonephritis and renal failure are the most significant causes of death in long-standing paraplegia.

Bowel Training

The loss of bowel function is considered to be one of the most stressful events when quality-of-life issues are considered in persons with SCI; however, successful bowel training is easier to institute than bladder management. The aim is to control defecation until an appropriate time and place are found. Merenda and Hickey (2005) propose four components in a successful bowel management program: desired stool consistency (i.e., a soft stool), a regular evacuation pattern, upright positioning for planned evacuation, and motivation and commitment from the child and family.

A diet with sufficient fiber (age in years plus 5 g is recommended) for adequate stool bulk and insertion of a glycerin or bisacodyl (Dulcolax) suppository at a convenient time, either morning or evening, are often all that is necessary to induce a bowel movement within a short time. The probability of an accident between times diminishes once the bowel is completely evacuated. The key to adequate bowel training is to maintain consistency in the time of day for evacuation. Stool softeners, such as docusate sodium (Colace) and senna (Senokot), may be prescribed, and manual anal stimulation may help initiate evacuation, especially in spastic paraplegia. Sometimes an oral laxative such as bisacodyl may be necessary. Once an appropriate regimen is established, little modification is required.

One surgical option is the antegrade continence enema, which involves the creation of a stoma whereby colonic washouts may be performed with the child sitting on the toilet. FES has also been used successfully in some children with SCI to achieve bowel training.

Autonomic Dysreflexia

Children with high-level lesions are susceptible to the development of autonomic dysreflexia, which requires prompt action to prevent encephalopathy and shock. Clinical manifestations of autonomic dysreflexia include an increase in systemic blood pressure, headache, bradycardia, profuse diaphoresis, cardiac arrhythmias, flushing, piloerection, blurred vision, nasal congestion, anxiety, spots on the visual field, or absent or minimum symptoms. A quick assessment may rule out other causes, such as orthostatic intolerance. After that, vital signs, including blood pressure, are taken while the bladder is checked for distention (the usual precipitating cause). The bladder is drained slowly; if this does not relieve symptoms, any tight clothing is loosened, and the bowel is checked for the presence of impacted feces.

Other potential causes of autonomic dysreflexia in children with an SCI include bowel impaction and abdominal distention, pressure ulcers, tight clothing, burns, DVT, menses, trauma, fractures, pregnancy, labor, surgery or invasive procedures, any painful stimulus, and hyperthermia (Vogel et al., 2012). If removal of the causative agent is unsuccessful in controlling the syndrome, IV administration of an antihypertensive drug is indicated, followed by oral maintenance doses. Antispasmodics may also be administered.

Remobilization

As soon as the condition warrants, the child is moved from a reclining to an upright position. Cardiovascular deconditioning and impaired autonomic responses below the level of injury will cause pooling of blood in the extremities (because of peripheral vasodilation); a drop in blood pressure; and a feeling of lightheadedness, dizziness, or fainting on sudden assumption of an upright posture, often referred to as **orthostatic intolerance**. Therefore an upright position must be accomplished gradually by first placing the child (who is secured by passive restraint) on a head-up tilt table. The table is slowly elevated from a horizontal to a 30-degree semireclining position. This is performed twice daily for 20 to 30 minutes, with the angle gradually increased until the vertical angle is reached.

During the procedure the vital signs are monitored, and the child's behavior is observed for subjective symptoms of syncope. The pooling of blood is reduced by using elastic antiembolism stockings and sequential pneumatic compression devices, which consist of inflatable sleeves that fit on the legs and compress the leg muscles for cyclic emptying and filling of leg veins. The process of achieving an upright posture may require several weeks. After tolerance is achieved, the child will be ready to begin using a wheelchair. Getting the child up should be accomplished slowly by gradually elevating the bed over 20 to 30 minutes before placing the child in the wheelchair and then gradually lowering the legs after the child has been in the chair for a short time.

All adaptive devices help children increase their mobility, function, and endurance. The child with some lower extremity function progresses to parallel bars and then to a walker. The child with tetraplegia learns to use a wheelchair—among the most valuable aids available to the child with an SCI. The wheelchair should be selected carefully in relation to where it will be used, the architectural barriers, and the child's functional capacity. For children with severe upper extremity paralysis, a variety of motorized wheelchairs are used; however, the more complex they are, the greater their cost, weight, and tendency to break down. Wheelchair tolerance is gained over time and is accompanied by measures to prevent orthostatic hypotension and pressure sores.

A variety of orthoses and other appliances can be adapted for use by many children. The primary purpose of lower extremity bracing in the child with an SCI is for ambulation, although correction of deformities may be attempted. However, the efficacy is limited because of the tendency to develop pressure lesions over insensate areas. The higher the lesion, the more support is required, with the accompanying difficulties of getting into the orthosis and the greater energy expended in using the appliance. The energy required in walking with crutches and braces is two to four times greater than that required for normal walking.

Children, with their natural and overwhelming desire for mobility, usually attain or even surpass the maximum expectation in ambulation. However, as they approach adulthood, the increasing weight and energy cost usually cause them to resort to predominant use of the wheelchair for mobility and the pursuit of more intellectual and vocational interests. Wheelchair mobility has the advantages of requiring no more energy than normal walking and allowing the person with paraplegia to maintain the speed of other pedestrians on level ground.

Physical Rehabilitation

The process of physical rehabilitation usually begins once the child is medically stable and associated problems have been managed. The major aims of physical rehabilitation are to prepare the child and family to achieve normalization and resume life at home and in the community. Additional goals of rehabilitation in children with SCI are to promote independence in mobility and self-care skills, academic achievement, independent living, and employment.

Members of the multidisciplinary rehabilitation team cooperate with one another and the family to identify the child's needs and to plan realistic interventions. Integration of activities is coordinated by one team member, most often a specialist in physical medicine and rehabilitation. Members of the team attempt to achieve their collaborative goals through mutual trust, good communication, professional respect, and sincere interest in the child and family. Training in the rehabilitation center promotes maximum achievement commensurate with each child's physical capacities. Instruction for home routine is stressed and includes all precautions and management implemented in the acute care center (e.g., skin care, nutrition, bladder and bowel training, gait training) and an exercise program.

Inpatient physical rehabilitation of children with tetraplegia takes approximately 2 to 4 months; children with paraplegia can achieve these goals in 1 to 3 months but require constant vigilance to avoid complications. Emotional adjustments take longer, especially in older children and adolescents. In most children the outlook is favorable unless the life-threatening consequences of urinary pathologic condition are severe or the emotional adjustment is poor.

Psychosocial Rehabilitation

Early-acquired or congenital disability is usually more readily accepted by children than paralysis that appears later in childhood. Rehabilitation efforts should include not only the child's emotional responses but also those of the persons closest to the child. Intensive education is important so that family members understand the nature of the disability, the therapeutic regimen, and complications and are able to provide the physical and emotional support the child needs.

As with any disability, treat children as normally as possible and encourage them in developmental tasks at the age at which they would typically be expected to acquire abilities and perform activities. However, the goals must be realistic, and children should not be forced beyond their capabilities. Vogel and colleagues (2012) emphasize the need for children and adolescents with SCI to assume responsibility for their own care. When this is not physically possible, they should direct others in their care. Encouraging self-care is important in the emotional and physical rehabilitation of the child or adolescent with SCI.

Severe depression can be emotionally and intellectually immobilizing, but it indicates that the child is no longer hiding behind denial. In rehabilitation it is desirable for the child to begin to express negative feelings toward the situation because these feelings, redirected by efforts of the rehabilitation team, are the ones that will motivate the child toward learning a new way of life. Anxiety and depression in young children and adolescents with SCI are associated with a poorer quality of life (Osorio et al., 2014).

The needs of young children and adolescents who are permanently disabled must be reevaluated periodically by the total rehabilitation team, including the children and their families. Vocational rehabilitation is important for helping these adolescents find meaningful work activities and enroll in formal educational programs as desired.

The outlook for children and adolescents with SCI is increasingly favorable for integration into society. Increased awareness of the needs of persons with disabilities has removed many structural and occupational barriers. The success of a rehabilitation program is judged not by how well children and adolescents manage within the rehabilitation setting but by how well they function on the outside. In addition to agencies that offer assistance to children with disabilities in general, some agencies provide specific assistance to paralyzed persons, including children.

Sexuality

Issues related to loss of sexual function also apply to adolescents with debilitating neuromuscular diseases such as Duchenne muscular dystrophy (DMD) and SMA. The problems of self-image are particularly significant when children with SCI reach puberty, especially if the disability was acquired during early adolescence. Sexual development and awareness and changing perceptions of body image are prominent aspects of adolescence; a loss that affects these areas is often devastating. Development of secondary sexual characteristics does not seem to be altered by SCIs, and it is now believed that with comprehensive rehabilitation, motivated young people can look forward to successful participation in marital and family activities.

In females, if the injury occurs after the onset of menstruation, there is usually a temporary cessation and irregularity in menstrual flow, but menstruation resumes in the majority of cases. Ovulation and conception are possible, but only about 50% of females experience vaginal or clitoral orgasms, although they can learn to use other erogenous zones for a sexual experience. This is important to emphasize in sex education because many females have the misconception that they are unable to conceive because they lack sensation. FES may help some women with SCI to achieve orgasm. Education is important because the pregnant paraplegic or tetraplegic patient may be unaware that she is in labor, and those with a high-level injury are subject to autonomic dysreflexia during labor.

More attention has been focused on rehabilitating male sexual function (erection and ejaculation) than female sexual function until the last 2 decades. A number of pharmacologic (prostaglandin E_1) and mechanical devices (e.g., penile implants, vacuum pump devices) now make it possible for males to participate in sexual intercourse and produce offspring, provided that fertility has not been affected by associated complications. Penile injections with vasoactive substances (prostaglandin E_1) are reported to be effective in 90% of men (DeForge, Blackmer, Garritty, et al., 2006). However, sildenafil (Viagra) is now considered the treatment of choice for the sexually active male. Adolescents with SCI should be counseled regarding condom use and the symptoms of latex allergy.

As soon as adolescent males become aware of their functional loss, they will be concerned about sexual capacities, regardless of the type of sexual activities experienced before the SCI. The health care professional should take the initiative in discussing sexuality with adolescents and their families. Parents of younger children may want to know about their children's sexual and reproductive potential. As their interest and understanding increase, adolescents need to know the specifics of physiology, the prognosis, and sexual techniques related to their particular problems. The practitioner should provide them with information about what can be expected regarding erection, ejaculation, and other sexual experiences.

A knowledgeable rehabilitation team is valuable to adolescents as they experience concerns regarding loss as a sexual being. This is especially true in paraplegia or tetraplegia. Most sexual counseling for adolescents with SCI focuses on developing the idea that sex means different things to different people. Most rehabilitation teams have an active counseling program to help adolescents learn intimacy and how to function sexually within their limitations. Through individual and group counseling they gain new attitudes concerning sexuality and experiences exclusive or inclusive of intercourse. Guidelines for sexual and reproductive health care of persons with SCI are published elsewhere (Consortium for Spinal Cord Medicine, 2010).

Transition to Adulthood

With the ultimate goal of making an effective transition to adulthood, adolescents with SCI often face challenges similar to others with chronic and debilitating conditions. Issues such as housing, education, personal assistance care, transportation, medical care, and specialized medical care must be addressed in a coordinated transition program (Vogel et al., 2012). The concepts of care coordination for children and adolescents requiring home care also apply to adolescents making the transition to adulthood because different health care services may be needed or requirements may change for benefits for those no longer dependent on parents.

MUSCULAR DYSFUNCTION

JUVENILE DERMATOMYOSITIS

Juvenile dermatomyositis (JDM) is a relatively rare systemic autoimmune vasculopathy that often occurs after a triggering event such as infection with group A beta-hemolytic streptococci, enterovirus (coxsackievirus B), or parvovirus B19. An environmental trigger such as excessive sun exposure has also been proposed in some children. In children, one of the human leukocyte antigens (DQA1*0501, B8, DRB*0301, or DQA1*0301) is present on chromosome 6 and may be associated with increased susceptibility to the disease (Feldman, Rider, Reed, et al., 2008; Robinson & Reed, 2020). White girls are twice as likely to be affected as boys. The peak age at onset is between 4 and 10 years of age. Children with onset before age 7 years may experience milder symptoms.

The diagnosis is often established through the following clinical presentations: bilateral symmetric proximal weakness; a characteristic heliotropic rash of the eyelids; Gottron papules on the knuckles, knees, and elbows; Gottron sign; elevated serum enzymes (aldolase, creatine kinase, aspartase aminotransferase, and lactate dehydrogenase); altered EMG; and abnormal muscle biopsy. An atraumatic alternative to muscle biopsy is an MRI. Nailfold capillaroscopy shows decreased capillary density and presence of disease activity and may be used to diagnose the condition (Wakiguchi, 2019).

For approximately half of affected children, the disease is acute and progresses rapidly. Children younger than 6 years of age often are seen initially with fever and signs of an upper respiratory tract illness. There is proximal limb and trunk muscle weakness and loss of reflexes. Consequently, the child may not be able to rise from the floor to a standing position without walking the hands up the legs (Gower sign). The disease often affects the neck muscles, and the child may have difficulty lifting the head or supporting it in an upright position. Muscles tend to be stiff and sore. A generalized vasculitis of small arteries and capillaries is one prominent feature of the disease. Masseter involvement with atrophy may occur, which makes it difficult to chew food during the active stage of the disease. Soft palate dysfunction may make speech difficult and interfere with breathing. Distal muscle strength and reflex responses remain unaffected. JDM is characterized by a red erythematous rash over the malar areas and nose and a violet discoloration of the eyelids. The skin over extensor muscle surfaces may be erythematous, scaly, and atopic. Calcium deposits (calcinosis) develop in muscle tissues as the disease progresses. Dystrophic calcifications may develop over areas exposed to pressure, including the elbows, knees, digits, and buttocks. These lesions may result in skin ulceration with subsequent infection, pain, and functional disability from joint contractures. The vasculitis may cause GI, renal, cardiac, and ophthalmologic symptoms as the disease progresses. A common problem in JDM is aspiration pneumonia, and measures should be taken to ensure that the child has an adequate airway at all times. Additional pulmonary involvement includes interstitial lung disease, so pulmonary function testing should be part of the medical management. There is evidence that adults with pediatric-onset JDM may develop cardiac problems such as heart failure. If the child has difficulty feeding, a gastrostomy may be used to supplement caloric intake until the drug regimen controls the symptoms.

JDM responds to high-dose oral corticosteroid therapy and methotrexate; in some children high-dose intermittent IV methylprednisone may be required. All children with JDM should use a sunscreen to protect against ultraviolet A and B rays. Vitamin D and adequate dietary intake of calcium are also recommended to increase and maintain bone density and minimize osteopenia (Feldman et al., 2008; Huber, 2012). IVIG has been effective in some children who were intolerant of high-dose corticosteroids. Other treatments that have been effective in adult myositis and in isolated cases of JDM include hydroxychloroquine, systemic tacrolimus, etanercept or infliximab, rituximab, and cyclosporin (Wakiguchi, 2019).

Physical therapy is essential to prevent contracture deformity and to rebuild muscle strength. Meticulous skin care is an important nursing consideration in the care of these patients.

Although the prognosis for survival has steadily improved, JDM remains a serious chronic illness. Death can occur in the acute phase as a result of myocarditis, progressive unresponsive myositis, perforation of the bowel, or, occasionally, lung involvement. The current mortality rate is approximately 1% (Robinson & Reed, 2020).

MUSCULAR DYSTROPHIES

The muscular dystrophies (MDs) constitute the largest and most important single group of muscle diseases of childhood. They have a genetic origin in which there is gradual, progressive degeneration of muscle fibers, and they are characterized by progressive weakness and wasting of symmetric groups of skeletal muscles, with increasing disability and deformity. In all forms of MD there is insidious loss of strength, but each differs in regard to the muscle groups affected, age of onset, rate of progression, and inheritance patterns (Fig. 30.7).

Treatment of the MDs consists mainly of providing supportive measures (including physical therapy; orthopedic procedures to minimize deformity; and ventilatory support, including airway clearance techniques) and assisting the affected child in meeting the demands of daily living.

Facioscapulohumeral (Landouzy-Dejerine) muscular dystrophy is inherited as an autosomal dominant disorder with onset in early adolescence. It is characterized by difficulty in raising the arms over the head, lack of facial mobility, and a forward slope of the shoulders. The progression is slow, and the life span is usually unaffected.

Limb-girdle muscular dystrophy (LGMD) is a heterogenous group of disorders with autosomal dominant and recessive inheritance whose clinical manifestations often appear in later childhood, adolescence, or early adulthood with variable but usually slow progression (Quan, 2011). All types of LGMD are characterized by weakness of proximal muscles of the pelvic and shoulder girdles. Other forms of MD include myotonic dystrophy, scapulohumeral MD (Emery-Dreifuss MD), fascioscapulohumeral MD (Landouzy-Dejerine disease), and congenital MD; these forms consist of subtypes of MD and are discussed at length elsewhere (Bharucha-Goebel, 2020). Duchenne muscular dystrophy is discussed in the following section.

DUCHENNE MUSCULAR DYSTROPHY

DMD is the most severe and most common MD of childhood. It is inherited as an X-linked recessive trait, and the single-gene defect is located on the short arm of the X chromosome. DMD has a high mutation rate, with a negative family history in approximately 65% to 75% of all cases; therefore genetic counseling is an important aspect of the care of the family. Approximately 30% of DMD patients are new mutations and the mother is not the carrier (Bharucha-Goebel, 2020).

As in all X-linked disorders, males are affected almost exclusively. The female carrier may have an elevated serum creatine kinase, but muscle weakness is usually not a problem; however, about 10% of female carriers develop cardiomyopathy (Manzur, Kinali, & Muntoni, 2008). In rare instances a female may be identified with DMD disease yet with muscular weakness that is milder than in boys

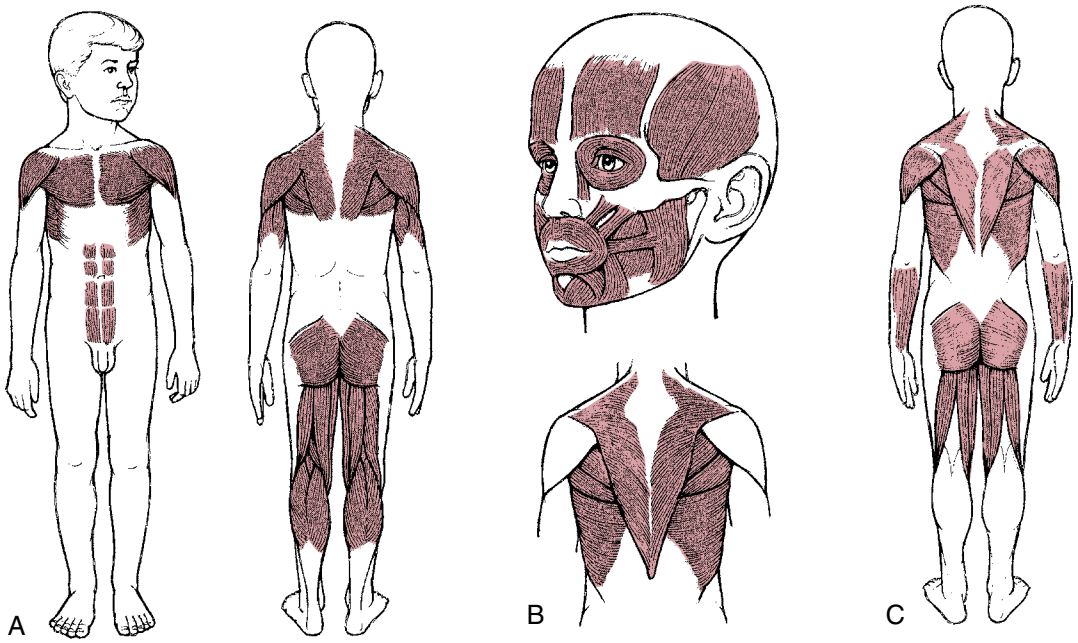

Fig. 30.7 Initial muscle groups involved in muscular dystrophies. **A,** Pseudohypertrophic (Duchenne). **B,** Facioscapulohumeral. **C,** Limb-girdle.

(Bharucha-Goebel, 2020). The incidence is approximately 1 in 3600 male births for the Duchenne form and approximately 1 in 30,000 live births for the Becker type, a milder variant (Bharucha-Goebel, 2020). Box 30.7 describes the characteristics of DMD.

At the genetic level, both DMD and Becker MD result from mutations of the gene that encodes dystrophin, a protein product in skeletal muscle. Dystrophin is absent from the muscle of children with DMD and is reduced or abnormal in children with Becker MD. The absence of dystrophin leads to a number of problems in muscle, including muscle fiber degeneration. A deficiency of dystrophin isoforms in brain tissue causes cognitive and intellectual impairment. Children with Becker MD have a later onset of symptoms, which are usually not as severe as those seen in DMD. There is a strong correlation between the clinical severity of these disorders and the type of genetic mutation and dystrophin protein alterations. Survival has increased with newer ventilation technologies, and median age is reported as high as 27 years in those being ventilated; types of ventilation used were not described in the report (Rall & Grimm, 2012).

Clinical Manifestations

Most children with DMD reach the appropriate developmental milestones early in life, although they may have mild, subtle delays. Evidence of muscle weakness usually appears during the third to seventh year, although there may have been a history of delay in motor development, particularly walking. Difficulties in running, riding a bicycle, and climbing stairs are usually the first symptoms noted. Later, abnormal gait on a level surface becomes apparent. In the early years, rapid developmental gains may mask the progression of the disease. Questioning the parents may reveal that the child has difficulty in rising from a sitting or supine position. Occasionally the parents notice enlarged calves.

Typically, affected boys have a waddling gait and lordosis, fall frequently, and develop a characteristic manner of rising from a squatting or sitting position on the floor (Gower sign) (Fig. 30.8). Lordosis occurs as a result of weakened pelvic muscles, and the waddling gait is a result of weakness in the gluteus medius and maximus muscles (Battista, 2010). Muscles, especially in the calves, thighs, and upper arms, become enlarged from fatty infiltration and feel unusually firm or woody on palpation. The term *pseudohypertrophy* is derived from this muscular enlargement. Profound muscular atrophy occurs in the later stages; contractures and deformities involving large and small joints are common complications as the disease progresses. Ambulation usually becomes impossible by 12 years of age. The loss of mobilization further increases the spectrum of complications, which may include osteoporosis, fractures, constipation, skin breakdown, and psychosocial and behavioral problems. Atrophy of facial, oropharyngeal, and respiratory muscles does not occur until the advanced stage of the disease. Ultimately the disease process involves the diaphragm and auxiliary muscles of respiration, and cardiomegaly is common.

Mild to moderate mental impairment is commonly associated with MD. The mean intelligence quotient (IQ) is approximately 20 points below normal, and frank mental deficit is present in 20% to 30% of these children. Verbal IQ is markedly low in males with DMD, and emotional disturbance is more common than in other children with disabilities; however, children with DMD should be involved in early learning programs and eventually moved into regular classrooms as much as possible.

BOX 30.7 Characteristics of Duchenne Muscular Dystrophy

- Early onset, usually between 3 and 5 years of age
- Progressive muscular weakness, wasting, and contractures
- Calf muscle hypertrophy in most patients
- Loss of independent ambulation by 9 to 12 years of age
- Slowly progressive generalized weakness during adolescence
- Relentless progression until death from respiratory or cardiac failure

Complications

The major complications of MD include contractures, scoliosis, disuse atrophy, infections, obesity, and respiratory and cardiopulmonary problems. Contracture deformities of the hips, knees, and ankles occur from early selective muscle involvement and often exaggerate

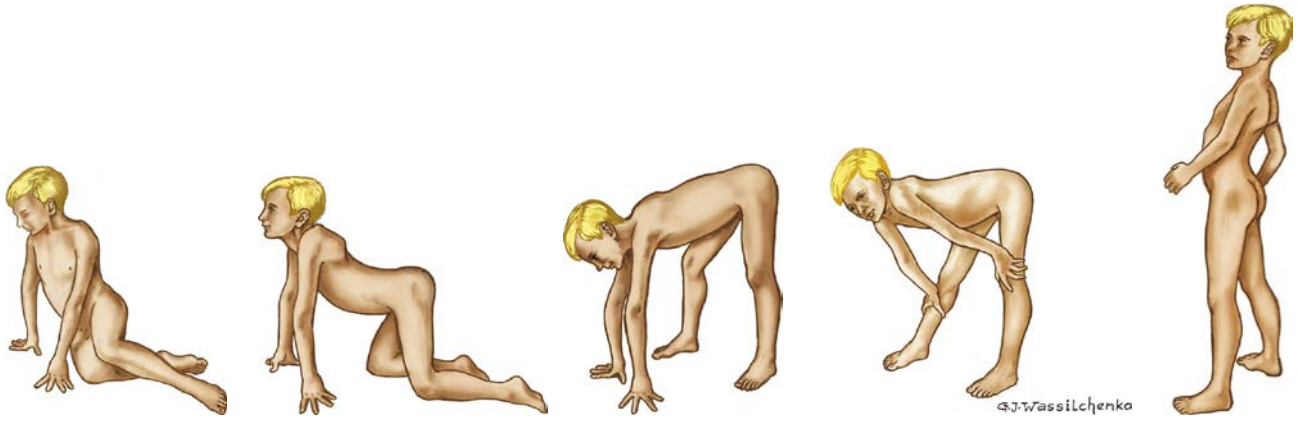

Fig. 30.8 Child with Duchenne muscular dystrophy attains standing posture by kneeling, then gradually pushing his torso upright (with knees straight) by "walking" his hands up his legs (Gower sign). Note marked lordosis in upright position.

the weakness. Passive range-of-motion exercises, stretching, and active exercises under the supervision of a PT are effective in treating reducible contractures. Nonreducible contractures require wedge casting or surgical reduction. Scoliosis caused by muscle imbalance is common in children who lose ambulatory capability and tends to progress even when the child becomes dependent on a wheelchair. Bracing with an orthosis may be required, but in many cases spinal fusion surgery is performed to prevent complications associated with cardiac and pulmonary restriction.

Atrophy of disuse from prolonged inactivity occurs readily when children are immobilized or confined to bed with illness, injury, or surgery. To minimize this complication, physical therapy should begin if bed rest extends beyond a few days. To maintain muscle strength, a daily goal for well children with moderate disability should be at least 3 hours of ambulation.

Pulmonary infections become increasingly frequent as the dystrophic process produces a progressive decrease in pulmonary vital capacity as a result of weakness of the primary, secondary, and associated muscles of respiration. Consequently, even minor upper respiratory tract infections may become serious in these children. The eventual cause of death is usually respiratory tract infection or cardiac failure; however, much progress has been made in providing ventilatory methods to prolong and maintain quality of life. Prompt and vigorous antibiotic therapy, supplemented by postural drainage and aggressive airway clearance methods, is effective. Because of the respiratory musculature weakness, these children are unable to cough effectively and secretions collect easily.

Obesity is a common complication that contributes to premature loss of ambulation. Children who have restricted opportunities for physical activity and who suffer from boredom easily consume calories in excess of their needs. This may be compounded by overfeeding by well-meaning family and friends. Proper dietary intake and a diversified recreational program help reduce the likelihood of obesity and enable children to maintain ambulation and functional independence for a longer time.

Cardiac manifestations are usually late events but may occur in ambulatory children. The most significant of these, cardiac failure, is difficult to correct in advanced cases, but treatment with digoxin and diuretics is often beneficial in the early stages of the disease.

Diagnostic Evaluation

DMD is suspected on the basis of clinical manifestations (see Box 30.7) and confirmed by molecular genetic detection of deficient dystrophin by DNA analysis from peripheral blood or in muscle tissue obtained by biopsy. The diagnosis of DMD is primarily established by blood polymerase chain reaction (PCR) for the dystrophin gene mutation (Bharucha-Goebel, 2020). Diagnostic techniques such as multiplex PCR have made it possible to diagnose 98% of the DMD mutations. Prenatal diagnosis is also possible as early as 12 weeks of gestation. However, ethical questions exist regarding diagnosing a condition in the fetus when no treatment exists.

Serum enzyme measurement, muscle biopsy, and EMG may also be used in establishing the diagnosis. Serum creatine kinase levels are extremely high in the first 2 years of life, before the onset of clinical weakness. If the child demonstrates the usual characteristics and has a positive family history for DMD and if the PCR is positive, the muscle biopsy may be deferred.

Muscle biopsy reveals degeneration of muscle fibers, with fibrosis and fatty tissue replacement. EMG readings show a decrease in amplitude and duration of motor unit potentials.

Therapeutic Management

Currently no curative treatment exists for childhood MD. Increased muscle bulk and muscle power have been reported after a course of corticosteroids. Several clinical trials demonstrated increased muscle strength and improved performance and pulmonary function, with significant decrease in the progression of weakness, when prednisone was administered for 6 months to 2 years (Manzur, Kuntzer, Pike, et al., 2008). Corticosteroid administration also prolonged ambulation, preserved respiratory function, and decreased the incidence of scoliosis and cardiomyopathy (Manzur, Kinali, & Muntoni, 2008). Major side effects in these studies included weight gain and a cushingoid facial appearance. The American Academy of Neurology has published a practice parameter for the administration of corticosteroids in the treatment of DMD (Moxley, Ashwal, Pandya, et al., 2005).

Maintaining optimum function in all muscles for as long as possible is the primary goal; secondary is the prevention of contractures. In general, children who remain as active as possible are able to avoid wheelchair confinement for a longer time. Maintenance of function often includes stretching exercises, strength and muscle training, breathing exercises and use of incentive spirometry to increase and maintain vital lung capacity, airway clearance, range-of-motion exercises, surgery to release contracture deformities, bracing, and performance of ADLs. Knee-ankle-foot orthoses have been shown to prolong ambulation for 18 to 24 months beyond the termination of independent ambulation. Serial casting of ankles has proven more effective than surgical release

of Achilles tendons in many children with DMD to prevent contractures (Manzur, Kinali, & Muntoni, 2008).

Parents should always be involved in making decisions about the child's care, and teaching on home safety and prevention of falls is important as well. Also encourage parents to have the child keep follow-up appointments for medical care and physical and occupational therapy. Because respiratory tract infections are most troublesome in these children, encourage regular influenza and pneumococcal vaccines and avoidance of contact with persons with respiratory tract infections as much as possible. Baseline pulmonary function testing, electrocardiograms, and echocardiograms are also recommended.

Eventually, respiratory and cardiac problems become the central focus of the debilitating illness. Referral to palliative care may help the family evaluate the benefits and burdens of various treatments. The child and parents should be involved in discussion of long-term ventilation options. Cardiac and respiratory assessment during wake-sleep cycles is imperative. Children with neuromuscular disease eventually develop abnormal breathing patterns, particularly during REM sleep, and hypoxia occurs as a result of inadequate oxygenation. The sleep-disordered breathing of DMD results in symptoms such as frequent night awakenings, morning headache, and daytime sleepiness. Polysomnography should be performed once daytime symptoms of sleep-disordered breathing occur. Noninvasive positive-pressure ventilation should be considered in such children to prevent further hypoventilation and cardiorespiratory deterioration (Culebras, 2008). Respiratory care for children with neuromuscular conditions such as SMA and DMD may involve the use of noninvasive ventilation with BiPAP on a temporary or full-time basis, mechanically assisted coughing (MAC), or tracheostomy and relief of airway obstruction with coughing and suctioning devices; the tracheostomy, however, is associated with more complications (Simonds, 2006; Young et al., 2007). Home pulse oximetry may be used to monitor oxygenation during sleep or to aid in decision making regarding the use of MAC to clear the airways. A polysomnogram may be used to evaluate the effectiveness of supplemental oxygen and noninvasive ventilation devices.

Several devices are available for children with neuromuscular disease to assist in clearing the airway when the cough reflex is ineffective or diminished. The *mechanical in-exsufflator* (MIE) (also referred to as cough assist) has been found to be safe and effective in the daily management of respiratory function (Kravitz, 2009). The MIE delivers positive inspiratory pressures at a set rate, followed by negative pressure exsufflation coordinated with the patient's own breathing rhythm. The exsufflation is designed to mimic a cough reflex so that mucus can be cleared effectively. Airway suctioning after exsufflation is accomplished as necessary to clear the airways. In children, the MIE device may be connected directly to a tracheostomy or used with a mouthpiece or face mask. Boitano's (2009) article provides a variety of equipment options, including various masks that can be used to deliver noninvasive positive pressure.

Manual cough-assisting techniques include glossopharyngeal breathing or air stacking (frog breathing); the abdominal thrust, which is similar to the Heimlich maneuver (Kravitz, 2009); and manual hyperinflation with a self-inflating resuscitation bag (without oxygen) and a mouthpiece. Hyperinflation may be used in conjunction with abdominal thrusts to improve peak cough flows (Boitano, 2009).

The use of routine chest physiotherapy for DMD has not been adequately evaluated for its effectiveness in clearing the airway of mucus except when there is focal atelectasis and mucous plugging the airways (Kravitz, 2009).

Survival in individuals with DMD may be prolonged several years with the use of noninvasive ventilation and airway clearance devices such as cough assist as alternatives to tracheotomy and airway suctioning (Simonds, 2006). Care considerations for Duchenne muscular dystrophy, sponsored by the Centers for Disease Control and Prevention, were published in *Lancet Neurology* in 2010, and in 2018 these guidelines were updated (Birnkrant, Bushby, Bann, et al., 2018).

The American Academy of Pediatrics (2005) recommends an extensive cardiac evaluation of the child diagnosed with either DMD or Becker MD. Patients with neuromuscular conditions may not have the typical signs and symptoms of cardiac dysfunction. Therefore symptoms such as weight loss, nausea and vomiting, cough, increased fatigue on performance of ADLs, and orthopnea should be carefully evaluated to detect early signs of cardiomyopathy.

Research evaluating a number of treatments for DMD is in progress. These include clinical trials with glutamine and creatine monohydrate to preserve muscle strength; utrophin, a protein that is similar to dystrophin and that in large quantities may counteract the effects of the dystrophin deficiency (Chakkalakal, Thompson, Parks, et al., 2005; Miura & Jardin, 2006); and the enzyme CT GalNAc transferase, which blocks muscle wasting in mice. Deflazacort, a corticosteroid, was approved in 2017 by the US Food and Drug Administration for those age 5 years and older to work as an antiinflammatory and immunosuppressant. Oral albuterol administered daily for 12 weeks increased lean body mass and decreased fat mass in a group of 14 ambulatory boys with Becker MD and DMD; however, overall muscle strength improvement was not observed (Skura, Fowler, Wetzel, et al., 2008).

Guidelines for the standardization of diagnosis and therapeutic management of DMD have been published elsewhere (Bushby, Finkel, Birnkrant, et al., 2010).

Nursing Care Management

The care and management of a child with MD involve the combined efforts of a multidisciplinary health care team. Nurses can help clarify the roles of these health care professionals to family and others. The major emphasis of nursing care is to assist the child and family in coping with the progressive, incapacitating, and fatal nature of the disease; to help design a program that will afford a greater degree of independence and reduce the predictable and preventable disabilities associated with the disorder; and to help the child and family deal constructively with the limitations the disease imposes on their daily lives. Because of advances in technology, children with MD may live into early adulthood; therefore the goals of care should also involve decisions regarding quality of life, achievement of independence, and transition to adulthood.

Working closely with other team members, nurses assist the family in developing the child's self-help skills to give the child the satisfaction of being as independent as possible for as long as possible. It is tempting for parents to overprotect their affected children. Children derive pleasure and build self-esteem from performing actions that visibly please their parents. Therefore parents must be helped to develop a balance between limiting the child's activity because of muscular weakness and allowing the child to accomplish things alone. This requires continual evaluation of the child's capabilities, which are often difficult to assess. Most children with MD instinctively recognize the need to be as independent as possible and strive to do so.

Practical difficulties faced by families are the physical limitations of housing, transportation, and mobility. Housing accommodations must be made so that the wheelchair-bound child can be mobile in the home setting. Transportation in a car restraint seat adapted for the child with weakened neck and back musculature will be necessary, and eventually a wheelchair-accessible vehicle will be required. Discuss diet, nutritional needs, and nutrition modification according to the needs of the individual child and family. Nutritional needs decrease once the child becomes wheelchair bound, and dietary modifications

should be made in conjunction with a pediatric dietitian to ensure that the child is receiving an adequate amount of the necessary nutrients to maintain bone health and prevent constipation.

Parents' social activities may be restricted, and the family's activities must be continually modified to meet the needs of the affected child. When the child becomes increasingly incapacitated, the family may consider home care to provide the care needed. The nurse as case manager can assist the family in making this difficult transition. Unless the child is severely incapacitated, he or she should also be involved in the decisions regarding such care. Nurses can assist with decision making by exploring all available options and resources and supporting the child and family in the decision.

Each child's therapy program is tailored to individual needs and capabilities, and family members should be active participants. Parents often need assistance with the physical therapy program and education on a home regimen of exercises and activity. Many parents erroneously believe that by exerting sufficient effort, the child can overcome the weakness and prevent progression of the disease process. They should also be advised to notify the nurse or other designated person when the child becomes even temporarily bedridden so that the exercise program can be modified and continued during this time.

Children with MD tend to become socially isolated as their physical condition deteriorates to the point that they can no longer keep up with friends and classmates. Their physical capabilities diminish, and their dependency increases at the age at which most children are expanding their range of interests and relationships. To gain peer associations, they often learn and use behaviors that bring them the rewards of other children's company. These friends are often children who have been rejected by more able-bodied classmates.

Older boys with MD may also need psychiatric or psychologic counseling to deal with issues such as depression, anger, and quality of life. Parents need encouragement to become involved in support groups because there is evidence that adequate social support from family, community, and other parents is crucial to appropriate coping in families with children with chronic illness.

Regardless of the success of the program and how well the family adapts to the disorder, superimposed on the physical and emotional problems associated with the child's long-term disability is the constant specter of the disease's ultimate outcome. These families encounter all the manifestations of the child with a chronic and fatal illness (see Chapter 17).

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A newborn is born with a myelomeningocele and a surgical repair is planned for the next day. What actions would the nurse take to care for the myelomonocyte sac before the surgical repair? **Select all that apply.**
   - **A.** Apply a sterile, moist nonadherent dressing to the sac.
   - **B.** Take a rectal temperature every 2 hours before surgery.
   - **C.** Irrigate the sac and surrounding skin with chlorhexidine.
   - **D.** Diaper the infant while making sure it does not touch the sac.
   - **E.** Maintain the legs in abduction with a pad between the knees.
   - **F.** Position the newborn in a prone position with hips slightly flexed.
   - **G.** Place the newborn in an incubator or warmer without clothing or cover.

2. The nurse is completing an assessment on a 3-month-old male who is in the pediatrician's office because the infant had fever and diarrhea the past 2 days. The infant's history reveals he was exposed to maternal chorioamnionitis and born prematurely at 32 weeks' gestation. The nurse performs a history and assessment and finds the following. Which assessment **findings require follow-up** by the nurse**? Select all that apply.**
   - **A.** head lag
   - **B.** arms are stiff
   - **C.** does not smile
   - **D.** floppy posture
   - **E.** unable to roll over
   - **F.** feeding difficulties
   - **G.** irritable and cries often
   - **H.** unable to sit without support
   - **I.** unable to pass object between hands

3. A 5-year-old boy with spina bifida has bladder dysfunction and is unable to empty his bladder without assistance. He also struggles with bowel control and is taking dietary fiber supplements, and suppositories to assist with regular bowel movements. He was born with a myelomeningocele and had surgical repair 48 hours after birth. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.** Based on the child's diagnosis and history, the nurse understands that a _____1_____ may produce urinary system _____2_____ The nurse would teach the parents and child a method to empty the bladder such as _____3_____.

Options for 1	Options for 2	Options for 3
renal cyst	infection	foley catheter placement
kidney stone	failure	clean intermittent catheterization
neuropathic bladder	strictures	sterile intermittent catheterization
rectal fissure	distress	suprapubic aspiration

4. A 6-year-old boy is admitted with increasing symptoms of muscle weakness including difficulties running, riding his bike and climbing stairs. In the hospital he undergoes numerous lab tests, muscle biopsy and EMG. He is diagnosed with Duchene Muscular Dystrophy (DMD). The nurse plans to provide discharge teaching and answer questions the parents and patient ask. **Use an X for the health teaching statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
"DMD is inherited as an X-linked recessive trait and affects boys."			
"Your child may need to have casts on his legs to help him walk."			
"You will learn stretching exercises and strength and muscle training to help your child."			
"You should call your health care provider if any respiratory symptoms occur."			
"Your child should be hospitalized when ambulation becomes impossible."			
"It is important for your child to remain as independent as possible."			
"Breathing exercises will help maintain his vital lung capacity."

- Inflammation
- Infection

INTEGUMENTARY DYSFUNCTION

SKIN LESIONS

Lesions of the skin result from a variety of etiologic factors. Skin lesions originate from (1) contact with injurious agents, such as infective organisms, toxic chemicals, and physical trauma; (2) hereditary factors; (3) external factors, such as allergens; or (4) systemic diseases, such as varicella, lupus erythematosus, and nutritional deficiency diseases. Responses are highly individualized in children. An agent that is harmless to one individual may be damaging to another, and a single agent may produce varying degrees of responses in different individuals.

Another factor in the etiology of skin manifestations is the child's age. For example, infants and young children are subject to "birthmark" malformations and atopic dermatitis that appear early in life. The school-age child is susceptible to tinea (ringworm) of the scalp, and acne is a characteristic skin disorder of puberty. Children's typical social environments also make them susceptible to skin disorders; the most recent national survey notes that up to 20% of American children experience atopy. Exposure to smoke and children with food allergies, particularly peanut allergy, have also been associated with higher rates of atopic dermatitis and eczema. Contact dermatitis, such as poison ivy, is seen only when the noxious agent is found in the environment. Similarly, insect bites are associated with seasonal activities during the summer and fall months.

Skin of Younger Children

The major skin layers arise from different embryologic origins. Early in the embryonic period, a single layer of epithelium forms from the ectoderm while simultaneously the corium develops from the mesenchyme. In infants and small children, the epidermis is loosely bound to the dermis. This poor adherence causes the layers to separate easily during an inflammatory process to form blisters. This is especially true in preterm infants, who have a propensity to blister formation and separation of the skin with minor trauma such as the removal of adhesive tape. In contrast, the skin of older children is thinner, and the cells of all the strata are more compressed.

Pathophysiology of Dermatitis

More than half of the dermatologic problems in children are various forms of dermatitis. This implies a sequence of inflammatory changes in the skin that are grossly and microscopically similar but diverse in course and causation. Acute responses produce intercellular and intracellular edema, the formation of intradermal vesicles, and an initial infiltration of inflammatory cells into the epidermis. In the dermis, there is edema, vascular dilation, and early perivascular cellular infiltration. The location and manner of these reactions produce the lesions characteristic of each disorder. The changes are usually reversible, and the skin ordinarily recovers without blemish unless complicating factors such as ulceration from the primary irritant, scratching, and infection are introduced or underlying vascular disease develops. In chronic conditions, permanent effects are seen that vary according to the disorder, the general condition of the affected individual, and the available therapy.

Diagnostic Evaluation

Although the history and subjective symptoms of skin lesions are explored first, the obvious objective characteristics of the lesions are often noted simultaneously. Many skin lesions are diagnosed after careful inspection.

History and Symptoms

Many cutaneous lesions are associated with local symptoms. The most common local symptom is itching (**pruritus**), which varies in frequency and intensity. Pain or tenderness often accompanies some skin lesions. Other skin sensations such as burning, prickling, stinging, or crawling are also described. Alterations in local feeling include absence of sensation (**anesthesia**); excessive sensitivity (**hyperesthesia**); diminished sensation (**hypesthesia** or **hypoesthesia**); or abnormal sensation, such as burning or prickling (**paresthesia**). These symptoms may remain

localized or migrate. They may also be constant or intermittent and may be aggravated by a specific activity, such as exposure to sunlight.

It is important to determine whether the child has an allergic condition such as asthma or history of a previous skin disease. Atopic dermatitis, often associated with allergies, frequently begins in infancy. Important questions for the parent include when the lesion or symptom first appeared; whether it occurred with ingestion of a food or other substance, including any medication; and whether the condition was related to activity such as contact with plants, insects, or chemicals. Finally, inquire if other children in the home or classroom have similar symptoms and if the child's parents or siblings have a history of atopy or allergic skin conditions.

Objective Findings

The skin lesions' distribution, size, location, and morphology provide significant information. Skin lesions assume distinct characteristics that are related to the pathologic process. Nurses should become familiar with the common terms that are applied to skin lesions because these terms are used in the processes of record keeping and communication. These terms include the following:

Erythema—A reddened area caused by increased amounts of oxygenated blood in the dermal vasculature

Ecchymoses (bruises)—Localized red or purple discolorations caused by extravasation of blood into dermis and subcutaneous tissues

Petechiae—Pinpoint, tiny, and sharp circumscribed spots in the superficial layers of the epidermis

Primary lesions—Skin changes produced by a causative factor; common primary lesions in pediatric skin disorders are macules, papules, and vesicles

Secondary lesions—Changes that result from alteration in the primary lesions, such as those caused by rubbing, scratching, medication, or involution and healing

Distribution pattern—The pattern in which lesions are distributed over the body, whether local or generalized, and the specific areas associated with the lesions

Configuration and arrangement—The size, shape, and arrangement of a lesion or groups of lesions (e.g., **discrete**, **clustered**, **diffuse**, or **confluent**)

Extrinsic causes usually result from physical, chemical, or allergic irritants or from an infectious agent such as bacteria, fungi, viruses, or animal parasites. Intrinsic causes such as a specific infection (e.g., measles, chickenpox), drug sensitization, or other allergic phenomena can produce skin manifestations.

Laboratory Studies

When it is suspected that a skin problem might be related to a systemic disease, such as one of the collagen diseases or an immunodeficiency disease, studies are needed to rule out these possibilities. Diagnostic techniques include microscopic examination, cultures, skin scrapings or biopsy, cytodiagnosis, patch testing, and Wood light examination. Allergic skin testing and other laboratory tests such as blood count and sedimentation rate are used when indicated.

WOUNDS

Wounds are structural or physiologic disruptions of the skin that activate normal or abnormal tissue repair responses. Wounds are classified as acute or chronic. **Acute wounds** are those that heal uneventfully within 2 to 3 weeks. **Chronic wounds** are those that do not heal in the expected time frame or are associated with complications. Cofactors that disrupt or delay wound healing include compromised perfusion, malnutrition, and infection. In children, most wounds are acute and can be prevented from becoming chronic wounds through appropriate nursing care. Wounds are classified in the same manner as burns: superficial, partial thickness, full thickness, and complex wounds that include muscle and/or bone. Some types of acute wounds are the following:

Abrasion—Removal of the superficial layers of skin by rubbing or scraping

Avulsion—Forcible pulling out or extraction of tissue

Laceration—Torn or jagged wound; accidental cut wound

Incision—Division of the skin made with a sharp object; cut

Penetrating wound—Disruption of the skin surface that extends into underlying tissue or into a body cavity

Puncture—Wound with a relatively small opening compared with the depth

Epidermal Injuries

Abrasions are the most common epidermal wounds in children, usually in the form of a skinned knee or elbow. In most injuries, the margins of the abraded area are superficial, involving only the outer layers of epidermis, although the central portion may extend into the dermis. Initially the defect is filled by a blood clot and necrotic debris, which subsequently dehydrate to form a scab. Epithelial tissue is composed of labile cells, which are constantly destroyed and replaced throughout the life span. Injury to these tissues results in **regeneration** (i.e., rapid replacement by similar cells).

Injury to Deeper Tissues

Tissues composed of **permanent cells** such as muscle and nerve cells are unable to regenerate. These tissues repair themselves by substituting fibrous connective tissue for the injured tissue. This fibrous tissue, or **scar**, serves as a patch to preserve or restore the continuity of the tissue. Wounds involving permanent cells include surgical incisions, lacerations, ulcers, evulsions, and full-thickness burns. Injured cells of glandular organs and bones, composed of stable cells, multiply less vigorously and heal more slowly. With some wounds an overgrowth of nerve endings may occur, resulting in **allodynia**, or the sensation of pain from normally nonpainful stimuli, such as light touch.

Process of Wound Healing

The nonspecific repair mechanism of wound healing with scar formation involves the processes of inflammation, fibroplasia, scar contraction, and scar maturation. The initial response at the site of injury is **inflammation**, a vascular and cellular response that prepares the tissues for the subsequent repair process. There is a transient constriction of transected blood vessels, lasting 5 to 10 minutes, followed by active vasodilation of all local small vessels and increased blood flow to the area. This is accompanied by increased permeability of small venules, which allows plasma to leak into surrounding tissues (edema). A blood clot is formed along wound edges, providing a framework for future growth of capillaries (**angiogenesis**) and epithelial cells.

At the same time, vessel walls become lined with leukocytes, primarily neutrophils, which pass through the walls and concentrate at the injured site, where they ingest bacteria and debris (**phagocytosis**). Neutrophils are superseded by macrophages, which continue phagocytosis, and by growth factors needed for skin repair and angiogenesis. Fibroblasts attracted to the area from blood vessels deposit fibrin throughout the clot. Adjacent capillaries begin to form buds that stretch across the supporting fibrin threads, and epithelial cells secrete a fibrolytic enzyme that allows their advancement across the wound. This initial phase of wound healing takes place during the first 3 to 5 days after injury. The wound is weakest at this time.

Fibroplasia (granulation or proliferation), the second phase of healing, continues for 5 days to 4 weeks. Fibroblasts, immature connective tissue cells, migrate to the healing site and begin to secrete collagen into the meshwork spaces. Granulation tissue is highly vascular, "beefy" red, shiny connective tissue that organizes and restructures, forming thicker, stronger fibers arranged in orderly layers. A thin layer of epithelial tissue is regenerated over the surface of the wound, and leukocytes gradually disappear from the area. The wound is fragile at this time, and granulation tissue bleeds profusely if disturbed.

During contraction and maturation, the third and fourth phases of wound healing, collagen continues to be deposited and organized into layers, compressing the new blood vessels and gradually stopping blood flow across the wound. Fibroblasts disappear as the wound becomes stronger. Fibroblast movement causes contraction of the healing area, which helps bring wound edges closer together. A mature scar is then formed. Initially the scar is pink or hypopigmented and elevated. With maturation, the scar becomes pale, does not tan when exposed to sunlight, will not sweat or produce hair, and may itch. The maturation process continues for years, the extent to which the scar remodels varies among individuals.

Types of Wound Healing

Children have a highly elastic skin quality. This quality, combined with the rapid healing process during the latency and puberty developmental growth periods, results in abundant scar tissue that pulls on wounds during the healing process. Healing of wounds takes place in one of three ways: by primary, secondary, or tertiary intention (Fig. 31.1). **Primary intention** healing takes place when all layers of the wound margins (skin, subcutaneous tissue, and muscle) are neatly approximated, as with a surgical incision. Unless infection interferes or the wound edges separate, these wounds heal with a minimum of scarring.

Repair by **secondary intention** takes place in wounds that occur from ulceration and lacerations in which the edges cannot be approximated, such as an avulsion or a third-degree burn. The inflammatory reaction may be greater, and the chance of infection is increased. Often debris, cells, and exudate must be cleaned away (debrided) before healing can take place. Healing takes place from the edges inward and from the bottom of the wound upward until the defect is filled. More granulation tissue and a larger scar are formed than in healing by primary intention.

Repair by **tertiary intention** takes place when suturing is delayed after injury or the wound later breaks down and is sutured or resutured when granulation is present. More granulation tissue is formed than in healing by primary intention, and there is a greater chance that microorganisms will invade the wound, resulting in a larger and deeper scar than healing by primary intention. Frequently, suturing of a contaminated wound is deliberately delayed to afford better removal of infection before closing.

Factors That Influence Healing

During the past decade, understanding of wound healing has revolutionized the interventions used to promote healing. Emphasis has shifted from interventions directed at maintaining a dry environment that promotes eschar formation to those that promote a moist, crust-free environment that enhances the migration of epithelial cells across the wound and facilitates resurfacing. An acute full-thickness wound kept in a moist environment usually reepithelializes in 12 to 15 days, whereas the same wound kept open to the air heals in approximately 25 to 30 days.

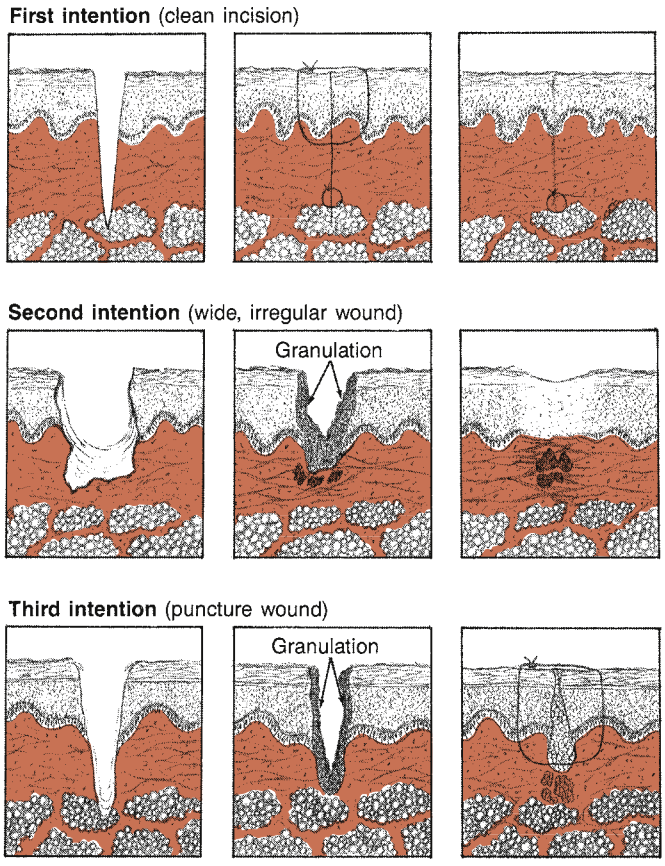

Fig. 31.1 Types of wound healing.

Eschar (thick, fibrin-containing necrotic tissue) also interferes with healing by preventing wound contraction. In most situations it is best to remove eschar and other dead tissue from the wound. Repeated application of occlusive dressings mobilizes the body's own enzymes to lyse the eschar, a process known as **autolysis**.

Adequate nutrition is essential for wound healing. In particular, sufficient protein, calories, vitamins C and D, and zinc are needed for healing of extensive wounds, such as burns. Supplemental nutrition is an integral aspect of treatment of severe wounds.

Numerous factors delay healing of the skin (Table 31.1). Some traditional practices are ineffective or even harmful; for example, antiseptics that were once used to help prevent infections (hydrogen peroxide and povidone-iodine [Betadine] solutions) are now known to have cytotoxic effects on healthy cells and minimal effect on controlling infections. Povidone-iodine may be absorbed through the skin in neonates and young children and must be used with caution in patients with thyroid or renal disease. Factors that delay wound healing, particularly in the home environment, include exposure to smoke or other allergens, dry or arid air, noncompliance or inconsistent adherence to the treatment regimen, and stress.

General Therapeutic Management

The human body intrinsically attempts to heal itself; therefore treatment is directed toward eliminating or ameliorating factors that interfere with normal healing processes. Some disorders may demand aggressive therapy, but by and large the major aim of any treatment is to prevent further damage, eliminate the cause, prevent complications, and provide relief from discomfort while tissues undergo healing. When possible, eliminate factors that contribute to the dermatitis and prolong the course of the disease. The most common offenders in

TABLE 31.1 Factors That Delay Wound Healing

Factor	Effect on Healing
Dry wound environment	Allows epithelial cells to dry out and die; impairs migration of epithelial cells across wound surface
Nutritional deficiencies	
• Vitamin A	Results in inadequate inflammatory response
• Vitamin B_1	Results in decreased collagen formation
• Vitamin C	Inhibits formation of collagen fibers and capillary development
• Vitamin D	Regulates growth and differentiation of cell types, inhibits hyperproliferation of cells
• Protein	Reduces supply of amino acids for tissue repair
• Zinc	Impairs epithelialization
Immunocompromised	Results in inadequate or delayed inflammatory response
Impaired circulation	Inhibits inflammatory response and removal of debris from wound area Reduces supply of nutrients to wound area
Stress (pain, poor sleep)	Releases catecholamines that cause vasoconstriction
Antiseptics	
• Hydrogen peroxide	Toxic to fibroblasts; can cause subcutaneous gas formation (mimics gas-forming infection)
• Povidone-iodine	Toxic to white and red blood cells and fibroblasts
• Chlorhexidine	Toxic to white blood cells
Medications	
• Corticosteroids	Impair phagocytosis Inhibit fibroblast proliferation Depress formation of granulation tissue Inhibit wound contraction
• Chemotherapy	Interrupts the cell cycle; damages DNA or prevents DNA repair
• Antiinflammatory drugs	Decrease the inflammatory phase
Foreign bodies	Increase inflammatory response Inhibit wound closure
Infection	Increases inflammatory response Increases tissue destruction
Mechanical friction	Damages or destroys granulation tissue
Fluid accumulation in area	Inhibits tissues from approximating
Radiation	Inhibits fibroblastic activity and capillary formation May cause tissue necrosis
Diseases	
• Diabetes mellitus	Inhibits collagen synthesis Impairs circulation and capillary growth Hyperglycemia impairs phagocytosis
• Anemia	Reduces oxygen supply to tissues
• Peripheral vascular disease	Reduces oxygen supply to wounds
• Uremia	Decreases collagen and granulation tissue

DNA, Deoxyribonucleic acid.

pediatrics are environmental factors, including soaps (bubble baths and shampoos) and lotions; garments that are made of synthetic materials, have a rough texture (wool), or are tight-fitting; prolonged exposure to damp undergarments or swimsuits; and natural elements (plants and insects, dirt, sand, heat, cold, moisture, and wind). Dermatitis can also be aggravated by home remedies, poor nutrition, exposure to smoke, scratching or physical irritation of the site, and medications.

Dressings

No one dressing meets the needs of all wounds. The traditional dry gauze dressing should not be used on open wounds because it allows the wound surface to dry, does little to prevent bacterial invasion, and adheres to the dried scab so that removal disturbs the newly regenerating epithelial cells. In most instances, traditional gauze dressings have been replaced by dressings that promote moist wound healing. Moist wound healing increases the rate of collagen synthesis and reepithelialization, and decreases pain and inflammation. It also creates an environment for autolytic debridement of necrotic tissue, which creates a clean wound bed and enhances granulation. However, a balance must be achieved between creating a moist wound bed and maintaining a dry periwound area that protects the skin and wound from maceration. The dressing type and frequency of dressing changes help achieve this balance. The frequency of dressing changes is based on the presence of infection, the type of dressing, the location of the wound, and the amount of drainage. Dressings should always be changed when they are loose or soiled. They should be changed more frequently in areas where contamination is likely (e.g., the sacral area, the buttocks, the tracheal area) or when wound infection is suspected or present.

Dressings serve the following functions: (1) provide a moist healing environment, (2) protect the wound from infection and trauma, (3) provide compression in the event of anticipated bleeding or swelling, (4) apply medication, (5) absorb drainage, (6) debride necrotic tissue, (7) reduce pain, and (8) control odor. To ensure a moist environment, cover wounds with an occlusive ointment or dressing (Table 31.2).

Occlusive dressings can be classified according to their degree of permeability. The term *occlusive* is synonymous with impermeable, *semiocclusive* is synonymous with semipermeable, and *nonocclusive* is synonymous with permeable. No one dressing meets the needs of all types of wounds. The traditional gauze dressing is a permeable dressing that reduces the moisture content in a wound by absorbing exudate and allowing it to evaporate. Dry gauze dressings have been replaced by new "active occlusive" dressings, which allow for moist wound healing rather than the traditional dry wound environment that created an increased risk for wound sepsis and trauma during removal. The use of silver-impregnated dressings for the treatment of wound care has reemerged. Although several studies suggest that silver decreases the bacteria and bioburden in the wound and improves short-term healing of wounds and ulcers, the long-term effects remain unclear. Due to the possibility of silver toxicity in children with silver-containing dressings, caution is strongly recommended when applying these dressings in the pediatric population (King, Stellar, Blevins, et al., 2014).

Topical Therapy

A variety of agents and methods are available for treatment of dermatologic problems. In selecting a therapeutic program, the practitioner considers (1) the active ingredient of the agent, (2) the vehicle or base, (3) the cosmetic effect, (4) the cost, (5) instructions for the agent's use, and (6) the family preference. Practitioners aim to avoid overtreatment, particularly in young children. For example, when the dermatitis is acute, short-term topical medications such as steroids are used to reduce irritation, inflammation, and spread of the disorder, then quickly tapered to mild

TABLE 31.2 Dressing Category Definitions and Examples of Products

Category	Description	Examples
Gauze or sponge for external use	Nonresorbable Sterile or nonsterile Strip, piece, or pad Woven or nonwoven mesh cotton cellulose Simple chemical derivatives of cellulose Intended for medical purposes	Pads Island dressings
Hydrophilic wound dressing	Sterile or nonsterile Nonresorbable Material with hydrophilic properties No added drugs or biologics Intended to cover wound and absorb exudate	Alginate dressings Foam dressings Hydropolymer dressings Sheet gel dressings Hydrocolloid dressings Composite dressings
Occlusive wound dressing	Sterile or nonsterile Nonresorbable Synthetic polymeric material with or without adhesive backing Intended to cover wound, provide or support moist wound environment, and allow exchange of gases	Transparent adhesive dressings Thin film dressings Foam dressings Hydrocolloid dressings Composite dressings Hydropolymer dressings
Hydrogel wound dressing	Sterile or nonsterile Nonresorbable Matrix of hydrophilic polymers or other material combined with at least 50% water Intended to cover wound; absorb wound exudates; control bleeding or fluid loss; and protect against abrasion, friction, desiccation, and contamination	Alginate dressings Hydropolymer dressings Hydrogel dressings Gauze dressing impregnated with hydrogel (without active ingredients)
Porcine wound dressing	Made from pigskin Temporary burn dressing	

or less frequent dosages to prevent side effects or long-term consequences. Chemicals that are nonirritating to intact skin (soaps and lotions) should be avoided because they can be quite irritating to inflamed or wounded skin, especially in children, whose skin is more absorbent.

Tepid or cool baths or the topical application of tepid or cool moist compresses may be used to treat the disorder, reduce the itching associated with many diseases, or decrease external stimuli. Baths are especially useful in the treatment of widespread dermatitis because they evenly distribute the soothing antipruritic and antiinflammatory solution, usually an oatmeal or mineral oil preparation. The temperature of the bathwater should be tepid, and the treatment usually lasts 15 to 30 minutes. Therapeutic baths are always more interesting for the child when toys are available in the tub for water play.

Topical agents are applied to skin lesions to ease discomfort, prevent further injury, and facilitate healing. The emollient action of ointments and allergen-free lotions provides a soothing film over the skin surface that reduces external stimuli. Most preparations are placed directly on the skin and left uncovered; some may be applied under an occlusive dressing. The occlusive dressing promotes moisture retention and decreases evaporation of the therapeutic preparation. A thin application of the ointment or cream is covered with plastic film and anchored with adhesive or covered with a commercial transparent dressing. Apply any topical applications in a systematic manner following the contour of the body surface (not simply up and down). Children love to be "painted," so lotion applications can be fun when an ordinary soft-bristle paintbrush is used. Regardless of the type of preparation used, parents need detailed information on the medication being applied, how to apply it, and how long the preparation should remain on the skin or under an occlusive dressing.

! NURSING ALERT

Application of heat tends to aggravate most conditions, and its use is generally reserved for reducing specific inflammatory processes, such as folliculitis and cellulitis.

Topical corticosteroid therapy. Glucocorticoids are the therapeutic agents used most frequently for skin disorders. Their local antiinflammatory effects are merely palliative, so the medication is applied until the condition undergoes a remission or the causative agent is eliminated. Corticosteroids are applied directly to the affected area, are essentially nonsensitizing, and have only minor side effects. As with the use of any steroids, their use in large amounts may mask signs of infection, and symptoms may be exacerbated after termination of the drug. Families are cautioned that the medication cannot be used for all skin disorders. The concentrations available without prescription are not adequate for stubborn skin conditions (e.g., psoriasis, eczema) and may further aggravate inflammation caused by fungus or bacteria. When appropriate, it is important to counsel parents to apply only a thin film and to massage it into the skin because most parents and children apply more topical hydrocortisone than necessary for effective treatment. Parents and children should also be advised to use the application for no more than 5 to 7 days because these agents may cause depigmentation and other changes in the skin with extended use.

Other topical therapies. Other topical treatments include chemical cautery (especially useful for warts), cryosurgery, electrodesiccation (chiefly used for warts, granulomas, and nevi), ultraviolet (UV) light therapy (primarily used in psoriasis and acne), laser therapy (especially for birthmarks), and special acne therapies such as dermabrasion and chemical peels. **Topical immunomodulators** are effective in reducing the itching of atopic dermatitis (eczema) and preventing flare-ups in children resistant to first-line treatment options. However, the US Food and Drug Administration issued a black box warning cautioning against the use of these topicals as first-line treatments in children younger than 2 years of age after chronic use of these medications was linked to possible skin cancer and lymphoma (Margolis, Abuabara, Hoffstad, et al., 2015). To date, no evidence has been published linking malignancy to the use of pimecrolimus cream (Elidel) in infants and children, but safety and efficacy are considered before using these medications in children (Margolis et al., 2015). Nonprescription and prescription topical antibiotics (lotions, gels, ointments, or creams) may also be used to treat minor wounds and acne. Again, families should be instructed to apply only a thin layer of medication at determined daily intervals for a limited number of days to the wound or affected area(s); each application of medication should be followed by careful hand washing.

! NURSING ALERT

Provide written instructions and demonstrate to parents the correct amount of topical medication to apply (e.g., size of a pea, thin film to cover). If more than one preparation is to be applied, mark the containers 1 and 2 to help parents remember the correct order for application to the skin. While educating children and their caregivers about medications, the nurse should emphasize that *more* medication or increased frequency of applications is *not better* when using topical medications and may carry the risk of being harmful, especially in the case of topical steroids.

Systemic Therapy

Systemic drugs may be used as an adjunct to topical therapy in some dermatologic disorders. The drugs most frequently used are corticosteroids, antibiotics, and antifungal agents. Corticosteroids are valuable in the treatment of severe skin disorders because of their capacity to inhibit inflammatory and allergic reactions. The dosage is carefully adjusted and gradually tapered to the minimum dosage that is effective and tolerated. Prolonged use of systematic corticosteroids may temporarily suppress the child's growth.

Antibiotics are used in cases of severe, chronic, or widespread skin infections. However, because these drugs tend to produce hypersensitivity in some patients, they are used with caution. Oral antifungal agents are the only effective means for treating systemic fungal infections and tinea capitus.

Nursing Care Management

To help establish a diagnosis, it is important for nurses to accurately describe any deviation in the character of the skin, using both inspection and palpation. Note the color, shape, size, character, and distribution of the lesions or wounds. Describe the individual lesions using the accepted terminology, understanding that there may be more than one type of wound, lesion, or rash. Assess wounds for depth of tissue damage, evidence of healing, and signs of infection (e.g., drainage, warmth, odor).

To confirm or amplify the assessment findings made by inspection, gently palpate the skin to detect characteristics such as temperature, moisture, texture, elasticity, and the presence of edema. Indicate whether the findings are restricted to the area of the lesion(s) or are generalized.

! NURSING ALERT

Signs of wound infection include the following:
- Increased erythema, especially beyond wound margin
- Edema
- Purulent exudate
- Odor
- Pain at the site or extending beyond the wound margin
- Increased temperature

A detailed history of the child's presenting illness, condition, or wound and the description (or appearance) of symptoms provide additional information. Older children may be able to tell you precipitating factors they may have been exposed to, timing of the disorder, and treatments they have already tried. They are also usually able to describe the condition as painful, itching, or tingling or use other descriptive terms and associated symptoms related to the condition. In younger children, the nurse can determine much by noting behavior during the intake interview and the caregivers' account of the symptoms or illness and the reaction to any home treatments. Besides asking about medical history and noting the allergy and medication list of the patient, a careful nursing history may provide clues that will assist in determining an uncertain diagnosis. During the interview process, the nurse should ask the following questions:

- How long has this been occurring?
- Is the child scratching the area?
- Is the child restless or irritable?
- Does the child favor or avoid using a certain body part?
- Has the child had a fever or other illnesses recently?
- Has the child been around chemicals, woodlands, gardens, or woodpiles?
- Has the child traveled recently or visited someone's home for the first time?
- Has the child recently eaten a new food?
- Do any classmates, playmates, or siblings have similar lesions or illnesses?
- What has been done to treat the symptoms so far? Have any medications or home remedies been used?

Therapeutic treatments of skin disorders are typically aimed at providing comfort measures: rest, protection from infection or spread of the condition, and relief of discomfort. Specific treatments, such as a definitive medication or physical treatment or technique, may be prescribed for chronic conditions or wounds. Only a few skin disorders are contagious, so it is usually not necessary to isolate the affected child unless there is a danger that the child may acquire a secondary infection (e.g., the child who is receiving large doses of corticosteroids or other immunosuppressant drugs or the child with an immunologic deficiency disorder). However, when the skin manifestation is a viral exanthem such as chickenpox or an easily spread vector such as lice, the recommendation is to prevent exposing other susceptible children until the disorder is almost healed or the treatment is complete.

Wound Care

Parents can generally manage small skin wounds at home. Instruct parents to wash their hands and then wash the wound gently with mild soap and water. Topical antibiotics and nonadherent dressings are usually applied to the wound while it is in the primary healing stage. Caution parents to avoid povidone-iodine, alcohol, and hydrogen

peroxide because these products are toxic to wounds. Wounds covering a very large area (>15% of the body) need medical attention with the child undergoing conscious sedation and analgesia.

! NURSING ALERT

Do not put anything in a wound that you would not put in the eye. The safest solution is normal saline.

Open wounds are typically covered with a nonadherent dressing, such as a commercial adhesive bandage, although larger wounds may benefit from the use of occlusive dressings. If occlusive dressings are applied, instruct parents on their correct application and removal. For example, hydrocolloid dressings adhere best if a wide margin is left around the wound and the dressing is pressed against intact skin until it adheres. The edges of the dressing can be secured to the healthy skin margins with waterproof tape. The dressings are removed if leakage occurs or after specific time intervals, usually for a period of 7 days.

! NURSING ALERT

Advise parents that the yellow gel forming under hydrocolloid dressings may look like pus and has a distinct odor (somewhat fruity) but is normal leakage.

Dressings are removed carefully to protect intact skin and the epithelial surface of the wound. If the affected skin has significant hair growth, the nurse may consider removing a small patch or strip of hair surrounding the wound to improve dressing adherence and decrease discomfort for the child during dressing changes. When removing transparent or hydrocolloid dressings, the nurse or parent raises one edge of the dressing and pulls *parallel* to the skin to loosen the adhesive. The child may assist the nurse or caregiver in the dressing change procedure by firmly holding the skin taut as the adhesive dressing is removed. If a dressing sticks to the wound base when it is being removed, saturate the dressing with normal saline or clean water to loosen it and then proceed with care. Another useful technique for applying dressings to wounds is "picture-framing." The wound is "framed" on all sides with the application of a skin barrier dressing that stays in place around the wound (e.g., DuoDERM, Coloplast). This technique protects the healthy skin from injury during repeated dressing changes because the adhesive can be secured to the skin barrier surrounding the wound rather than directly to the skin. Lacerations present a special challenge with cleaning and dressing. The injured child and family are usually distressed by the bleeding associated with the wound and may be experiencing variable degrees of anxiety, fear, and shock. Because scalp and facial lacerations tend to bleed profusely, they are especially frightening. The initial nursing intervention is to calmly apply direct pressure to the area and to attempt to calm the child before further examination. Unless there is bleeding from a severed artery, the wound is cleansed with a forced stream of sterile tepid water or normal saline (via syringe). The wound is then examined for extent and depth of injury and presence of foreign material such as dirt, glass, or fabric fragments. Before suturing lacerations or wounds, a topical anesthetic or intradermal buffered lidocaine should be used to reduce discomfort and promote cooperation of the child during the procedure.

The location of the wound dictates careful physical assessment. For example, wounds over bony areas may contain bone chips, and clear fluid seeping from severe head wounds may indicate cerebrospinal fluid. For severe wounds that cannot be completely evaluated immediately and lacerations that require suturing, apply a clean pressure dressing over the affected area and transfer the child for emergency medical care. Puncture wounds should initially be irrigated with sterile saline and then soaked in a basin of warm soapy water for several minutes before applying a clean dressing. Causing the puncture wound to rebleed may be indicated to ensure that no foreign body is embedded in the wound. Puncture wounds of the head, chest, or abdomen, or those that could still contain a portion of the puncturing object must be evaluated further by a practitioner and may require an x-ray to confirm that all foreign material has been removed from the wound. Caution parents against opening ("popping") wounds, blisters, or vesicles, or kissing a wound "to make it better." The skin can easily become contaminated from germs in the human mouth. If scabs form, they are allowed to slough off without assistance; picking or early removal may cause scarring and secondary infection. Advise parents to seek medical help if there is evidence of infection.

Relief of Symptoms

Most of the therapeutic regimens are intended to promote wound healing, prevent infection, and provide relief of pruritus, the most common subjective complaint. Preventing scratching is of primary importance. Itching is believed to often result from stimulation of C fibers at the dermoepidermal junction and the release of histamine and endopeptidases. These fibers are similar to but distinct from pain fibers and may be stimulated with a single scratch. Cooling the affected area and increasing the skin pH with an alkaline-containing compress, such as a baking soda or Burow solution, or a tepid bath reduce the child's external stimuli and the urge to scratch. Older children usually can avoid self-contaminating the wound, though they may occasionally need to be reminded to stop scratching or rubbing. In younger and uncooperative children, techniques and devices such as mittens (especially during sleep) or special hand coverings are required. Keeping fingernails short and clean helps reduce scratching and the chance of secondary infection of the wound. Clothing and bed linens should be soft, smooth, lightweight, and made of natural fibers to decrease the irritation from friction and stimulation. Antipruritic medications such as diphenhydramine (Benadryl) or hydroxyzine (Atarax) may be prescribed for severe itching, especially if it disrupts the child's sleep.

Wet compresses or dressings cool the skin by evaporation, relieve itching and inflammation, and cleanse the area by loosening and removing crusts and debris. A variety of ingredients, such as plain water or Burow solution (available without a prescription), can be applied on Kerlix gauze; plain gauze; or (preferably) soft cotton cloths such as freshly laundered towels, bed sheets, or pillowcases.

Pain and discomfort are usually managed with nonpharmacologic measures such as positioning and rest, distraction techniques, and individual preferences of comfort. Occlusive dressings applied over wounds reduce pain similar to cool or tepid compresses. Doses of mild analgesics such as acetaminophen or ibuprofen, prescribed based on the patient's weight, may be recommended. Severe pain requires prescribed analgesic medication and careful nursing assessment for infection or an underlying cause of discomfort. For severe wounds and burns, prescribed analgesic medications should be administered before each dressing change, debridement procedure, or cleansing, allowing adequate time for the medicine to take therapeutic effect (see Chapter 5, Pain Management).

Wound healing may be facilitated by recombinant growth factor or a vacuum-assisted closure device. These therapies may be used when wounds are large and in a location that creates challenges for therapy (e.g., sacral or groin wound) or when the child has associated conditions such as malnutrition or a comprised immune system, putting "normal" wound healing at risk. Recombinant growth factors are human platelet–derived growth factors that are engineered outside the

body. They foster the formation of new granulation tissue by stimulating the migration of fibroblasts, macrophages, smooth muscle cells, and capillary endothelial cells to the wound site.

The vacuum-assisted closure (VAC) device uses a technique that involves placing a foam dressing into the wound, covering it with an occlusive dressing, and applying gentle, continuous suction. The negative pressure of the suction is applied from the foam dressing to the wound surfaces. The mechanical force removes excess fluids from the wound, stimulates formation of granulation tissue, restores capillary flow, and fosters closure of the wound. VAC has been used to prepare wounds for a skin graft and to treat surgical wounds, burns, and pressure ulcers (Han & Ceilley, 2017). The safety and efficacy of the VAC technique for infants and children has been documented in recent studies (Koehler, Jinbo, Johnson, et al., 2014; Satteson, Crantford, Wood, et al., 2015; Takahara, Sai, Kagatani, et al., 2014).

Home Care and Family Support

Care of a child with a dermatologic condition always involves the family, but few situations require hospitalization, and most care is delivered at home. Because the family members must carry out the treatment plan, their cooperation is essential. Regimens that are routine for health care professionals to accomplish in the clinic, hospital, or primary care provider's office may be frustrating and baffling for caregivers in the home. The family may also need assistance in adapting equipment available for home therapy.

It is important that the child and family be given as detailed explanations as possible about both the expected and the unexpected results of treatment, including any side effects that might occur. If unexplained reactions develop, direct the family to discontinue treatment and report the reactions to the appropriate person. Discourage the use of over-the-counter medicines and homeopathic treatments unless the preparations have been discussed with the health care provider and have received approval.

Because the skin is the most visible portion of the body, defects in its surface alter its appearance and cause distress for the child. Skin problems may also result in rejection by others. Parents of other children may fear that their children will "catch" the disorder. Occasionally, the affected child's own family members reduce their interaction or physical contact with the child, especially close physical contact, or demonstrate distaste for the condition, which the child may interpret as rejection or punishment. This is seldom a concern for children with dermatitis of short duration, but chronic conditions can frequently create problems and affect the child's self-esteem.

INFECTIONS OF THE SKIN

BACTERIAL INFECTIONS

Normally, the skin harbors a variety of bacterial flora, including the major pathogenic varieties of staphylococci and streptococci. The degree of pathogenicity of the organism depends on its invasiveness and toxicity, the integrity of the skin (the host's barrier), and the host's immune and cellular defenses. Children with congenital or acquired immunodeficiency disorders (e.g., acquired immune deficiency syndrome [AIDS]), children receiving immunosuppressant therapy, and those with a malignancy such as leukemia or lymphoma are at risk for developing bacterial infections.

Because of the characteristic "walling-off" process of the inflammatory reaction (abscess formation), staphylococci are more difficult to treat, and the local infected area is associated with an increase in bacteria all over the skin surface that serves as a source of continuing infection. Since the early 2000s, the number of methicillin-resistant *Staphylococcus aureus* (MRSA) community-acquired infections rose dramatically until reaching a peak in 2007 and then steadily declined (Kaplan, 2016). These factors underline the importance of careful hand washing and cleanliness when caring for infected children and their lesions to prevent the spread of infection and as an essential prophylactic measure when caring for infants and small children. Common bacterial skin disorders are outlined in Table 31.3 (Figs. 31.2 and 31.3).

Nursing Care Management

The major nursing functions related to bacterial skin infections are to prevent the spread of infection and to prevent complications. Impetigo contagiosa and MRSA infection can easily spread by self-inoculation; therefore caution the child against touching the involved area. Hand washing is mandatory before and after contact with an affected child. Also emphasize hand washing to both the child and the family. Many children with atopic dermatitis are colonized with MRSA (Chaptini, Quinn, & Marshman, 2016). For many bacterial infections, and for MRSA infection in particular, the child should be provided with washcloths and towels separate from those of other family members. The child's clothes should be changed daily and washed in hot water. Razors used for shaving should be discarded after each use and not shared. To prevent recurrence, some infectious disease specialists recommend bathing in a chlorine bath daily for 5 to 14 days, although evidence of the effectiveness is inconclusive (Gupta, Lyons, & Rosen, 2015; Kaplan, Forbes, Hammerman, et al., 2014). For the chlorine bathing, 1 teaspoon of bleach is diluted in 13 gallons of water or ¼ cup of bleach is diluted in a standard 50-gallon tub one-fourth filled with water (Gupta et al., 2015). In addition, mupirocin can be applied to the nares of patients and families twice daily for 5 to 10 days to prevent reinfection (Gupta et al., 2015).

Children and parents are often tempted to squeeze follicular lesions. They must be warned that squeezing will not hasten the resolution of the infection and that there is a risk of making the lesion worse or spreading the infection. No attempt should be made to puncture the surface of the pustule with a needle or sharp instrument. A child with a sty may waken with the eyelids of the affected eye sealed shut with exudate. The child or the parents are instructed to gently wipe the eyelid from the inner to the outer edge with warm water and a clean washcloth until the exudate is removed.

The child with limited cellulitis of an extremity is usually managed at home on a regimen of oral antibiotics and warm compresses. The parents are taught the procedures and instructed in administration of the medication. Children with more extensive cellulitis, especially around a joint with lymphadenitis or on the face, are usually admitted to the hospital for parenteral antibiotics with continued treatment at home. Nurses are responsible for teaching the family to administer the medication and apply compresses.

VIRAL INFECTIONS

Viruses are intracellular parasites that produce their effect by using the intracellular substances of the host cells. Composed of only a deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) core enclosed in an antigenic protein shell, viruses are unable to provide for their own metabolic needs or to reproduce themselves. After a virus penetrates a cell of the host organism, it sheds the outer shell and disappears within the cell, where the nucleic acid core stimulates the host cell to form more virus material from its intracellular substance. In a viral infection, the epidermal cells react with

TABLE 31.3 Bacterial Infections

Disorder and Organism	Manifestations	Management	Comments
Impetigo contagiosa—*Staphylococcus* (see Fig. 31.2)	Begins as a reddish macule Becomes vesicular Ruptures easily, leaving superficial, moist erosion Tends to spread peripherally in sharply marginated irregular outlines Exudate dries to form heavy, honey-colored crusts Pruritus common Systemic effects—Minimal or asymptomatic	Topical bactericidal ointment mupirocin or triple antibiotic ointment Oral or parenteral antibiotics (penicillin) in severe or extensive lesions Vancomycin for MRSA	Tends to heal without scarring unless secondary infection Autoinoculable and contagious Common in toddlers and preschoolers May be superimposed on eczema
Pyoderma—*Staphylococcus, Streptococcus*	Deeper extension of infection into dermis Tissue reaction more severe Systemic effects—Fever, lymphangitis, sepsis, liver disease, heart disease	Soap and water cleansing Topical antiseptic, such as chlorhexidine Mupirocin Antibiotics depending on causative organism: Cephalexin, nafcillin, intramuscular benzathine penicillin Bathing with antibacterial soap as prescribed Do not share washcloths or towels	Autoinoculable and contagious May heal with or without scarring
Folliculitis (pimple), furuncle (boil), carbuncle (multiple boils)—*Staphylococcus aureus,* MRSA	Folliculitis—Infection of hair follicle Furuncle—Larger lesion with more redness and swelling at a single follicle Carbuncle—More extensive lesion with widespread inflammation and "pointing" at several follicular orifices Systemic effects—Malaise if severe	Skin cleanliness Local warm, moist compresses Topical application of antibiotic agents Systemic antibiotics in severe cases Incision and drainage of severe lesions, followed by wound irrigations with antibiotics or suitable drain implantation MRSA infections: • 5-inch soak of ½ cup bleach diluted in a standard 50-gallon tub one-fourth filled with water once or twice weekly • No sharing of towels or washcloths, changing of clothes and underwear daily, and laundering in hot water • Disposal of razors after one use • Application of mupirocin to nares bid for 2-4 wk	Autoinoculable and contagious Furuncle and carbuncle tend to heal with scar formation Lesions should never be squeezed
Cellulitis—*Streptococcus, Staphylococcus, Haemophilus influenzae* (see Fig. 31.3)	Inflammation of skin and subcutaneous tissues with intense redness, swelling, and firm infiltration Lymphangitis "streaking" frequently seen Involvement of regional lymph nodes common May progress to abscess formation Systemic effects—Fever, malaise	Oral or parenteral antibiotics Rest and immobilization of both affected area and child	Hospitalization may be necessary for child with systemic symptoms Otitis media may be associated with facial cellulites
Staphylococcal scalded skin syndrome—*S. aureus*	Macular erythema with "sandpaper" texture of involved skin Epidermis becomes wrinkled (in days or less), and large bullae appear Localized bullous impetigo in older child	Systemic antibiotics Gentle cleansing with saline, Burow solution, or 0.25% silver nitrate compresses	Infants subject to fluid loss; impaired body temperature regulation; and secondary infection, such as pneumonia, cellulitis, and septicemia Heals without scarring

bid, Two times daily; *MRSA,* methicillin-resistant *Staphylococcus aureus*.

inflammation and vesiculation (as in herpes simplex) or by proliferating to form growths (warts).

Many of the communicable viral diseases of childhood are associated with rashes, and each rash is characteristic. The type of lesion and the configuration of rubeola, rubella, and chickenpox are described in Chapter 6, Table 6.3. Other common viral disorders of the skin are outlined in Table 31.4.

Dermatophytoses (Fungal Infections)

The dermatophytoses (ringworm) are infections caused by a group of closely related filamentous fungi that invade primarily the stratum corneum, hair, and nails. These are superficial infections by organisms that live on, not in, the skin. Dermatophytoses are designated by the Latin word *tinea,* with further designation relating to the area of the

Fig. 31.2 Impetigo contagiosa. (From Weston, W. L., & Lane, A. T. [2007]. *Color textbook of pediatric dermatology* [4th ed.]. St. Louis, MO: Mosby.)

Fig. 31.3 Cellulitis of cheek from a puncture wound. (From Weston, W. L., & Lane, A. T. [2007]. *Color textbook of pediatric dermatology* [4th ed.]. St. Louis, MO: Mosby.)

body where they are found (e.g., tinea capitis [ringworm of the scalp]). Table 31.5 outlines common dermatophytoses (Fig. 31.4).

Dermatophyte infections are most often transmitted from one person to another or from infected animals to humans. Because the keratin is desquamated constantly, the fungus must multiply at a rate that equals the rate of keratin production to maintain itself; otherwise the infection would be shed with the discarded skin cells. Diagnosis is made from microscopic examination of scrapings taken from the advancing periphery of the lesion, which almost always produces a scale.

Nursing Care Management

When teaching families how to care for ringworm, the nurse should emphasize good health and hygiene. Because of the infectious nature of the disease, affected children should not exchange grooming items, headgear, scarves, or other articles of apparel that have been in proximity to the infected area with other children. Affected children are provided with their own towels and directed to wear a protective cap at night to avoid transmitting the fungus to bedding, especially if they sleep with another person. Because the infection can be acquired by animal-to-human transmission, all household pets should be examined for the disorder. Other sources of infection are seats in locker rooms, tanning beds, seats in public transportation vehicles, helmets, and gymnasium mats.

Both 2% ketoconazole and 1% selenium sulfide shampoos may reduce colony counts of dermatophytes. These shampoos can be used in combination with oral therapy to reduce the transmission of disease to others. The shampoo should be applied to the scalp for 5 to 10 minutes at least three times per week. The child may return to school after the therapy is initiated.

Alternatively, if the child is treated with the drug griseofulvin, the therapy frequently continues for weeks or months, and because subjective symptoms subside, children or parents may be tempted to decrease or discontinue the drug. The nurse should emphasize to family members the importance of maintaining the prescribed dosage schedule and of taking the medication with high-fat foods for best absorption. They are also instructed on possible drug side effects, such as headache, gastrointestinal upset, fatigue, insomnia, and photosensitivity. For children who take the drug over many months, periodic testing is required to monitor leukopenia and assess liver and renal function. Other antifungal medications such as terbinafine, itraconazole, and fluconazole can be used.

SYSTEMIC MYCOTIC (FUNGAL) INFECTIONS

Mycotic (systemic or deep fungal) infections have the capacity to invade the viscera, as well as the skin. The most common infections are the lung diseases, which are usually acquired by inhalation of fungal spores. These fungi produce a variable spectrum of disease, and some are common in certain geographic areas. They are not transmitted from person to person but appear to reside in the soil, from which their spores are airborne. The cutaneous lesions caused by deep fungal infections are granulomatous and appear as ulcers, plaques, nodules, fungating masses, and abscesses. The course of deep fungal diseases is chronic with slow progression that favors sensitization (Table 31.6).

SKIN DISORDERS RELATED TO CHEMICAL OR PHYSICAL CONTACTS

CONTACT DERMATITIS

Contact dermatitis is an inflammatory reaction of the skin to chemical substances, natural or synthetic, that evoke a hypersensitivity response or direct irritation. The initial reaction occurs in an exposed region, most commonly the face and neck, backs of the hands, forearms, male genitalia, and lower legs. There is characteristically a sharp demarcation between inflamed and normal skin that ranges from a faint, transient erythema to massive bullae on an erythematous swollen base. Itching is a constant symptom.

The cause may be a primary irritant or a sensitizing agent. A **primary irritant** is one that irritates any skin. A **sensitizing agent** produces an irritation on those individuals who have encountered the irritant or something chemically related to it, have undergone an immunologic change, and have become sensitized. Prior exposure is not necessarily a factor in the reaction. A sensitizer irritates in relatively low concentrations only persons who are allergic to it.

The major goal in treatment is to prevent further exposure of the skin to the offending substance. Provided there is no further irritation, the skin's normal recuperative powers will often produce healing without treatment. The most frequent offenders are plant (poison ivy, oak, or sumac), animal (wool, feathers, and furs), and metal irritants (nickel found in jewelry and the snaps on sleepers and denim). In infants, contact dermatitis occurs on the convex surfaces of the diaper area. Other agents that produce contact dermatitis include vegetable irritants (oleoresins, oils, and turpentine), synthetic fabrics (e.g., shoe components), dyes, cosmetics, perfumes, and soaps (including bubble baths).

TABLE 31.4 Viral Infections

Infection	Manifestations	Management	Comments
Verruca (warts) Cause—Human papillomavirus (various types)	Usually well-circumscribed, gray or brown, elevated, firm papules with a roughened, finely papillomatous texture Occur anywhere but usually appear on exposed areas such as fingers, hands, face, and soles May be single or multiple Asymptomatic	Not uniformly successful Local destructive therapy, individualized according to location, type, and number—surgical removal, electrocautery, curettage, cryotherapy (liquid nitrogen), caustic solutions (lactic acid and salicylic acid in flexible collodion, retinoic acid, salicylic acid plasters), laser ablation	Common in children Tend to disappear spontaneously Course unpredictable Most destructive techniques tend to leave scars Autoinoculable Repeated irritation will cause to enlarge
Verruca plantaris (plantar wart)	Located on plantar surface of feet and, because of pressure, are practically flat; may be surrounded by a collar of hyperkeratosis	Caustic chemical solution applied to wart and wear foam insole with hole cut to relieve pressure on wart; soak 20 min after 2-3 days; repeat until wart comes out	Destructive techniques tend to leave scars, which may cause problems with walking
Herpes simplex virus Type I (cold sore, fever blister) Type II (genital)	Grouped, burning, and itching vesicles on inflammatory base, usually on or near mucocutaneous junctions (lips, nose, genitalia, buttocks) Vesicles dry, forming a crust followed by exfoliation and spontaneous healing in 8-10 days May be accompanied by regional lymphadenopathy	Avoidance of secondary infection Burow solution compresses during weeping stages Oral antiviral (acyclovir [Zovirax]) for initial infection or to reduce severity in recurrence; may also be given prophylactically for recurrent Valacyclovir (Valtrex), an oral antiviral, used for episodic treatment of recurrent genital herpes; reduces pain, stops viral shedding, and has a more convenient administration schedule than acyclovir; primarily recommended for immunocompromised patients	Heal without scarring unless secondary infection Type I cold sores prevented by using sunscreens protecting against ultraviolet A and ultraviolet B light to prevent lip blisters Aggravated by corticosteroids Positive psychologic effect from treatment May be fatal in children with depressed immunity
Varicella-zoster virus (herpes zoster; shingles)	Caused by same virus that causes varicella (chickenpox) Virus has affinity for posterior root ganglia, posterior horn of spinal cord, and skin; crops of vesicles usually confined to dermatome following along course of affected nerve Usually preceded by neuralgic pain (rare in children), hyperesthesias, or itching May be accompanied by constitutional symptoms	Symptomatic Analgesics for pain Drying lotions sometimes helpful Ophthalmic variety: systemic corticotropin (adrenocorticotropic hormone) or corticosteroids Acyclovir or valacyclovir Preventive vaccine is available for persons >50 years old	Pain in children usually minimal Postherpetic pain does not occur in children Chickenpox may follow exposure; isolate affected child from other children in a hospital or school May occur in children with depressed immunity; can be fatal
Molluscum contagiosum Cause—Pox virus	Flesh-colored papules (1-20) with a central caseous plug (umbilicated) that occur on trunk, face and extremities; may be transmitted by sexual contact Usually asymptomatic	Cases in well children resolve spontaneously in about 18 months Treatment reserved for cosmetic purposes; alleviate discomfort; reduce autoinoculation; prevent secondary infection Numerous chemical removing agents, including tretinoin gel 0.01% or cantharidin (Cantharone) liquid; podophyllin; imiquimod cream These are painful treatments: Use local anesthesia Curettage, electrodessication, or cryotherapy	Common in school-age children Spread by skin-to-skin contact, including autoinoculation and fomite-to-skin contact Outbreaks in child care centers have been reported

Nursing Care Management

Nurses frequently detect evidence of contact dermatitis during routine physical assessments. Skin manifestations in specific areas suggest limited contact, such as around the eyes (mascara), areas of the body covered by clothing but not protected by undergarments (wool), or areas of the body not covered by clothing (UV injury). Generalized involvement is more likely to be caused by bubble bath, laundry soap, body soap, or lotion. Often nurses can determine the offending agent and counsel families on management. If the lesions persist, are extensive, or show evidence of infection, medical evaluation is indicated.

POISON IVY, OAK, AND SUMAC

Contact with the dry or succulent portions of any of three poisonous plants (ivy, oak, and sumac) produces localized, streaked or spotty, oozing, and painful impetiginous lesions that are often highly urticarial. The offending substance in these plants is an oil, **urushiol**, which is extremely potent. Sensitivity to urushiol is not inborn but is developed after one or two exposures and may change over a lifetime. All parts of the plants, including dried leaves and stems, contain the oil (Fig. 31.5A). Even smoke from burning brush piles can produce a reaction.

Animals do not seem to be affected by the oil; however, dogs or other animals that have run or played in the plants may carry the sap

TABLE 31.5 Dermatophytoses (Fungal Infections)

Disease and Organism	Manifestations	Management	Comments
Tinea capitis—*Trichophyton tonsurans, Microsporum audouinii, Microsporum canis* (see Fig. 31.4A)	Lesions in scalp but may extend to hairline or neck Characteristic configuration of scaly, circumscribed patches or patchy, scaling areas of alopecia Generally asymptomatic but severe, deep inflammatory reaction may occur that manifests as boggy, encrusted lesions (kerions) Pruritic Diagnosis: Microscopic examination of scales	Oral griseofulvin or terbinafine Oral ketoconazole for difficult cases Selenium sulfide shampoos, used twice a week, may decrease infection and fungal shedding (American Academy of Pediatrics, 2018) Kerion: Griseofulvin and possibly oral corticosteroids for 2 wk to achieve therapeutic effect (American Academy of Pediatrics, 2018)	Person-to-person transmission Animal-to-person transmission Rarely, permanent loss of hair *audouinii* transmitted from one human to another directly or from personal items; *M. canis* usually contracted from household pets, especially cats Atopic individuals more susceptible
Tinea corporis—*Trichophyton rubrum, Trichophyton mentagrophytes, M. canis, Epidermophyton* (see Fig. 31.4B)	Generally round or oval, erythematous scaling patch that spreads peripherally and clears centrally; may involve nails (tinea unguium) Diagnosis—Direct microscopic examination of scales Usually unilateral	Oral griseofulvin Local application of antifungal preparation such as tolnaftate, naftifine, miconazole, terbinafine, clotrimazole; applied 2.5 cm (1 inch) beyond periphery of lesion; application continued 1-2 wk after no sign of lesion Topical antifungals with high-potency steroids are not recommended as they may lead to further infection and have local and systemic side effects (American Academy of Pediatrics, 2018)	Usually of animal origin from infected pets but may occur from human transmission, soil, or fomites Majority of infections in children caused by *M. canis* and *M. audouinii* Tinea gladiatorum is commonly seen in wrestlers
Tinea cruris ("jock itch")—*Epidermophyton floccosum, T. rubrum, T. mentagrophytes*	Skin response similar to tinea corporis Localized to medial proximal aspect of thigh and crural fold; may involve scrotum in males Pruritic Diagnosis—Same as for tinea corporis	Local application of tolnaftate liquid, terbinafine, clotrimazole, ciclopirox twice daily for 2-4 wk	Rare in preadolescent children Health education on transmission via person-to-person (direct or indirect) Occurs in close association with tinea pedis and tinea unguium
Tinea pedis ("athlete's foot")—*T. rubrum, Trichophyton interdigitale, E. floccosum* Tinea unguium: Nail infection	On intertriginous areas between toes or on plantar surface of feet Lesions vary: Maceration and fissuring between toes Patches with pinhead-size vesicles on plantar surface Pruritic Diagnosis—Direct microscopic examination of scrapings	Local applications of terbinafine, ciclopirox or clotrimazole, or miconazole, or ketoconazole Oral itraconazole, terbinafine, or griseofulvin for severe infections or those that do not respond to topical acute infections—Compresses or soaks with Burow solution (1:80) (American Academy of Pediatrics, 2018) Elimination of conditions of heat and perspiration by use of clean, light socks and well-ventilated shoes; avoidance of occlusive shoes	Most frequent in adolescents and adults; rare in children, but occurrence increases with wearing of plastic shoes Common in locations such as showers, locker rooms, and swimming pools where fungi proliferate
Candidiasis (moniliasis)—*Candida albicans*	Grows in chronically moist areas Inflamed areas with white exudate, peeling, and easy bleeding Pruritic Diagnosis—Characteristic appearance; microscopic identification of scrapings; candidemia diagnosed from cultures (blood, cerebrospinal fluid, bone marrow); tissue biopsy Chronic or recurrent often seen with HIV infection and immunocompromised child	Neonatal thrush, oral nystatin Older children, clotrimazole troches applied to lesions (American Academy of Pediatrics, 2018) Fluconazole or itraconazole for immunocompromised Esophagitis: Treat with oral or IV fluconazole or itraconazole; IV amphotericin, voriconazole, micafungin Treat skin lesions with topical nystatin, miconazole, clotrimazole, ketoconazole, econazole, or ciclopirox (American Academy of Pediatrics, 2018) Vulvovaginal: Clotrimazole, miconazole, butoconazole, terconazole, and tioconazole used topically (American Academy of Pediatrics, 2018)	Common form of diaper dermatitis (see Fig. 31.10) Oral form common in infants (see Chapter 8) Vaginal form in females Disseminated disease in very low birth weight infants and immunosuppressed children

HIV, Human immunodeficiency virus; *IV,* intravenous.

Fig. 31.4 A, Tinea capitis. B, Tinea corporis. Both infections are caused by *Microsporum canis,* the "kitten" or "puppy" fungus. (From Habif, T. P. [2004]. Clinical dermatology: *A color guide to diagnosis and therapy* [4th ed.]. St. Louis, MO: Mosby.)

TABLE 31.6 Systemic Mycoses

Disorder and Organism	Skin Manifestations	Systemic Manifestations	Management	Comments
North American blastomycosis—*Blastomyces dermatitidis*	Chronic granulomatous lesions and microabscesses in any part of body Initial lesion is a papule; undergoes ulceration and peripheral spread	Pulmonary symptoms, such as cough, fever, chest pain, weakness, and weight loss; rarely develop ARDS Possible skeletal involvement, with bone destruction and formation of cutaneous abscesses	IV amphotericin B Oral fluconazole or itraconazole for mild or moderate cases after amphotericin B (American Academy of Pediatrics, 2018)	Usual portal of entry is lungs Source of infection unknown Pulmonary infections may be mild and self-limiting and require no treatment Progressive disease often fatal
Cryptococcosis—*Cryptococcus neoformans* (*Torula histolytica*)	Usually on face; acneiform, firm, nodular, painless eruption	CNS manifestations—Headache, dizziness, stiff neck, and signs of increased intracranial pressure Low-grade fever, mild cough, lung infiltration	IV amphotericin B; may be administered intrathecal for CNS involvement Oral flucytosine then fluconazole for meningitis Excision and drainage of local lesions	Acquired by inhalation of contaminated soil (bird feces) Endemic in Mississippi and Ohio River valleys Increased incidence in persons with defects in T lymphocyte–mediated immunity (HIV, leukemia, systemic lupus, AIDS, or organ transplant) No person-to-person transmission
Histoplasmosis—*Histoplasma capsulatum*	Not distinctive or uniform but most appear as punched-out or granulomatous ulcers Erythema nodosum in adolescents	General systemic symptoms may include pallor, diarrhea, vomiting, irregular spiking temperature, hepatosplenomegaly, and pulmonary symptoms Any tissue of body may be involved with related symptoms	IV amphotericin B for severe cases Itraconazole for mild to moderate infections	Organism cultured from soil, especially where contaminated with fowl droppings Fungus enters through skin or mucous membranes of mouth and respiratory tract Endemic in Mississippi and Ohio River valleys Disseminated diseases most common in infants and children younger than 2 years
Coccidioidomycosis (valley fever)—*Coccidioides immitis* and *Coccidioides posadasii*	Erythema nodosum Erythema multiforme Erythematous maculopapular rash	Primary lung disease usually asymptomatic: 60% of children Symptoms: Cough, fever, malaise, myalgia, headache, chest pain May be sign of acute febrile illness Disseminated disease is very serious; occurs in infants (meningitis)	Fluconazole or itraconazole for 3-6 months IV amphotericin B if no response to above Surgical resection of persistent pulmonary cavities	Inhalation of aerospores from soil Endemic in southwestern United States (*C. immitis* occurs almost exclusively in California) Usually resolves spontaneously Increased incidence in dark-skinned races (Filipino, African American, Hispanic), pregnant women, diabetics, persons with cardiopulmonary disease, and infants <1 year old

AIDS, Acquired immune deficiency syndrome; *ARDS,* acute respiratory distress syndrome; *CNS,* central nervous system; *HIV,* human immunodeficiency virus; *IV,* intravenous.

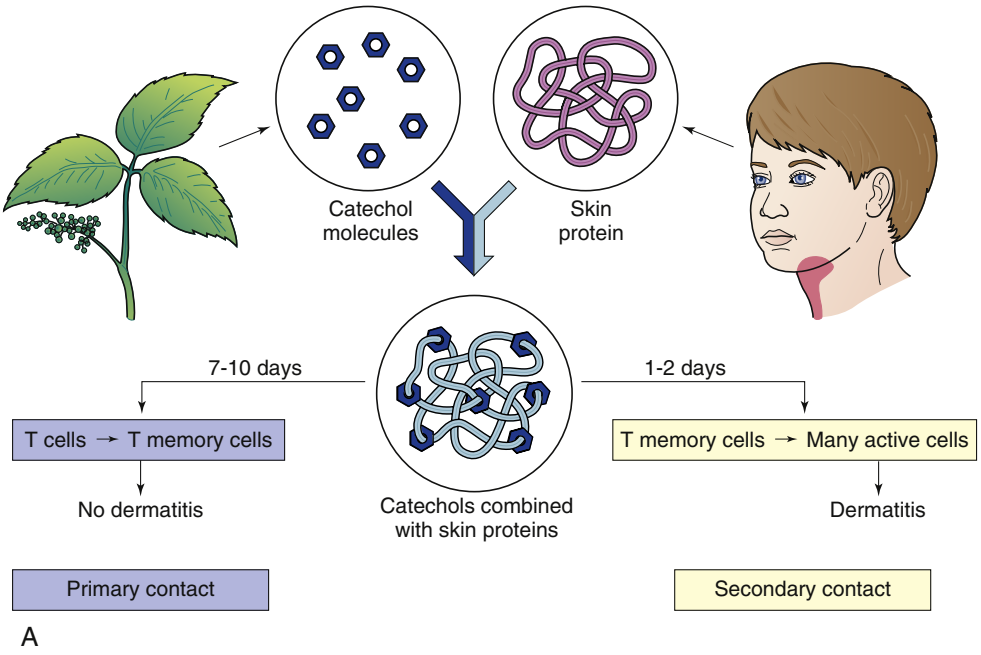

Fig. 31.5 **A,** Development of allergic contact dermatitis. **B,** Poison ivy lesions; note the "streaked" blisters surrounding one large blister. (**A,** From McCance, K., & Huether, S. [2010]. Pathophysiology: The biological basis for disease in adults and children [6th ed.]. St. Louis, MO: Mosby. **B,** From Habif, T. P. [2010]. Clinical dermatology: A color guide to diagnosis and therapy [5th ed.]. St. Louis, MO: Mosby.)

on their fur, and animals that eat the plants can transfer the oil in their saliva. Shoes, tools, and toys can transfer the oil. Golf balls that have been in the rough are another source of contact.

Urushiol takes effect as soon as it touches the skin. It penetrates through the epidermis as a mixture of compound molecules called *catechols.* These catechols bond skin proteins and initiate an immune response. The full-blown reaction is evident after about 2 days, with redness, swelling, and itching at the site of contact. Several days later, streaked or spotty blisters oozing serum from damaged cells produce the characteristic impetiginous lesions (see Fig. 31.5B). The lesions dry and heal spontaneously, and itching stops by 10 to 14 days.

Therapeutic Management

Treatment of the lesions includes application of calamine lotion, soothing Burow solution compresses, and/or Aveeno baths to relieve discomfort. Topical corticosteroid gel is effective for prevention or relief of inflammation, especially when applied before blisters form. Oral corticosteroids may be needed for severe reactions and those affecting the face, throat, or genital region. A sedative such as diphenhydramine may be ordered.

Nursing Care Management

The earlier the skin is cleansed, the greater the chance of removing the urushiol before it attaches to the skin. When it is known that the child has made contact with the plant, the area is immediately flushed (preferably within 15 minutes) with *cold* running water to neutralize the urushiol not yet bonded to the skin. Once the oil has been removed from the skin, the allergen has been neutralized. The rash that results from poison ivy cannot be spread to another child; only direct contact with the oil can cause the response. Harsh soap and scrubbing the exposed skin is contraindicated because it removes protective skin oils and dilutes the urushiol, allowing it to spread. All clothing that has come in contact with the plant is removed with care and thoroughly laundered in hot water and detergent. Every effort is made to prevent the child from scratching the lesions. Although the lesions do not spread by contact with the blister serum or from scratching, they can become secondarily infected.

Prevention

Prevention is best accomplished by avoiding contact and removing the plant from the environment. Teach all children, especially those known to be sensitive, to recognize the plant. Information regarding

means for destroying plants can be obtained from the US Department of Agriculture or US Forestry Service. Home garden sprays that kill broad-leaf plants or all vegetation (e.g., Roundup, Spectracide) are ineffective. If poisonous plants are growing in public community area, the local authorities should be contacted to remove the plants.

DRUG REACTIONS

Although drugs can adversely affect any organ of the body, reactions to medications are seen more often in the skin than in any other organ. The reaction may be a result of toxicity related to drug concentration, individual intolerance to the therapeutic dosage of the drug, or an allergic or idiosyncratic response. The manifestations may be associated with side effects or secondary effects of a drug, either of which are unrelated to its primary pharmacologic actions.

Although any drug is capable of producing a reaction in the susceptible individual, some drugs have a tendency to produce a particular reaction consistently (e.g., hives after a dose of antibiotics in an individual with sensitivity), and others are more likely to produce an untoward effect (e.g., nausea, vomiting, diarrhea). Many are allergenic responses that occur after a previous administration of the drug, even a topical application. Other factors influence a drug response in a particular individual. For example, the incidence of adverse reaction increases with the dosage amount and number of drugs given simultaneously.

! NURSING ALERT

Intravenous drugs are more likely to cause a reaction than oral drugs. If a reaction occurs, stop the drug but maintain the infusion with normal saline.

Manifestations of drug reactions may be delayed or immediate. A period of 7 days is usually required for a child to develop sensitivity to a drug that has never been administered previously. With prior sensitivity, the manifestations appear almost immediately. Rashes that are exanthematous, urticarial, or eczematoid are the most common manifestation of adverse drug reactions in children. However, individual drug reactions may vary from a single lesion to extensive, generalized epidermal necrosis such as that seen in Stevens-Johnson syndrome. Cutaneous manifestations can resemble almost any skin disease and can be seen in almost any degree of severity. With few exceptions, the distribution of a drug eruption is widespread because it results from a circulating agent; appears as an inflammatory response with itching; is sudden in onset; and may be associated with constitutional symptoms such as fever, malaise, gastrointestinal upset, anemia, or liver and kidney damage.

Another common adverse medication response in children is a fixed eruption (i.e., a recurrent eruption at the same site with each administration of the offending drug). The lesion, a purplish red round or oval plaque with a sharp border seen most frequently on the extremities, disappears slowly, and the pigmentation deepens with each episode.

In most cases, treatment for simple cutaneous reactions consists of discontinuing the drug. Sometimes a decision is made to continue the drug (e.g., an antibiotic in a small child) until the cause of the rash is clearly indicated and the negative or mild effects of the rash outweigh the benefits of the antibiotic (or other medication) treatment. Once the medication reaction is identified, it is well documented in the patient's medical record and avoided in the future. The provider will either substitute the offending medication with treatment in a comparative class or simply discontinue treatment, depending on the patient scenario. Often antihistamines may be ordered to relieve urticaric rashes. A tapering course of corticosteroids may be used for widespread and severe rashes. Severe anaphylactic reactions are a medical emergency (see Chapter 23, Anaphylaxis).

Nursing Care Management

The most effective means of management is prevention, documentation, and assessment. Frequent offenders in drug reactions are penicillin and sulfonamides, and nurses must be alert to this possibility. However, even commonplace drugs such as aspirin and barbiturates, chemical agents in some foods, flavoring agents, and preservatives can produce an undesired response. Parents always remember details of their child's severe reaction. As the nurse takes a careful medical history, details of a previous drug reaction should include the name and dose of the drug, nature of the reaction, and how soon after administration the reaction occurred. This information should be carefully noted in the medical record (see Chapter 4, History Taking). A careful nursing assessment (observation, inspection, and palpation) of the skin is paramount for any child receiving medication, especially intravenously. Noting the child's behavior and frequency of scratching is also critical. Nurses who identify a new rash after medication is administered or suspect a medication sensitivity in a patient whose rash is enlarging, increasingly itchy, or widespread on the child's body should withhold any further dose and report the eruption to the practitioner. Persons who have severe reactions should wear a medical identification bracelet or necklace in case of emergency or inadvertent administration of the offending agent.

FOREIGN BODIES

Small wooden, glass, or metal splinters and thorns from plants can usually be safely removed with a pointed needle and tweezers that have been sterilized with either alcohol or a flame. The area around the sliver is washed thoroughly with soap and water before removal is attempted, and the child should be cooperative and calm before removal is attempted. The sliver is exposed with the needle and then grasped firmly by the tweezers and pulled out. Some foreign bodies, such as a fishhook, pieces of glass, a difficult-to-see object, or a deeply embedded object (e.g., a needle in a foot or near a joint), require medical evaluation.

Small cactus prickles or spines are troublesome to remove, and attempts may be distressing to the child and family. Large spines or clumps can be removed with tweezers. Small prickles or spines may be removed by the following methods:

- Apply a thin layer of water-soluble household glue and cover it with gauze; when the glue dries, peel off the gauze.
- Apply hair removal wax or body sugar, let it dry, and remove.
- Place cellophane tape, sticky side down, over the spines and lift it off.

SKIN DISORDERS RELATED TO ANIMAL CONTACTS

ARTHROPOD BITES AND STINGS

Arthropods include insects and arachnids, such as mites, ticks, spiders, and scorpions. Most arthropods in the United States, including tarantulas, are relatively harmless. Although all spiders produce venom that is injected via fangs, some are unable to pierce the skin, and others produce venom that is insufficiently toxic to be harmful. Only scorpions and two spiders—the brown recluse and the black widow—inject venom deadly enough to require immediate attention. Children bitten by these arachnids must receive medical attention as soon as possible. Major offending creatures, their manifestations, and management are outlined in Table 31.7. A brown recluse spider bite is shown in Fig. 31.6.

TABLE 31.7 Skin Lesions Caused by Arthropods

Mechanism and Characteristic	Manifestations	Management
Insect Bites—Flies, Gnats, Mosquitoes, Fleas		
Mechanism—Foreign protein in insects' saliva introduced when skin is penetrated for a blood meal Distribution: Almost everywhere—Fleas, mosquitoes, ants Suburbs and rural areas—Bees Urban areas—Hornets, wasps, yellow jackets	Hypersensitivity reaction Papular urticaria Firm papules; may be capped by vesicles or excoriated Little or no reaction in nonsensitized person	Treatment: Use antipruritic agents and baths Administer antihistamines Prevent secondary infection Prevention: Avoid contact Remove focus, such as untreated furniture, mattresses, carpets, and pets, where insects may live Apply insect repellent when exposure is anticipated
Chiggers—Harvest Mites		
Mechanism—Attach with claws and secrete a digestive substance that liquefies the host's epidermis	Erythematous papules Intense itching Favor warm areas of body, especially intertriginous areas and areas covered with clothing	Treatment: May require systemic steroids for extensive bites Prevention: Avoid contact, especially in areas of tall grass and underbrush Apply insect repellant when exposure is anticipated Spray insecticides such as diazinon in yards
Hymenopterans—Bees, Wasps, Hornets, Yellow Jackets, Fire Ants		
Mechanism: Injection of venom through stinging apparatus Venom contains histamine; allergenic proteins; and often a spreading factor, hyaluronidase Severe reactions caused by hypersensitivity or multiple stings	Local reaction—Small red area, wheal, itching, and heat Systemic reactions—May be mild to severe, including generalized edema, pain, nausea and vomiting, confusion, respiratory impairment, and shock	Treatment: Carefully scrape off stinger or pull out stinger as quickly as possible Cleanse with soap and water Apply cool compresses Apply common household product (e.g., lemon juice, paste made with aspirin or baking soda) Administer antihistamines Severe reactions—Administer epinephrine, corticosteroids; treat for shock Prevention: Teach child to wear shoes; to avoid wearing bright clothing, flowery prints, shiny jewelry, or perfumed grooming products (cologne, scented hairspray), which might attract the insect; and to avoid places where the insect may be contacted Hypersensitive children should wear medical identification to indicate allergy and therapy needed; family should keep emergency medication and be taught its administration
Black Widow Spider		
Mechanism—Venom injected through a clawlike appendage; has neurotoxic action Characteristics: Shiny black spider, with a body about 1.25 cm (0.5 inch) long and a red or orange hourglass-shaped marking on underside Avoids light and bites in self-defense	Mild sting at time of bite Area becomes swollen, painful, and erythematous Dizziness, weakness, and abdominal pain May produce delirium, paralysis, seizures, and (if large amount of venom absorbed) death	Treatment: Cleanse wound with antiseptic Apply cool compresses Administer antivenin Administer muscle relaxant, such as calcium gluconate; analgesics or sedatives; hydrocortisone or diazepam intravenously Prevention—Teach children to avoid places that harbor the spider (e.g., woodpiles)
Brown Recluse Spider		
Mechanism: Venom injected via fangs Venom contains powerful necrotoxin Characteristics: Slender spider, with long legs and body length of 1-2 cm; color is fawn to dark brown; recognized by fiddle-shaped mark on head Shy; bites only when annoyed or surprised Prefers dark areas where seldom disturbed	Mild sting at time of bite Transient erythema followed by bleb or blister; mild to severe pain in 2-8 h; purple, star-shaped area in 3-4 days; necrotic ulceration in 7-14 days (see Fig. 31.6) Systemic reactions may include fever, malaise, restlessness, nausea, vomiting, and joint pain Generalized petechial eruption Wounds heal with scar formation	Treatment: Apply cool compresses locally Administer antibiotics, corticosteroids Relieve pain Wound may require skin graft Prevention—Teach children to avoid possible nesting sites

TABLE 31.7 Skin Lesions Caused by Arthropods—cont'd

Mechanism and Characteristic	Manifestations	Management
Scorpions		
Mechanism: Sting by means of a hooked caudal stinger that discharges venom Venom of more venomous species contains hemolysins, endotheliolysins, and neurotoxins Characteristics—Usual habitat southwestern United States	Intense local pain, erythema, numbness, burning, restlessness, vomiting Ascending motor paralysis with seizures, weakness, rapid pulse, excessive salivation, thirst, dysuria, pulmonary edema, coma, and death Some species produce only local tissue reaction with swelling at puncture site (distinctive) Symptoms subside in a few hours Deaths occur among children <4 years of age, usually in first 24 h	Treatment: Delay absorption of venom by keeping child quiet; place involved area in dependent position Administer antivenin Relieve pain Admit to pediatric intensive care unit for surveillance Prevention—Teach children to avoid possible nesting sites
Ticks		
Mechanism—In process of sucking blood, head and mouth parts are buried in skin Characteristics: Feed on blood of mammals Significant in humans because of pathologic organism carried May be vectors of various infectious diseases, such as Rocky Mountain spotted fever, Q fever, tularemia, relapsing fever, Lyme disease, tick paralysis Must attach and feed for 1-2 h to transmit disease Usual habitat is wooded area	Tick usually attached to skin with head embedded Firm, discrete, intensely pruritic nodules at site of attachment May cause urticaria or persistent localized edema	Treatment: Grasp tick with tweezers (forceps) as close as possible to point of attachment Pull straight up with steady, even pressure; if using bare hands, use a tissue to touch tick during removal; wash hands thoroughly with soap and water Remove any remaining part (e.g., head) with sterile needle Cleanse wounds with soap and disinfectant Prevention—Teach children to avoid areas where prevalent Inspect skin (especially scalp) after being in wooded areas

Fig. 31.6 Brown recluse spider bite. Note central necrosis surrounded by purplish area and blisters. (From Weston, W. L., & Lane, A. T. [2007]. *Color textbook of pediatric dermatology* [4th ed.]. St. Louis, MO: Mosby.)

When a hymenopteran (bees in particular) stings, its barbed stinger penetrates the skin. As long as the stinger remains in the skin, the muscles push the stinger deeper, and the venom is pumped into the wound. The best approach is to remove the stinger as quickly as possible and to get away from the vicinity of other insects to prevent further injury. Children who have become sensitized to hymenopteran bites may demonstrate a severe systemic response that can be life threatening. One sting can produce generalized urticaria, respiratory difficulty (from laryngeal edema), hypotension, and death. Intramuscular administration of epinephrine provides immediate relief and must be available for emergency use.

Hypersensitive children should wear a medical identification bracelet. They should also have a kit that contains epinephrine and a hypodermic syringe. Families are reminded to check the expiration date on the kit and to replace an outdated one. They should determine whether a nurse is available at the school and find out what the school policy is regarding administration of drugs. If a school nurse is not present, someone at the school should be designated to inject the epinephrine in case of an emergency.

SCABIES

Scabies is an endemic infestation caused by the scabies mite, *Sarcoptes scabiei.* Lesions are created as the impregnated female burrows into the stratum corneum of the epidermis (never into living tissue) to deposit her eggs and feces. The inflammatory response causes intense pruritus that leads to punctate discrete excoriations secondary to the itching (Box 31.1). Maculopapular lesions are characteristically distributed in intertriginous areas: interdigital surfaces, the axillary-cubital area, popliteal folds, and the inguinal region. The observer must look for discrete papules, burrows, or vesicles (Fig. 31.7). Scabies is transmitted primarily through prolonged close personal contact, and it affects persons regardless of age, sex, personal hygiene, or socioeconomic status.

Nursing Care Management

The treatment of scabies is the application of a scabicide. The drug of choice in children and infants older than 2 months of age is permethrin 5% cream (Elimite). Alternative drugs are 10% crotamiton (cream or lotion) or oral ivermectin. Lindane can be neurotoxic and is contraindicated by the American Academy of Pediatrics (2018).

BOX 31.1 Clinical Manifestations of Scabies

Lesion

Children—Minute grayish brown, threadlike (mite burrows), pruritic
- Black dot at end of burrow (mite)

Infants—Eczematous eruption, pruritic

Distribution

Generally in intertriginous areas—Interdigital, axillary-cubital, popliteal, inguinal

Children older than 2 years of age—Primarily hands and wrists

Children younger than 2 years—Primarily feet and ankles

Fig. 31.7 Scabies. (From McCance, K., & Huether, S. [2010]. *Pathophysiology: The biological basis for disease in adults and children* [6th ed.]. St. Louis, MO: Mosby/Elsevier.)

Ivermectin, an oral medication, may be used to treat scabies in patients with secondary excoriations for whom topical scabicides are irritating and not well tolerated or whose infestation is refractory. However, the safety and efficacy of ivermectin for children weighing less than 15 kg (33 pounds) has not been established.

Because of the length of time between infestation and physical symptoms (30 to 60 days), all persons who were in close contact with the affected child need treatment. This may include boyfriends or girlfriends, babysitters, grandparents, and immediate family members. The objective is to treat as thoroughly as possible the first time. Enough medication for the entire family should be prescribed, with 2 oz allowed for each adult and 1 oz for each child.

PEDICULOSIS CAPITIS

Pediculosis capitis (head lice) is an infestation of the scalp by *Pediculus humanus capitis,* a common parasite in school-age children. These lice infestations create embarrassment and concern in the family and community. They can also cause a child to be ridiculed by other children. An important nursing role is education about pediculosis. Nurses should emphasize that anyone can get pediculosis; it has no respect for age, socioeconomic level, or cleanliness.

The adult louse lives only about 48 hours when away from a human host, and the life span of the average female is 1 month. The female lays her eggs at night at the junction of a hair shaft and close to the skin because the eggs need a warm environment. The **nits**, or eggs, hatch in approximately 7 to 10 days. Itching, caused by the crawling insect and saliva on the skin, is usually the only symptom. The louse is a blood-sucking organism that requires approximately five meals a day. Common areas involved are the occipital area, behind the ears, and the nape of the neck (Box 31.2).

BOX 31.2 Clinical Manifestations of Pediculosis

Pruritus (caused by crawling insects and insect saliva on skin)
Nits observable on hair shaft (see Fig. 31.8)

Distribution

Occipital area
Behind ears
Nape of neck
Eyebrows and eyelashes (occasionally) (caused by pubic lice)

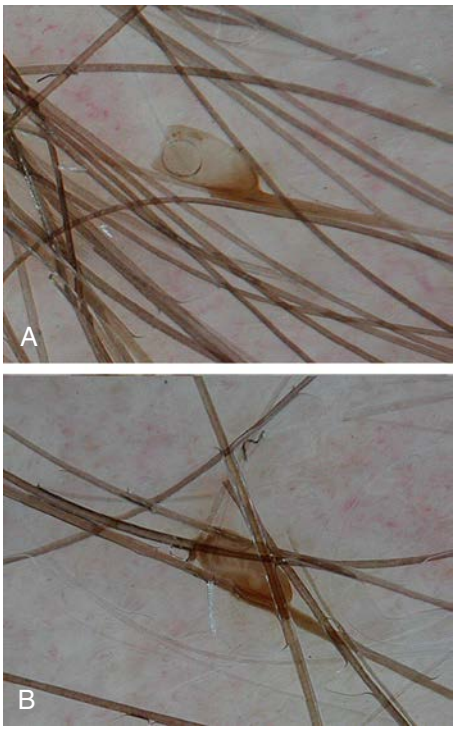

Fig. 31.8 A, Empty nit case. B, Viable nits. (From Stefani, A. D., Hofmann-Wellenhof, R., & Zalaudek, I. [2006]. Dermoscopy for diagnosis and treatment monitoring of pediculosis capitis. *Journal of the American Academy of Dermatology, 54*(5), 909–911.)

Diagnostic Evaluation

Diagnosis is made by observation of the white eggs (nits) firmly attached to the hair shafts (Fig. 31.8). Lice are small and grayish tan, have no wings, and are visible to the naked eye. Observation of the white eggs (nits) firmly attached to the hair shafts confirms the diagnosis. The nits, or eggs, appear as tiny whitish oval specks adhering to the hair shaft about 6 mm (0.25 inch) from the scalp. The adherent nature of the nits distinguishes them from dandruff, which falls off readily. Empty nit cases, indicating hatched lice, are translucent rather than white and are located more than 6 mm from the scalp. Because of their brief life span and mobility, adult lice are more difficult to locate. Nits must be differentiated from dandruff, lint, hair spray, and other items of similar size and shape. Scratch marks or inflammatory papules, caused by secondary infection, are also found on the scalp in the vulnerable areas.

Therapeutic Management

Treatment consists of the application of pediculicides and manual removal of nit cases. The drug of choice for infants and children is permethrin 1% cream rinse (Nix), which kills adult lice and nits. This product and preparations of pyrethrin with piperonyl butoxide (RID or A-200 Pyrinate) can be obtained without a prescription and are effective and safe. A second treatment at 7 to 10 days is advised to ensure a cure. If neither permethrin nor pyrethrin products are effective, the prescription drug 0.5% malathion, which has been approved for treatment of head lice, can be used. However, malathion is not recommended for children younger than 2 years of age.

Because of concerns that head lice may be developing resistance to chemical shampoos and that repeated exposure of children to strong chemicals on the scalp may be unwise, effective nonchemical control measures are essential. Removal of nits from the child's hair with a metal nit comb daily is a control measure following treatment with a pediculicide.

Nursing Care Management

An important nursing role is educating the parents about pediculosis. Nurses should emphasize that *anyone* can get pediculosis; it has no respect for age, gender, socioeconomic level, or cleanliness. Lice do not jump or fly, but they can be transmitted from one person to another on personal items. Children are cautioned against sharing combs, hair ornaments, hats, caps, scarves, coats, and other items used on or near the hair. Lice are not carried or transmitted by pets (Gunning, Kiraly, & Pippitt, 2019).

Nurses or parents should carefully inspect children who scratch their heads more than usual for bite marks, redness, and nits. The hair is systematically spread with two flat-sided sticks or tongue depressors, and the scalp is observed for any movement that indicates a louse. Nurses should wear gloves when examining the hair.

If evidence of infestation is found, it is important to treat the child according to the directions on the label of the pediculicide. Permethrin 1% lotion or shampoo (Nix) is recommended for first-line treatment. Alternative treatments should not be used unless permethrin fails after two treatments (Gunning et al., 2019). Parents are advised to read the directions carefully before beginning treatment. The child is made as comfortable as possible during the application process because the pediculicide must remain on the scalp and hair for several minutes. A useful strategy is playing "beauty parlor" while shampooing. The child lies supine with the head over a sink or basin and covers the eyes with a dry towel or washcloth. This prevents medication, which can cause chemical conjunctivitis, from splashing into the eyes. If eye irritation occurs, the eyes must be flushed well with tepid water. It is not necessary to remove the nits after treatment because only live lice cause infestation. However, because none of the pediculicides is 100% effective in killing all of the eggs, the makers of some pediculicides recommend manual removal of the nits after treatment. An extra-fine-tooth comb that is included in many commercial pediculicides or is available at community pharmacies facilitates manual removal. Live lice survive for up to 48 hours away from the host, but nits are shed into the environment and are capable of hatching in 7 to 10 days; retreatment is required. Therefore measures must be taken to prevent further infestation (see Community Focus box). Spraying with insecticide is not recommended because of the danger to children and animals. Families should also be advised that the pediculicide is relatively expensive, especially when several members of the household require treatment. Families may be inclined to try home remedies such as petroleum jelly, oils, vinegar, butter, alcohol, and mayonnaise to treat the lice; however, there is no evidence demonstrating the effectiveness of these remedies (Gunning et al., 2019).

COMMUNITY FOCUS

Focus Preventing the Spread and Recurrence of Pediculosis

- Machine wash all washable clothing, towels, and bed linens in water hotter than 130°F and dry them in a hot dryer for at least 20 minutes. Dry clean nonwashable items.
- Thoroughly vacuum carpets, car seats, pillows, stuffed animals, rugs, mattresses, and upholstered furniture.
- Seal nonwashable items in plastic bags for 14 days if unable to dry clean or vacuum.
- Soak combs, brushes, and hair accessories in lice-killing products for 1 hour or in boiling water for 10 minutes.
- In daycare centers, store children's clothing items such as hats and scarves and other headgear in separate cubicles.
- Discourage the sharing of items such as hats, scarves, hair accessories, combs, and brushes among children in group settings such as daycare centers and schools.
- Avoid physical contact with infected individuals and their belongings, especially clothing and bedding.
- Inspect children in a group setting regularly for head lice.
- Provide educational programs on the transmission of pediculosis, its detection, and treatment.

Modified from Chin, J. (Ed.). (2000). *Control of communicable diseases manual.* Washington, DC: American Public Health Association; and Gunning, K., Kiraly, B., & Pippitt, K. (2019). Lice and scabies: Treatment update. *American Family Physician, 99*(10), 635–642.

RICKETTSIAL DISEASES

The organisms responsible for a number of disorders are transmitted to human beings via arthropods (Table 31.8). Mammals become infected only through the bites of infected lice, fleas, ticks, and mites, all of which serve as both infectors and reservoirs. Rickettsiae are intracellular parasites, similar in size to bacteria that inhabit the alimentary tract of a wide range of natural hosts. Rickettsial diseases are more common in temperate and tropical climates where humans live in association with arthropods. Infection in humans is incidental (except epidemic typhus) and not necessary for the survival of the rickettsial species. However, after the organism invades a human, it causes a disease that varies in intensity from a benign, self-limiting illness to a disease that is fulminating and fatal.

LYME DISEASE

Lyme disease is the most common tickborne disorder in the United States. It is caused by the spirochete *Borrelia burgdorferi,* which enters the skin and bloodstream through the saliva and feces of ticks, especially the deer tick (Steere, Strle, Wormser, et al., 2016). Most cases of Lyme disease are reported in the Northeast from southern Maine to northern Virginia in the months of May through October and more commonly occur in children 5 to 15 years of age and adults 45 to 55 years of age (Steere et al., 2016).

Clinical Manifestations

The disease may be initially seen in any of three stages. The first stage, early localized disease, consists of the tick bite at the time of inoculation, followed in 3 to 30 days by the development of erythema migrans at the site of the bite. The lesion begins as a small erythematous papule that enlarges radially up to 30 cm (12 inches) over a period of days to weeks. It results in a large circumferential ring with a raised, edematous

TABLE 31.8 Eruptions Caused by Rickettsiae

Disorder, Organism, and Host	Manifestations	Management	Comments
Rocky Mountain spotted fever—*Rickettsia rickettsii* Arthropod—Tick Transmission—Tick Mammal source—Wild rodents, dogs	Gradual onset—Fever, malaise, anorexia, myalgia Abrupt onset—Rapid temperature elevation, chills, vomiting, myalgia, severe headache Maculopapular or petechial rash primarily on extremities (ankles and wrists) but may spread to other areas, characteristically on palms and soles	Control—Protection from tick bite by wearing proper apparel, tick repellent Tetracycline or chloramphenicol Vigorous supportive therapy	Usually self-limiting in children Onset in children may resemble any infectious disease Severe disease rare in children Inspect children and dogs regularly if they play in wooded areas See Table 31.7 for management of ticks
Epidemic typhus—*Rickettsia prowazekii* Arthropod—Body louse Transmission—Infected feces into broken skin Mammal source—Humans	Abrupt onset of chills, fever, diffuse myalgia, headache, malaise Maculopapular rash becoming petechial 4-7 days later, spreading from trunk outward	Control—Immediate destruction of vectors Tetracycline or chloramphenicol Supportive treatment	Isolate patient until deloused See discussion in this chapter for management of pediculosis Excreta from infected lice also in dust; patient's clothing, bedding, and possessions are disinfected and washed in hot water
Endemic typhus—*Rickettsia typhi* Arthropod—Rat fleas or lice Transmission—Flea bite; inhaling or ingesting flea excreta Mammal source—Rats	Headache, arthralgia, backache followed by fever; may last 9-14 days Maculopapular rash after 1-8 days of fever; begins in trunk and spreads to periphery; rarely involves face, palms, soles	Control—Eliminate rat reservoir, insect vectors, or both Tetracycline or chloramphenicol Supportive treatment	Fairly common in United States Shorter duration than epidemic typhus Mild, seldom fatal illness Difficult to distinguish from epidemic typhus
Rickettsialpox—*Rickettsia akari* Arthropod—Mouse mite Transmission—Mite Mammal source—House mouse	Maculopapular rash following primary lesion; eschar at site of bite; fever, chills, headache	Control—Eradication of rodent reservoir and mite vector Tetracycline or chloramphenicol Supportive treatment	Self-limiting nonfatal disease Initially endemic in New York City but now found in many cities in United States

Fig. 31.9 Lyme disease. Note annular red rings in erythema chronicum migrans. (From Weston, W. L., & Lane, A. T. [2007]. *Color textbook of pediatric dermatology* [4th ed.]. St. Louis, MO: Mosby.)

doughnut-like border resulting in a bull's-eye appearance (Fig. 31.9). The thigh, groin, and axilla are common sites. The lesion is described as "burning," feels warm to the touch, and occasionally is pruritic. The single annular rash may be associated with fever, myalgia, headache, or malaise.

The second stage, early disseminated disease, occurs 3 to 10 weeks after inoculation. Many patients develop multiple smaller, secondary annular lesions without the indurated center. They may occur anywhere except on the palms and soles, and in untreated patients they disappear in 3 to 4 weeks. Constitutional symptoms, including fever, headache, malaise, fatigue, anorexia, stiff neck, generalized lymphadenopathy, splenomegaly, conjunctivitis, sore throat, abdominal pain, and cough, are often observed. A focal neurologic finding of cranial nerve palsy (seventh nerve palsy) occurs in 3% to 5% of cases. Additional manifestations include ophthalmic conditions such as optic neuritis, uveitis, conjunctivitis, and keratitis.

Finally, the third stage and the most serious stage of the disease is characterized by systemic involvement of neurologic, cardiac, and musculoskeletal systems that appears 2 to 12 months after inoculation. Lyme arthritis is the most common manifestation with pain, swelling, and effusion. In children the arthritis is characterized by intermittently painful swollen joints (primarily the knees), with spontaneous remissions and exacerbations. Rare neurologic features of pediatric Lyme disease may include meningitis, encephalitis, and polyneuritis (Koedel, Fingerle, & Pfister, 2015). Cardiac complications, which may appear in a small percentage of persons during the early phase of the infection, are commonly acute atrioventricular conduction abnormalities and less commonly pericarditis or mild left ventricular dysfunction (Steere et al., 2016).

Diagnostic Evaluation

Diagnosis is based primarily on the history, observation of the lesion, and clinical manifestations. Serologic testing for Lyme disease at the time of a recognized tick bite is not recommended because antibodies are not detectable in most persons (American Academy of Pediatrics, 2018). Laboratory diagnosis can be established in later stages with a two-step approach that includes the screening test enzyme immunoassay or immunofluorescent immunoassay and, if the results are equivocal or positive, with Western immunoblot testing, as outlined by the Centers for Disease Control and Prevention (2017) and adopted by the American Academy of Pediatrics (2018).

Therapeutic Management

Early and appropriate treatment is essential to prevent complications. Children older than 8 years of age are treated with oral doxycycline; amoxicillin is recommended for children younger than 8 years of age (American Academy of Pediatrics, 2018). For patients who are allergic to penicillin, alternative drugs include cefuroxime or erythromycin.

The length of treatment depends on the clinical response and other disease manifestations, but it usually lasts from 14 to 21 days (American Academy of Pediatrics, 2018). The treatment is effective in preventing second-stage manifestations in most cases. Persons who have removed ticks from themselves should be monitored closely for signs and symptoms of tickborne diseases for 30 days; in particular, they should be monitored for erythema migrans, a red expanding skin lesion at the site of the tick bite that may suggest Lyme disease. People who develop a skin lesion or viral infection–like illness within 1 month of an attached tick should seek prompt medical attention. Treatment of erythema migrans most often prevents development of later stages of Lyme disease.

Neurologic, cardiac, and arthritic manifestations are managed with oral or intravenous (IV) antibiotics, such as ceftriaxone, cefotaxime, or penicillin G. Follow-up care is important in ensuring that treatment is initiated or terminated as needed.

Nursing Care Management

The major emphasis of nursing care should be educating parents to protect their children from exposure to ticks. Children should avoid tick-infested areas or wear light-colored clothing so that ticks can be spotted easily, tuck pant legs into socks, and wear a long-sleeved shirt tucked into pants when in wooded areas. Parents and children need to perform regular tick checks when they are in infested areas (with special attention to the scalp, neck, armpits, and groin areas). Parents should also be alert for signs of the skin lesion, especially if their children have been in tick-infested areas. The American Academy of Pediatrics (2018) points out that the risk of infection after a deer tick bite, even in endemic regions of the United States, is 1% to 4%; children bitten by a deer tick in nonendemic regions should not receive antibiotic prophylaxis.

Parents should also be educated on tick removal in the event of a tick bite. The tick should be grasped firmly with tweezers and pulled straight out. The application of nail polish or petroleum jelly is not recommended and does not appear to affect tick withdrawal, as has been hypothesized. Concerns about tick engorgement or tick remains (such as the tick head) left in the person's body appear to be unfounded; there is no need for medical examination of the tick itself. After the tick is removed, wash the bite area with an iodine scrub, rubbing alcohol, or plain soap and water.

Insect repellents containing diethyltoluamide (DEET) and permethrin can protect against ticks, but parents should use these chemicals cautiously. Although there have been reports of serious neurologic complications in children resulting from frequent and excessive application of DEET repellants, the risk is low when they are used properly. Products with DEET should be applied sparingly according to label instructions and not applied to a child's face, hands, or any areas of irritated skin. Plant essential oils, such as juniper and Chinese weeping cedar essential oil, have been reported as being safe and effective as an insect repellent without the effects of chemicals (Eisen & Dolan, 2016). Permethrin-treated clothing has also been shown to be effective in repelling ticks (Eisen & Dolan, 2016). After the child returns indoors, treated skin should be washed with soap and water. Information about Lyme disease can be obtained from the American Lyme Disease Foundation, Inc.,[a] or from the Centers for Disease Control and Prevention (https://www.cdc.gov/lyme/).

Pet Bites

Animal bites are common in childhood. Wild animal bites are discussed in relation to rabies in Chapter 30. The present discussion is directed primarily toward dog bites because most animal bites to children are caused by dogs. Cat bites are less frequent, although cat scratches are extremely common (see Cat Scratch Disease later in the chapter).

Most injuries caused by dogs or cats are to the upper extremities. Small children are likely to be bitten or scratched on the head, face, and neck because they tend to put their heads near the animal's head and flail their arms rather than protecting their heads. Most dogs involved are owned by the family of the victim or by a neighbor. Injuries vary in intensity from small puncture wounds to complete evulsion of tissue that is associated with significant crush injury. Animal bites are potentially serious because of the likelihood of significant infection.

Therapeutic Management

General wound care consists of rinsing the wound with copious amounts of saline or lactated Ringer solution under pressure via a large syringe and of washing the surrounding skin with mild soap. A clean pressure dressing is applied, and the extremity is elevated if the wound is bleeding. Medical evaluation is advised because of the danger of tetanus and rabies, although dogs in most urban areas are required to be immunized against rabies. Bites from wild animals, such as squirrels, bats, raccoons, foxes, and skunks, are potentially dangerous.

Prophylactic antibiotics are indicated for puncture wounds and wounds in areas that may prove to be cosmetically or functionally impaired if infected. Extensive lacerations are debrided and loosely sutured to allow drainage in the event of infection. Tetanus toxoid is administered according to standard guidelines (see Chapter 6, Immunizations), and rabies protocol is followed (see Chapter 30, Rabies). Injuries to poorly vascularized areas, such as the hands, are more likely to become infected than those in more vascularized areas, such as the face; puncture wounds are more likely to become infected than lacerations.

Nursing Care Management

The most important aspect related to animal bites is prevention. Children should understand animal behavior and develop respect for animals (see Community Focus box). Parents should monitor their children's behavior with dogs and instruct them not to tease or surprise dogs, invade their territory, interfere with their feeding or sleeping, take their toys, or interact with sick or injured dogs or dogs with pups. Parents who are considering getting a pet, especially a dog, for themselves or their children, should select a dog that has a high level of sociability with, and is unlikely to be a danger to, children.

HUMAN BITES

Children often acquire lacerations from the teeth of other humans in rough play, during fights, or as victims of child abuse. Some young children bite others out of frustration or anger. Because human dental plaque and gingiva harbor pathogenic organisms, all human bites

COMMUNITY FOCUS

Animal Safety

To avoid bites and scratches

- Never bother a pet when it's eating or pull its food or water away.
- Don't tease a dog or cat or pull its tail or ears.
- Never bother a pet when it's sleeping.
- Don't take a toy or bone away from a cat or dog or hold it out of reach of the animal.
- Never try to get near a pet with its babies (like a cat with kittens or a dog with puppies). Animal mothers are very protective and will bite to keep you away.
- When lifting a rabbit, hamster, guinea pig, or gerbil from its cage, do it slowly. Be sure to hold the animal underneath its belly.
- Never pick up or hold a rabbit by its ears.
- When pulling an iguana, lizard, snake, or other reptile from its tank, do it slowly and carefully. Then wash your hands right away because reptiles can carry bacteria like Salmonella on their skin.
- Never stick your bare hand into a fish tank — most fish can't hurt you. But a few types of fish can and do sting if they get upset. The water also contains germs that could cause a skin infection.
- If a pet looks sick or is injured, stay far away. An animal that normally loves to be petted and played with may get very upset and even bite when it is feeling ill. Tell an adult so he or she can get help for the animal.

To keep your cool around dogs

- Never pet or touch a strange dog, even if it runs up to you and seems like it might be friendly.
- If a dog starts running toward you, don't run. Running away can make the dog want to chase after you — even if it doesn't want to hurt you, its instincts will tell it to chase.
- If a strange dog approaches you, try to stand very still. This may be scary for a minute or two, but often the dog will become bored and walk away. If the dog tries to sniff you, let it sniff — this is its way of checking you out.
- Walk away from a strange dog very slowly. Don't wave your arms around or make a lot of noise because these actions will only excite the dog. Look straight ahead and not into the dog's eyes.
- If you are very afraid of a strange dog or a strange dog tries to bite or attack you, tell an adult as soon as possible. He or she can find the dog's owner.

should receive attention. Delayed treatment increases the risk of infection.

The wound is washed vigorously with soap and water, and a pressure dressing is applied to stop bleeding. Ice applications minimize discomfort and swelling. Increased pain or redness at the wound site is an indication that the child should receive medical attention for antibiotic therapy. Tetanus toxoid is needed if the child is insufficiently immunized. Wounds larger than 6 mm should receive medical attention.

CAT SCRATCH DISEASE

Cat scratch disease is the most common cause of regional lymphadenitis in children and adolescents. It usually follows the scratch or bite of an animal (a cat or kitten in 99% of cases) and is caused by *Bartonella henselae,* a gram-negative bacterium. The disease is usually a benign, self-limiting illness that resolves spontaneously in about 4 to 6 weeks (American Academy of Pediatrics, 2018).

The usual manifestations are a painless, nonpruritic erythematous papule at the site of inoculation, followed by regional lymphadenitis. The lymph nodes most commonly involved are axillary epitrochlear, cervical, submandibular, inguinal, and preauricular. The disease may persist for several months before gradual resolution. In some children, especially those who are immunocompromised, the adenitis may progress to suppuration. Some children may develop serious complications that include encephalitis, hepatitis, and Parinaud oculoglandular syndrome. This syndrome is characterized by granulomatous lesions on the palpebral conjunctiva associated with swelling of the ipsilateral preauricular nodes.

Diagnosis is made on the basis of (1) history of contact with a cat or kitten, (2) the presence of regional lymphadenopathy for several days, and (3) serologic identification of the causative organism by indirect fluorescent antibody assay or polymerase chain reaction test (American Academy of Pediatrics, 2018).

Treatment is primarily supportive. Some experts recommend a 5-day course of oral azithromycin to hasten recovery (American Academy of Pediatrics, 2018). Antibiotics do not shorten the duration or prevent progression to suppuration but may be helpful in severe forms of the disease. Trimethoprim-sulfamethoxazole, ciprofloxacin, gentamicin, and rifampin have shown some benefit in uncontrolled clinical studies. Enlarged painful nodes may be treated by needle aspiration.

Children should be cautioned about playing with aggressive kittens that bite or scratch. Wounds should be washed with soap and water. Analgesics may be given for discomfort. Most children can continue normal activities during the disease. The animals are not ill during the time they transmit the disease, and most authorities do not recommend disposal of a cherished pet.

MISCELLANEOUS SKIN DISORDERS

A number of miscellaneous skin lesions occur in children. Some occur as a result of congenital disorders and are inherited as an autosomal dominant trait (Table 31.9). **Ichthyoses** are a heterogeneous group of disorders characterized by scaling that create challenging problems in treatment. These disorders are not discussed in detail here because of their wide variability.

SKIN DISORDERS ASSOCIATED WITH SPECIFIC AGE-GROUPS

Several common dermatologic conditions are confined to children in specific age-groups. These conditions include diaper, atopic, and seborrheic dermatitis, which occurs predominantly in infants, and acne, which is most common in adolescence.

DIAPER DERMATITIS

Diaper dermatitis is common in infants and one of several acute inflammatory skin disorders caused either directly or indirectly by wearing diapers. The peak age of occurrence is 9 to 12 months of age, and the incidence is greater in bottle-fed infants than in breastfed infants.

Pathophysiology and Clinical Manifestations

Diaper dermatitis is caused by prolonged and repetitive contact with an irritant (e.g., urine, feces, soaps, detergents, ointments, friction). Although the irritant in most cases is urine and feces, a combination of factors contributes to irritation.

Prolonged contact of the skin with diaper wetness produces higher friction, greater abrasion damage, increased transepidermal

TABLE 31.9 Miscellaneous Skin Disorders

Disease and Causative Agent	Local Manifestations	Management	Comments
Urticaria—Usually allergic response to drugs or infection	Development of wheals Vary in size and configuration and tend to appear quickly, spread irregularly, and fade within a few hours May be constant or intermittent, sparse or profuse, small or large, discrete or confluent May be acute, chronic, or recurrent in acute attacks	Topical soothing and antipruritic applications Antihistamines Cortisone in severe cases Severe involvement may require epinephrine	Known etiologic agents should be avoided May be accompanied by malaise, fever, lymphadenopathy Severe cases may involve mucous membranes, internal organs, and joints Obstruction to air passages constitutes medical emergency
Intertrigo—Mechanical trauma and aggravating factors of excessive heat, moisture, and sweat retention	Red, inflamed, moist, partially denuded, marginated areas, the shape of which is determined by location Appears where opposing skin surfaces rub together, such as intergluteal folds, groin, neck, and axilla Excessive moisture and obesity are often factors	Maintenance of cleanliness and dryness of affected areas Skinfolds kept separated with a generous supply of nonmedicated powder Expose to air and light Remove excess clothing	A form of diaper irritation Prevent recurrence by keeping susceptible areas clean and dry Frequently associated with overheating from too much clothing Common in tracheostomy patients with short necks and copious secretions
Psoriasis—Cause unknown; hereditary predisposition; may be triggered by stress	Round, thick, dry, reddish patches covered with coarse, silvery scales over trunk and extremities; first lesions commonly appear in scalp; facial lesions more common in children than in adults Affected cells proliferate at a much more rapid rate than normal cells	Tar preparations in combination with ultraviolet B light or natural sunlight Topical corticosteroids Topical vitamin D analog calcipotriene Phenol and saline solutions followed by a tar shampoo to remove scales Keratolytic agents (salicylic acid) Acitretin Emollients may provide relief	Uncommon in children younger than 6 years Affected patients are otherwise healthy Coal tar acts synergistically with ultraviolet light Keratolytic agents enhance absorption of corticosteroids Humidifiers may help in winter
Alopecia[a]			
Alopecia areata	Sudden onset of asymptomatic, noninflammatory, round, bald patches in hairy parts of body	Psychologic support Minoxidil (peripheral vasodilator)	Family history in 10%-26% of cases Some concern regarding drug therapy safety Refer to support groups[a]
Traumatic alopecia	Traction alopecia around scalp margins from tight hair styles (e.g., braids, ponytails, cornrows)	Counseling on hair styling, use of hair cosmetics, hot combs, rollers	More prevalent in African American children and adolescents Prolonged traction can produce fibrosis of hair root and permanent loss
Trichotillomania	Compulsive hair pulling	Determine and treat cause	Chronic hair pulling may require psychologic therapy
Tinea capitis	See Table 31.5	See Table 31.5	See Table 31.5
Erythema multiforme (Stevens-Johnson syndrome)—Cause unknown; associated with ingestion of some drugs; often follows upper respiratory tract infection	Erythematous papular rash Lesions enlarge by peripheral expansion, develop central vesicle Involves most skin surfaces except scalp May extend to mucous membranes, especially oral, ocular, and urethral	Symptomatic and supportive Maintenance of adequate intake of fluids (oral or intravenous), calories, and protein Moist wound care, hydrogels such as CarraGauze, Vaseline, or Aquaphor Appropriate treatment of complications Diligent monitoring of urine volume and specific gravity, hemoglobin and hematocrit, serum electrolyte levels, total body weight	Rash often preceded by fever and malaise Complications include renal failure and severe eye disease Respiratory involvement in a number of cases Self-limiting, but recovery may extend for weeks; skin lesions may subside without scarring; mucous membrane lesions may persist for months Recurrence rate, 20%; mortality rate as high as 10% High mutation rate
Neurofibromatosis—Inherited disorder; autosomal dominant inheritance pattern	Café-au-lait spots, pigmented nevi, axillary freckling Slow-growing cutaneous and subcutaneous neurofibromas	Symptomatic treatment of associated manifestations (e.g., speech defects, seizures, skeletal defects [scoliosis, kyphosis], learning disabilities) Surgical removal of troublesome tumors	Refer to support groups[b] Family needs to know about genetic implications

Fig. 31.10 Irritant diaper dermatitis. Note the sharply demarcated edges. (From Habif, T. P. [2010]. *Clinical dermatology: A color guide to diagnosis and therapy* [5th ed.]. St. Louis, MO: Mosby.)

Fig. 31.11 Candidiasis of diaper area. Note the beefy red central erythema with satellite pustules. (From Paller, A. S., & Mancini, A. J. [2011]. *Hurwitz clinical pediatric dermatology* [4th ed.]. St. Louis, MO: Saunders Elsevier.)

permeability, and increased microbial counts. Healthy skin is less resistant to potential irritants.

Although ammonia was once thought to cause diaper rash because of the association between the strong odor on diapers and dermatitis, ammonia alone is not sufficient. The irritant quality of urine is related to an increase in pH from the breakdown of urea in the presence of fecal urease. The increased pH promotes the activity of fecal enzymes, principally the proteases and lipases, which act as irritants. Fecal enzymes also increase the permeability of skin to bile salts, another potential irritant in feces.

The eruption of diaper dermatitis is manifested primarily on convex surfaces or in folds. The lesions represent a variety of types and configurations. Eruptions involving the skin in most intimate contact with the diaper (e.g., the convex surfaces of buttocks, inner thighs, mons pubis, scrotum) but sparing the folds are likely to be caused by chemical irritants, especially from urine and feces (Fig. 31.10). Other causes are detergents or soaps from inadequately rinsed cloth diapers or the chemicals in disposable wipes. Perianal involvement is usually the result of chemical irritation from feces, especially diarrheal stools. *Candida albicans* infection produces perianal inflammation and a maculopapular rash with satellite lesions that may cross the inguinal fold (Fig. 31.11). It is seen in up to 90% of infants with chronic diaper dermatitis and should be considered in diaper rashes that are recalcitrant to treatment.

Nursing Care Management

Nursing interventions are aimed at altering the three factors that produce dermatitis: wetness, pH, and fecal irritants. The most significant factor amenable to intervention is the moist environment created in the diaper area. Changing the diaper as soon as it becomes wet eliminates a large part of the problem and removing the diaper to expose healthy skin to air facilitates drying. The use of a hair dryer or heat lamp is not recommended because these devices can cause burns.

Diaper construction has a significant impact on the incidence and severity of diaper dermatitis. Superabsorbent disposable paper diapers reduce diaper dermatitis. They contain an absorbent gelling material that binds water tightly to decrease skin wetness, maintains pH control by providing a buffering capacity, and decreases skin irritation by preventing mixing of urine and feces in the diaper. Guidelines for controlling diaper rash are presented in the Family-Centered Care box. A common misconception about using cornstarch on skin is that it promotes the growth of *C. albicans*. Neither cornstarch nor talcum powder promotes the growth of fungi under conditions normally found in the diaper area. Based on safety in terms of inhalation injury, cornstarch is the preferred product. Talcum powder should not be used.

FAMILY-CENTERED CARE

Controlling Diaper Rash

Keep skin dry.[a]
- Use superabsorbent disposable diapers to reduce skin wetness.
- Change diapers as soon as soiled—especially with stool—whenever possible, preferably once during the night.
- Expose healthy or only slightly irritated skin to air, not heat, to dry completely.

Apply ointment, such as zinc oxide or petrolatum, to protect skin, especially if skin is very red or has moist, open areas.
- Avoid removing skin barrier cream with each diaper change; remove waste material and reapply skin barrier cream.
- To completely remove ointment, especially zinc oxide, use mineral oil; do not wash vigorously.

Avoid overwashing the skin, especially with perfumed soaps or commercial wipes, which may be irritating.
- May use a moisturizer or nonsoap cleanser, such as cold cream or Cetaphil, to wipe urine from skin.
- Gently wipe stool from skin using a soft cloth and warm water.
- Use disposable diaper wipes that are detergent and alcohol-free.

[a]Powder helps keep the skin dry, but talcum powder is dangerous if breathed into the lungs. Plain cornstarch or cornstarch-based powder is safer. When using any powder product, first shake it into your hand and then apply it to the diaper area. Store the container away from the infant's reach; keep the container closed when not in use.

ATOPIC DERMATITIS (ECZEMA)

Atopic dermatitis (AD), also referred to as eczema, refers to a descriptive category of dermatologic diseases and not to a specific etiology. AD is a chronic relapsing inflammatory skin disorder that results in itching

Fig. 31.12 Atopic dermatitis. (From Gupta, D. [2015]. Atopic dermatitis. *Medical Clinics of North America, 99*(6), 1269–1285.)

and lesions (Fig. 31.12; Grey & Maquiness, 2016). It occurs in 20% of children (Page, Weston, & Loh, 2016). AD manifests in three forms based on the child's age and the distribution of lesions:

1. **Infantile** (**infantile eczema**)—Usually begins at 2 to 6 months of age; generally undergoes spontaneous remission by 3 years of age
2. **Childhood**—May follow the infantile form; occurs at 2 to 3 years of age; 90% of children have manifestations by age 5 years
3. **Preadolescent and adolescent**—Begins at about 12 years of age; may continue into the early adult years or indefinitely

The diagnosis of AD is based on a combination of history and morphologic findings (Box 31.3). Although symptoms can vary among individuals, one common symptom is pruritus. Itching can be mild, moderate, or severe, and can intensify the inflammation and erythema associated with the lesions; itching can become so severe that the lesions bleed. Lesions gradually disappear when the scratching is stopped.

Although the cause is not fully understood, AD is believed to have genetic and environmental factors (Nguyen, Leonard, & Eichenfield, 2015). Most children with infantile AD have a family history of eczema, asthma, food allergies, or allergic rhinitis, which strongly supports a genetic predisposition. The cause is unknown but appears to be related to abnormal function of the skin, including alterations in perspiration, peripheral vascular function, and heat tolerance. Manifestations of the chronic disease improve in humid climates and get worse in the fall and winter, when homes are heated and environmental humidity is lower. The disorder can be controlled but not cured. A recent study of 250 patients with AD showed that the severity of AD significantly affected their quality of life, with more severe disease resulting in a lower quality of life (Holm, Agner, Causen, et al., 2016). Furthermore, the study reported a lower quality of life among females and among patients with eczema on their face (Holm et al., 2016).

Therapeutic Management

The major goals of management are to (1) hydrate the skin, (2) relieve pruritus, (3) reduce flare-ups or inflammation, and (4) prevent and control secondary infection. The general measures for managing AD focus on reducing pruritus and other aspects of the disease. Management strategies include avoiding exposure to skin irritants or allergens; avoiding overheating; and administering medications such as antihistamines, topical immunomodulators, topical steroids, and (sometimes) mild sedatives as indicated.

Enhancing skin hydration and preventing dry, flaky skin are accomplished in a number of ways, depending on the child's skin characteristics and individual needs. A tepid bath with a mild soap (Dove or Neutrogena), no soap, or an emulsifying oil followed immediately by application of an emollient (within 3 minutes) assists in trapping moisture and preventing its loss. Bubble baths and harsh soaps should be avoided. The bath may need to be repeated once or twice daily,

BOX 31.3 Clinical Manifestations of Atopic Dermatitis

Distribution of Lesions

Infantile form—Generalized, especially face, scalp, neck, and extensor surfaces of extremities

Childhood form—Flexural areas (antecubital and popliteal fossae, neck), wrists, ankles, and feet

Preadolescent and adolescent form—Face, sides of neck, hands, feet, face, and antecubital and popliteal fossae (to a lesser extent)

Appearance of Lesions

Infantile Form

Erythema
Vesicles
Papules
Weeping
Oozing
Crusting
Scaling
Often symmetric

Childhood Form

Symmetric involvement
Clusters of small erythematous or flesh-colored papules or minimally scaling patches
Dry and may be hyperpigmented
Lichenification (thickened skin with accentuation of creases)
Keratosis pilaris (follicular hyperkeratosis) common

Adolescent or Adult Form

Same as childhood manifestations
Dry, thick lesions (lichenified plaques) common
Confluent papules

Other Physical Manifestations

Intense itching
Unaffected skin dry and rough
African American children likely to exhibit more papular or follicular lesions than white children
May exhibit one or more of the following:

- Lymphadenopathy, especially near affected sites
- Increased palmar creases (many cases)
- Atopic pleats (extra line or groove of lower eyelid)
- Prone to cold hands
- Pityriasis alba (small, poorly defined areas of hypopigmentation)
- Facial pallor (especially around nose, mouth, and ears)
- Bluish discoloration beneath eyes ("allergic shiners")
- Increased susceptibility to unusual cutaneous infections (especially viral)

depending on the child's status; excessive bathing without emollient application only dries out the skin. Some lotions are not effective, and emollients should be chosen carefully to prevent excessive skin drying. Aquaphor, Cetaphil, and Eucerin are acceptable lotions for skin hydration. A nighttime bath followed by emollient application and dressing in soft cotton pajamas may help alleviate most nighttime pruritus.

Sometimes colloid baths, such as the addition of 2 cups of cornstarch to a tub of warm water, provide temporary relief of itching and may help the child sleep if given before bedtime. Cool wet compresses are soothing to the skin and provide antiseptic protection.

Oral antihistamine drugs (such as hydroxyzine or diphenhydramine) usually relieve moderate or severe pruritus. Nonsedating antihistamines such as loratadine (Claritin) or fexofenadine (Allegra) may be preferred for daytime pruritus relief. Because pruritus increases at night, a mildly sedating antihistamine may be needed.

Occasional flare-ups require the use of topical steroids to diminish inflammation. Low-, moderate-, or high-potency topical corticosteroids are prescribed, depending on the degree of involvement, the area of the body to be treated, the child's age, the potential for local side effects (striae, skin atrophy, and pigment changes), and the type of vehicle to be used (e.g., cream, lotion, ointment). Patients receiving topical corticosteroid therapy for chronic conditions should be evaluated for risk factors for suboptimal linear growth and reduced bone density. Topical immunomodulators, a nonsteroidal treatment for AD, are best used at the beginning of a "flare-up" just as the skin becomes red and itches. Second-line management for children with AD includes immunomodulator medications such as tacrolimus and pimecrolimus (Grey & Maquiness, 2016). These medications are approved for use in children 2 years of age and older (Grey & Maquiness, 2016). Both drugs can be used freely on the face without worrying about steroid side effects.

If secondary skin infections occur in children with AD, these infections are managed with appropriate systemic antibiotics. Obtaining cultures from affected areas and the child's nares is helpful to ensure appropriate therapy (Page et al., 2016).

Nursing Care Management

Assessment of the child with AD includes a family history for evidence of atopy, a history of previous involvement, and any environmental or dietary factors associated with the present and previous exacerbations. The skin lesions are examined for type, distribution, and evidence of secondary infection. Parents are interviewed regarding the child's behavior, especially in relation to scratching, irritability, and sleeping patterns. Exploration of the family's feelings and methods of coping is also important.

The nursing care of the child with AD is challenging. Controlling the intense pruritus is imperative if the disorder is to be successfully managed because scratching leads to new lesions and may cause secondary infection. In addition to the medical regimen, other measures can be taken to prevent or minimize the scratching. Fingernails and toenails are cut short, kept clean, and filed frequently to prevent sharp edges. Gloves or cotton stockings can be placed over the hands and pinned to shirtsleeves. One-piece outfits with long sleeves and long pants also decrease direct contact with the skin. If gloves or socks are used, the child needs time to be free from such restrictions. An excellent time to remove gloves, socks, or other protective devices is during the bath or after receiving sedative or antipruritic medication.

Conditions that increase itching are eliminated when possible. Woolen clothes or blankets, rough fabrics, and furry stuffed animals are removed from the child's environment. Because heat and humidity cause perspiration (which intensifies itching), proper dress for climatic conditions is essential. Pruritus is often precipitated by exposure to the irritant effects of certain components of common products such as soaps, detergents, fabric softeners, perfumes, and powders. During cold months, synthetic fabrics (not wool) should be used for overcoats, hats, gloves, and snowsuits. Exposure to latex products, such as gloves and balloons, should also be avoided.

Clothes and sheets are laundered in a mild detergent and rinsed thoroughly in clear water (without fabric softeners or antistatic chemicals). Putting the clothes through a second complete wash cycle without using detergent reduces the amount of residue remaining in the fabric.

Preventing infection is usually accomplished by preventing scratching. Baths are given as prescribed; the water is kept tepid; and soaps (except as indicated), bubble baths, oils, and powders are avoided. Skin folds and diaper areas need frequent cleansing with plain water. A room humidifier or vaporizer may benefit children with extremely dry skin. Skin lesions are examined for signs of infection—usually honey-colored crusts or pustules with surrounding erythema. Any signs of infection are reported to the practitioner.

! NURSING ALERT

If the child is being treated with baths, it is imperative that an emollient preparation be applied immediately after bathing (while the skin is still slightly moist) to prevent drying.

Wet soaks and compresses are applied and medications for pruritus or infection are administered as directed. The family is given explicit instructions on the preparation and use of soaks, special baths, and topical medications, including the order of application if more than one is prescribed. It is important to emphasize that one thick application of topical medication is *not* equivalent to several thin applications and that excessive use of an agent (particularly steroids) can be hazardous. If children have difficulty remaining still for a 10- or 15-minute soak, bath, or dressing application, these can be carried out at naptime or when the child is engrossed in watching television, listening to a story, or playing with tub toys.

Diet modification may prevent skin exacerbations. When a hypoallergenic diet is prescribed, parents need help to understand the reason for the diet and the guidelines for avoiding hyperallergenic foods. Because hypoallergenic diets take time before visible effects are apparent, parents need reassurance that results may not be seen immediately. If airborne allergens make eczema worse, the family is counseled about "allergy proofing" the home (see Chapter 21, Asthma).

Family Support

Parents are assured that the lesions will not produce scarring (unless secondarily infected) and that the disease is not contagious. However, the child may have repeated exacerbations and remissions. Spontaneous and permanent remission takes place at approximately 2 to 3 years of age in most children with the infantile disorder.

During acute phases, emotional stress can become intense for the family. They need time to discuss negative feelings and to be reassured that these feelings are normal. Stress tends to aggravate the severity of the condition. Therefore efforts to relieve as much anxiety as possible in both the parents and the child have a beneficial emotional and physical effect.

SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a chronic, recurrent, inflammatory reaction of the skin. It occurs most commonly on the scalp (cradle cap) but

may involve the eyelids (blepharitis), external ear canal (otitis externa), nasolabial folds, and inguinal region. The cause is unknown, although it is more common in early infancy, when sebum production is increased. The lesions are characteristically thick, adherent, yellowish, scaly, oily patches that may or may not be mildly pruritic. Unlike AD, seborrheic dermatitis is not associated with a positive family history for allergy and is common in infants shortly after birth and in adolescents after puberty. Diagnosis is made primarily based on the appearance and the location of the crusts or scales.

Nursing Care Management

Cradle cap may be prevented with adequate scalp hygiene. Frequently, parents omit shampooing the infant's hair for fear of damaging the "soft spots," or fontanels. The nurse should discuss how to shampoo the infant's hair and emphasize that the fontanel is similar to skin anywhere else on the body—it does not puncture or tear with mild pressure.

When seborrheic lesions are present, direct the treatment at removing the scales or crusts. Parents are taught the appropriate procedure to clean the scalp. Education may need to include a demonstration. Shampooing should be done daily with a mild soap or commercial baby shampoo; medicated shampoos are not necessary, but an antiseborrheic shampoo containing sulfur and salicylic acid may be used. Shampoo is applied to the scalp and allowed to remain on the scalp until the crusts soften. Then the scalp is thoroughly rinsed. A fine-tooth comb or a soft facial brush helps remove the loosened crusts from the strands of hair after shampooing.

ACNE

Acne vulgaris is the most common skin problem treated by physicians during adolescence. Acne is caused by testosterone, a hormone present in boys and girls that increases during puberty. It stimulates the sebaceous glands of the skin to enlarge, or produce oil, and plug the pores. Comedogenesis (formation of comedones) results in a noninflammatory lesion that may be either an open comedone ("blackhead") or a closed comedone ("whitehead").

More than half of the adolescent population experiences acne by the end of the teenage years. Although the disorder can appear before the age of 10 years, the peak incidence occurs in middle to late adolescence (ages 16 to 17 years in girls and 17 to 18 years in boys). It is more common in boys than in girls. After this age period, the disease usually decreases in severity, but it may persist into adulthood. The degree to which an individual is affected may range from nothing more than a few isolated comedones to a severe inflammatory reaction. Although the disease is self-limiting and not life threatening, it has great significance to adolescents. Health professionals should not underestimate the impact that acne has on teens.

Numerous factors affect the development and course of acne. Its distribution in families and a high degree of concordance in identical twins suggest hereditary factors. Premenstrual flare-ups of acne occur in nearly 70% of adolescent girls, suggesting a hormonal cause. Studies do not indicate a clear association between stress and acne, but adolescents commonly cite stress as a cause for acne outbreaks. Cosmetics containing lanolin, petrolatum, vegetable oils, lauryl alcohol, butyl stearate, and oleic acid can increase comedone production. Exposure to oils in cooking grease can be a precursor in adolescents who work over fast-food restaurant hot oils. There may be an association with the intake of dairy products and high glycemic index foods that may potentiate hormonal and inflammatory factors that contribute to acne severity (Fiedler, Stangl, Fiedler, et al., 2017).

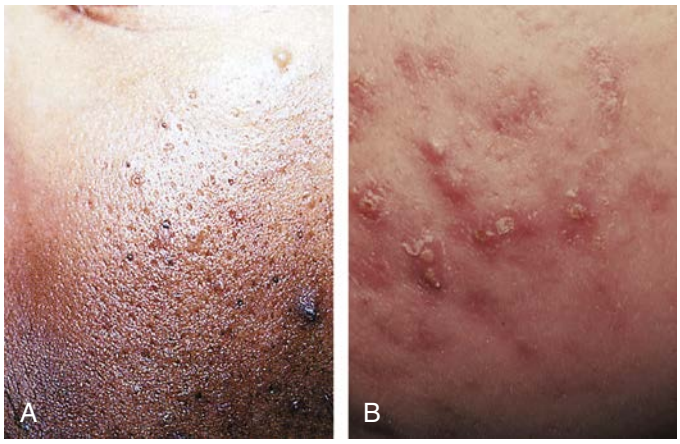

Fig. 31.13 Acne vulgaris. **A,** Acne vulgaris. **B,** Comedones with a few inflammatory pustules. (From Zitelli, B. J., McIntire, S. C., & Nowalk, A. J. [2012]. *Zitelli and Davis' atlas of pediatric physical diagnosis* [6th ed.]. St. Louis, MO: Saunders.)

Pathophysiology

Four pathophysiologic factors have the greatest influence on acne development: (1) excessive sebum production; (2) alterations in follicular growth; (3) differentiation with colonization of *Propionibacterium acnes;* and (4) an accompanying immune response and inflammation (Bhat, Latief, & Hassan, 2017). Acne severity is proportional to the sebum secretion rate, which is genetically determined and increases at the time of adrenocortical maturation. Inflammation occurs with the proliferation of *P. acnes,* which draws in neutrophils, causing inflammatory papules, pustules, nodules, and cysts (Fig. 31.13). Acne can be categorized as comedonal, inflammatory, or both and can be classified as mild, moderate, or severe based on the number and type of comedones and the extent of affected skin (Eichenfield, Krakowski, Piggott, et al., 2013).

Therapeutic Management

Successful management of acne depends on a cooperative effort among the health care provider, adolescent, and parents. Unlike many other dermatologic conditions, acne lesions resolve slowly, and improvement may not be apparent for at least 6 weeks. Individual comedones can take several weeks to months to resolve, and papules and pustules usually resolve in about 1 week. The multifactorial causes of acne necessitate a combined approach for successful treatment. Treatment consists of general measures of care and specific treatments determined by the type of lesions involved.

General Measures

The practitioner provides the adolescent with an overall explanation of the disease process, emphasizing the patient's involvement. Improvement of the adolescent's overall health status is part of the general management. Adequate rest, moderate exercise, a well-balanced diet, reduction of emotional stress, and elimination of any foci of infection are all part of general health promotion.

Cleansing

Dirt or oil on the surface of the skin does not cause acne. Gentle cleansing with a mild cleanser once or twice daily is usually sufficient. Antibacterial soaps are ineffective and may be drying when used in combination with topical acne medications. For some adolescents, hygiene of the hair and scalp appears to be related to the clinical activity of the acne. Acne on the forehead may improve with brushing the hair away from the forehead and more frequent shampooing.

Medications

Treatment success depends on commitment from the adolescent. Before prescribing treatment, the practitioner should determine the adolescent's level of comfort and readiness to begin treatment. The adolescent should be reminded that clinical improvement may take weeks to months. Early intervention, most often with topical medications, may prevent the development of more severe acne.

Tretinoin (Retin-A) is the only drug that effectively interrupts the abnormal follicular keratinization that produces microcomedones, the invisible precursors of the visible comedones. Tretinoin alone is usually sufficient for management of mild comedonal acne (Que, Whitaker-Worth, & Chang, 2016). Tretinoin is available as a cream, gel, or liquid. This drug can be extremely irritating to the skin and requires careful patient education for optimal usage. The patient should be instructed to begin with a pea-size dot of medication, which is divided into the three main areas of the face and then gently rubbed into each area. The medication should not be applied for at least 20 to 30 minutes after washing to decrease the burning sensation. The avoidance of the sun and the daily use of sunscreen must be emphasized because sun exposure can result in severe sunburn. Adolescents should be advised to apply the medication at night and to use a sunscreen with a sun protection factor (SPF) of at least 15 in the daytime.

Topical **benzoyl peroxide** is an antibacterial agent that inhibits the growth of *P. acnes* organisms. It is effective against both inflammatory and noninflammatory acne and is an effective first-line agent. This medication is available as a cream, lotion, gel, or wash. Benzoyl peroxide and salicylic acid are the most effective acne treatment kits available over the counter. The patient should be informed that the medication may have a bleaching effect on sheets, bedclothes, and towels. The adolescent can be reassured that skin bleaching will not occur. Accommodation to the medication can be gained with a gradual increase in the strength and frequency of application.

When inflammatory lesions accompany the comedones, a **topical antibacterial agent** may be prescribed. These agents are used to prevent new lesions and to treat preexisting acne. Clindamycin, erythromycin, metronidazole, and azelaic acid are currently available topical antibacterial therapy. A 5% dapsone gel has recently been approved for the treatment of inflammatory acne lesions and is reported to be effective when used in combination with a topical retinoid (Que et al., 2016). Retinoid in combination with antimicrobials also improves the penetration of these topical agents and is the only means to address three of the pathogenic causes of acne: keratinization, *P. acnes,* and inflammation. Side effects of the topical medications include erythema, dryness, and burning; using the medications every other day will decrease the adverse effects. Topical antimicrobials combined with benzoyl peroxide are more effective than either product alone; however, a yellowish discoloration of the skin occurs when topical dapsone is used in combination with benzoyl peroxide (Que et al., 2016).

Systemic antibiotic therapy is initiated when moderate to severe acne does not respond to topical treatments. The foundation for using systemic antibiotics in acne treatment has been the elimination of the inflammatory effects of *P. acnes* by suppressing the bacteria. Tetracycline, minocycline, and doxycycline are systematic antibiotics used to treat acne (Que et al., 2016). They are relatively free of side effects, with the exception of occasional gastrointestinal upset, photosensitivity, or vaginal candidiasis. Adolescent girls with mild to moderate acne may respond well to topical treatment and the addition of an **oral contraceptive pill** (OCP). OCPs reduce the endogenous androgen production and decrease the bioavailability of the woman's circulating androgens. Both of these actions result in decreased acne.

Isotretinoin, 13-cis-retinoic acid (Accutane), is a potent and effective oral agent that is reserved for severe cystic acne that has not responded to other treatments. Isotretinoin is the only agent available that affects factors involved in the development of acne. However, treatment with isotretinoin should be managed *only* by a dermatologist. Adolescents with multiple, active, deep dermal or subcutaneous cystic and nodular acne lesions are treated for 20 weeks. Multiple side effects can occur, including dry skin and mucous membranes, nasal irritation, dry eyes, decreased night vision, photosensitivity, arthralgia, headaches, mood changes, aggressive or violent behaviors, depression, and suicidal ideation. Adolescents taking this drug should be monitored for depression, depressive symptoms, and suicidal ideation (Oliveira, Sobreira, Velosa, et al., 2017). The drug should be given only at the recommended doses for no longer than the recommended duration. The most significant side effects of this drug are the teratogenic effects. Isotretinoin is absolutely contraindicated in pregnant women. Sexually active young women must use an effective contraceptive method during treatment and for 1 month after treatment. Patients receiving isotretinoin should also be monitored for elevated cholesterol and triglyceride levels. Significant elevation may require discontinuation of the medication.

Nursing Care Management

Because acne is so common and its appearance may seem so mild, the health care provider may underestimate the relative importance of the disease to the adolescent. The nurse should assess the individual adolescent's level of distress, current management, and perceived success of any regimen before initiating a referral. If adolescents do not perceive the acne to be a problem, they may lack motivation to follow the treatment plan.

The nurse can provide ongoing support for the adolescent when a treatment plan is initiated. Discuss the use of medications and basic skin care information in detail with the adolescent. Written instructions should accompany the verbal discussion. Information to dispel myths regarding the use of abrasive cleansing products can prevent unnecessary costs and trauma to the skin. Adolescents need education about the factors that aggravate and damage the skin, such as too vigorous scrubbing. In addition, picking, squeezing, and manual expression with fingernails break down the ductal walls of lesions and cause the acne to worsen. Mechanical irritation, such as vinyl helmet straps that rub areas predisposed to acne, can also cause the development of lesions.

BURNS

Burn injuries are usually attributed to extreme heat sources but may also result from exposure to cold, chemicals, electricity, or radiation. Most burns are relatively minor and can be treated in an outpatient setting. However, burns involving a large body surface area, critical body parts, or the geriatric or pediatric population often benefit from treatment in specialized burn centers. The American Burn Association has established criteria to guide decisions on the severity of injury and the need for transfer for specialized care.

The extent of tissue destruction is determined by the intensity of the heat source, the duration of contact or exposure, the conductivity of the tissue involved, and the rate at which the heat energy is dissipated by the skin. A brief exposure to high-intensity heat from a flame can produce burn injuries similar to those induced by long exposure to less intense heat in hot water.

When burns are categorized according to the patient's age and type of injury, the following patterns become apparent: (1) hot-water scalds are most frequent in toddlers; (2) flame-related burns are more common in older children; (3) when structural fires occur from children playing with matches or lighters, the majority are started by males,

with 43% of those started by children under age 6 years (National Fire Protection Association, 2014); and (4) nonaccidental burns indicate maltreatment.

Etiology of the Injury

Most burns result from contact with thermal agents such as a flame, hot surfaces, or hot liquids. The death rate from fire and burn injury has declined by 53% from 1999 to 2013 (Safe Kids Worldwide, 2015). The leading cause of death from unintentional injury in the United States differs according to age-group, but fire and burns ranks third in children 5 to 9 years old. Approximately 237 children 14 years old and younger died from fire or burn injuries in 2016 (Centers for Disease Control and Prevention, 2018). Electrical injuries caused by household current have the greatest incidence in young children, who insert conductive objects into electrical outlets and bite or suck on connected electrical cords. These burns occur most commonly during the spring and summer months and are also associated with risk-taking behaviors in boys. Direct contact with high- or low-voltage current, as well as lightning strikes, is the most frequent mechanism of injury. Trauma results from resistance of the tissue and path of electric current through tissue, muscle compartments, nerves, and vital organs. Criteria for admission, as derived from evidence-based practice for electrical burn injuries, includes a history of loss of consciousness, electrocardiographic (ECG) changes, 10% total body surface area (TBSA) affected, or the need for monitoring an affected extremity. Cardiac monitoring is therefore included in standard burn care when ECG changes are identified on admission (McLeod, Maringo, Doyle, et al., 2018).

Chemical burns are seen in the pediatric population and can cause extensive injury since noxious agents exist in many cleaning products commonly found in the home. The severity of injury is related to the chemical agent (acid, alkali, or organic compound) and the duration of contact. The mechanism of injury differs from other burns in that there is a chemical disruption and alteration of the physical properties of the exposed body area. In addition to concern for localized damage, the potential for systemic toxicity must be addressed, including exposure of the eyes to chemical agents, the ingestion of caustic substances, and inhalation of toxic gases produced from chemicals.

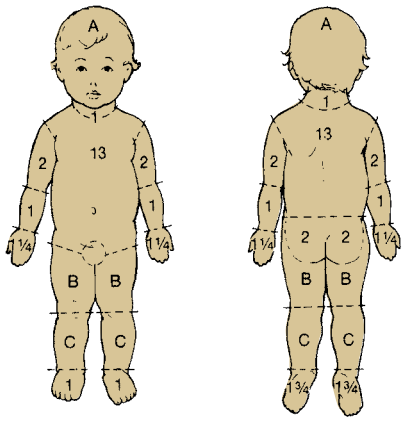
Nonaccidental trauma due to maltreatment most commonly occurs in children 3 years old and younger. Children younger than 3 years old suffering a burn injury are at risk for future maltreatment of any type before the age of 6 years (Pawlik, Kemp, Maguire, et al., 2016). With nonaccidental burn trauma, scald burns from hot water are the most common injury followed by contact burns. Nonaccidental burn trauma should be suspected if the burn distribution on the body is inconsistent with the reported incident or with the child's developmental level and there was a delay in seeking treatment

Characteristics of Burn Injury

The physiologic responses, treatment modalities, prognosis, and disposition of the injured child are all directly related to the *amount of tissue destroyed.* The severity of the burn injury is assessed based on the percentage of **total body surface area (TBSA)** burned and depth of the burn. Among children in the school-age group or younger age-groups, a burn that is 10% TBSA can be life threatening if not treated correctly. Other important factors in determining the seriousness of the injury are the child's age and general health, the causative agent, the location of the wounds, the presence of respiratory involvement, and any associated injury or condition.

Extent of Injury

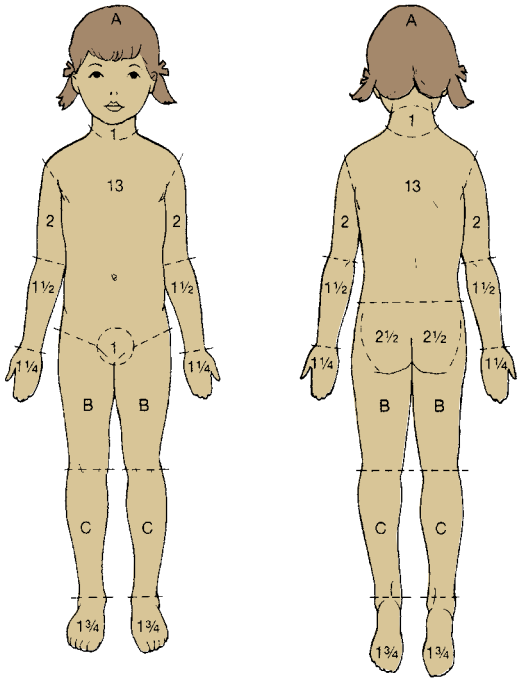
The extent of a burn is expressed as a percentage of the TBSA. This is most accurately estimated by using specially designed age-related charts (Fig. 31.14). It is more efficient to use a chart designed to assign body proportions to children of different ages.



A

RELATIVE PERCENTAGES OF AREAS AFFECTED BY GROWTH

AREA	BIRTH	AGE 1 YR	AGE 5 YR
A = ½ of head	9½	8½	6½
B = ½ of one thigh	2¾	3¼	4
C = ½ of one leg	2½	2½	2¾



B

RELATIVE PERCENTAGES OF AREAS AFFECTED BY GROWTH

AREA	AGE 10 YR	AGE 15 YR	ADULT
A = ½ of head	5½	4½	3½
B = ½ of one thigh	4½	4½	4¾
C = ½ of one leg	3	3¼	3½

Fig. 31.14 Estimation of distribution of burns in children. A, Children from birth to age 5 years. B, Older children.

Depth of Injury

A burn is a three-dimensional wound that is also assessed in relation to depth of injury. Traditionally, the terms *first, second,* and *third degree* have been used to describe the depth of tissue injury. However, with the current emphasis on wound healing, these have been replaced by more descriptive terms based on the extent of destruction to the epithelializing elements of the skin (Fig. 31.15).

		Wound Appearance	Wound Sensation	Course of Healing
Partial-Thickness Burn	1st Degree	Epidermis remains intact and without blisters Erythema; skin blanches with pressure	Painful	Discomfort lasts 48–72 hours. Desquamation occurs in 3–7 days.
Partial-Thickness Burn	2nd Degree	Wet, shiny, weeping surface Blisters Wound blanches with pressure	Painful Very sensitive to touch, air currents	Superficial partial-thickness burn heals in <21 days. Deep partial-thickness burn requires >21 days for healing. Healing rates vary with burn depth and presence or absence of infection.
Full-Thickness Burn	3rd Degree	Color variable (i.e., deep red, white, black, brown) Surface dry Thrombosed vessels visible No blanching	Insensate (↓ pinprick sensation)	Autografting is required for healing.
Full-Thickness Burn	4th Degree	Color variable Charring visible in deepest areas Extremity movement limited	Insensate	Amputation of extremities is likely. Autografting is required for healing.

Fig. 31.15 Classification of burn depth according to depth of injury. (From Black, J. M. [2008]. *Medical-surgical nursing: Clinical management for positive outcomes* [8th ed.]. Philadelphia, PA: Saunders.)

Superficial (first-degree) burns are usually of minor significance. This type of injury involves the epidermal layer only. There is often a latent period followed by erythema. Tissue damage is minimal, and there is no blistering. The protective functions of the skin (such as bacterial and vapor barriers) remain intact, and systemic effects are rare. Pain is the predominant symptom, and the burn heals in 5 to 10 days without scarring. A mild sunburn is an example of a superficial burn.

Partial-thickness (second-degree) burns involve the epidermis and varying degrees of the dermal layer. These wounds are painful, moist, red, and blistered. With superficial partial-thickness burns, dermal elements are intact, and the wound should heal in approximately 14 to 21 days with variable amounts of scarring (Fig. 31.16). The wound is extremely sensitive to temperature changes, exposure to air, and light touch. Although classified as second-degree or partial-thickness burn, deep dermal burns resemble full-thickness injuries in many respects except that sweat glands and hair follicles remain intact. The burn may appear mottled, with pink, red, or waxy white areas exhibiting blisters and edema formation. Systemic effects are similar to those encountered with full-thickness burns. Although many of these wounds heal spontaneously, healing time may be extended beyond 21 days. These burn wounds often heal with extensive scarring.

Full-thickness (third-degree) burns are serious injuries that involve the entire epidermis and dermis and extend into subcutaneous tissue (see Fig. 31.15). Nerve endings, sweat glands, and hair follicles are destroyed. The burn varies in color from red to tan, waxy white, brown, or black. It is distinguished by a dry, leathery appearance and texture since the elasticity of the dermis is compromised (Fig. 31.17). Normally, full-thickness burns lack sensation in the area of injury because of the destruction of nerve endings. However, most full-thickness burns have superficial and partial-thickness burned areas at the periphery of the burn where nerve endings are intact and exposed. As the peripheral fibers regenerate, severe painful sensations return. Full-thickness wounds are not capable of reepithelialization and require surgical excision and grafting to close the wound.

Fourth-degree burns are full-thickness burns that involve underlying structures such as muscle, fascia, and bone. The wound appears dull and dry, and ligaments, tendons, and bone may be exposed (Fig. 31.18).

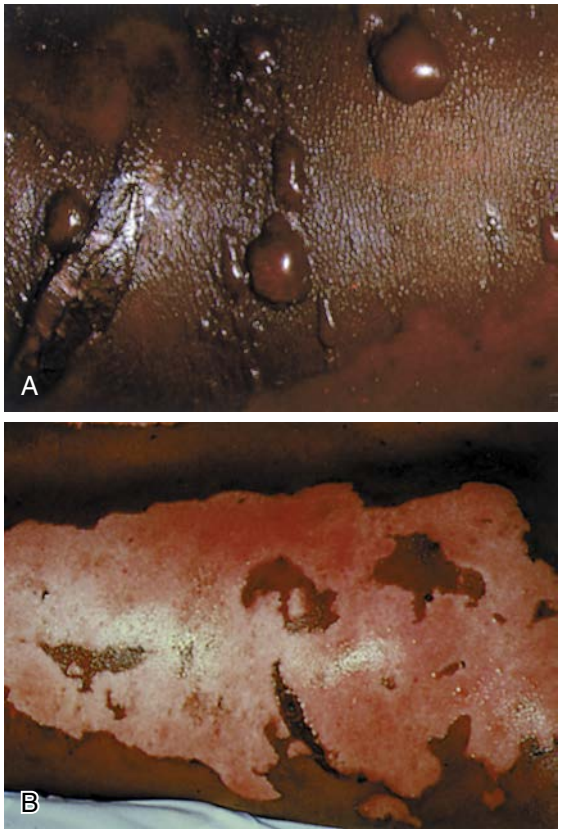


Fig. 31.16 Superficial partial-thickness burns on an African American child. **A,** Blisters intact. **B,** Blisters removed. (Courtesy Hillcrest Medical Center, Tulsa, OK.)

Severity of Injury

Burns are classified as minor, moderate, or major, which is useful in determining the disposition of the patient for treatment, which is guided by criteria developed by the American Burn Association (Table 31.10).

Fig. 31.17 *Bottom* to *top:* Deep partial-thickness burn (*red area*), full-thickness burn (*white area*), and full-thickness burn with eschar (*brown area*). (Courtesy Hillcrest Medical Center, Tulsa, OK.)

Fig. 31.18 Full-thickness burn with muscle and fascia involved. (Courtesy Hillcrest Medical Center, Tulsa, OK.)

Because the skin of infants is so thin, they are likely to sustain deeper injuries compared with older children. Children younger than 2 years old, especially those 6 months old or younger, have a significantly higher mortality rate than older children with burns of similar magnitude. Acute or chronic illnesses or superimposed injuries also complicate burn care and response to treatment.

Pathophysiology

Burn injuries produce both local and systemic effects that are related to the extent of tissue destruction. In superficial burns, the tissue damage is minimal. In partial-thickness burns, there is considerable edema and more severe capillary damage. With a major burn greater than 30% TBSA, there is a systemic response involving an increase in capillary permeability, allowing plasma proteins, fluids, and electrolytes to be lost. Maximum edema formation in a small burn occurs about 8 to 12 hours after injury (Rowan, Cancio, Elster, et al., 2015). After a larger burn, hypovolemia, associated with this phenomenon, will slow the rate of edema formation, with maximum effects at 18 to 24 hours.

Another systemic response is anemia, caused by direct heat destruction of red blood cells (RBCs), hemolysis of injured RBCs, and trapping of RBCs in the microvascular thrombi of damaged cells. A long-term decrease in the number of RBCs may occur as a result of increased RBC fragility. Initially, there is increased blood flow to the heart, brain, and kidneys, with decreased blood flow to the gastrointestinal tract. There is an increase in metabolism to maintain body heat, providing for the increased energy needs of the body.

Inhalation Injury

Trauma to the tracheobronchial tree often follows inhalation of heated gases and toxic chemicals produced during combustion. Although direct thermal injury to the upper airway may occur, heat damage below the vocal cords is rare. Inspired heated air is cooled in the upper airway before reaching the trachea. Reflex closure of the cords and laryngospasm also prevent full inhalation. However, evidence of direct thermal injury to the upper airway includes burns of the face and lips, singed nasal hairs, and laryngeal edema. Clinical manifestations may be delayed for as long as 24 to 48 hours (American Burn Association, 2016). Wheezing, increasing secretions, hoarseness, wet rales, and carbonaceous secretions are signs of respiratory tract involvement. Upper airway obstruction is often associated with burn shock and fluid resuscitation. In such situations, endotracheal intubation may also be necessary to preserve a patent airway.

Inhalation of carbon monoxide is suspected when the injury has occurred in an enclosed space. Carbon monoxide has a greater affinity for hemoglobin than oxygen, thereby depriving peripheral tissues and oxygen-dependent organs (e.g., heart, brain) of the oxygen needed for survival. Treatment is 100% oxygen, which reverses the situation rapidly. Mucosal erythema and edema followed by sloughing of the mucosa are manifestations of respiratory tract injury. A mucopurulent membrane replaces the mucosal lining and seriously compromises respiration and ventilation and possibly progresses to pneumonia. A significant increase in mortality has been observed with inhalation injury.

Complications

Burn-injured children are subject to a number of serious complications resulting from both the burn and systemic alterations. The immediate threat to life is related to airway compromise and profound burn shock. Burn shock occurs in the immediate postburn period and is marked by dramatic alterations in circulation. With fluid loss through the primary skin barrier, capillary permeability increases and vessels become dilated. Circulating blood volume decreases rapidly, and cardiac output is reduced. During healing, infection—both local and systemic sepsis—is the primary complication. Mortality associated with burns in children increases with the severity of the injury.

Pulmonary

Pulmonary problems are a major cause of fatality in children with direct burns or result in complications in the respiratory tract. Early in the postburn period, most pulmonary infections result from nosocomial exposure, immobility, and abdominal distention. The hematogenous variety occurs later and is related to the septic burn wound or other foci, such as phlebitis at the site of an invasive IV line. Respiratory problems include inhalation injuries, aspiration in unconscious patients, bacterial pneumonia, pulmonary edema, pulmonary embolus, posttraumatic pulmonary insufficiency, and atelectasis. The most common cause of respiratory failure in the pediatric age-group is bacterial pneumonia, which requires prolonged intubation and sometimes a tracheostomy. Tracheostomies increase the incidence of serious complications and are performed only in extreme cases.

A less common complication is pulmonary edema resulting from fluid overload or acute respiratory distress syndrome (ARDS) in association with gram-negative sepsis. ARDS results from pulmonary capillary damage and leakage of fluid into the interstitial spaces of the lung. A loss of compliance and interference with oxygenation are the consequences of pulmonary insufficiency in conjunction with systemic sepsis.

TABLE 31.10 Classification of Burn Severity Adapted From the American Burn Association's Criteria for Referral

	Minor[a]	Moderate	Major
% TBSA	<5% TBSA burn in young children <10% TBSA partial-thickness in children >10 years old	5-10% TBSA burn in young children	>10% TBSA burn in young children
Full-thickness burns	<2% full-thickness burn	2-5% full-thickness burn	>5% full-thickness burn
Other criteria		Suspected inhalation injury Circumferential burn Concomitant medical problem predisposing the patient to infection (e.g., diabetes, sickle cell disease)	Known inhalation injury Any significant burn to face, eyes, ears, genitalia, or joints Significant associated injuries (e.g., fracture, other major trauma)
Disposition	Usually outpatient	Admission to hospital, preferably one with expertise in burn care	Admission to a burn center

[a]Minor burns exclude any burn involving the face, hands, feet, perineum, or crossing joints; inhalation injury; circumferential burns; electrical injury; any injury with contaminant trauma; and children with psychosocial factors affecting the injury.
TBSA, Total body surface area.
Adapted from Committee on Trauma, American College of Surgeons. (2006). American Burn Association criteria for referral. In *Resources for optimal care of the injured patient*. Chicago, IL: American College of Surgeons.

Excessive Fluid Volume

Burns to the chest or abdomen decrease compliance and can contribute to a serious complication (increased intra-abdominal pressure) in burned individuals who receive larger than calculated amounts of fluids in the resuscitative period. Although children with increased intra-abdominal pressure readings tended to be younger, larger TBSA injuries and full-thickness components were significantly associated with elevated pressures and can result in tissue ischemia (Strang, Van Lieshout, Breederveld, et al., 2014). Increased intra-abdominal pressure has the potential to impair hemodynamics, pulmonary dysfunction, renal function, and hepatic malperfusion. Despite maintaining cardiac output with fluid replacement, renal function remains impaired in the presence of increased intra-abdominal pressure. To restore perfusion in children who have developed increased abdominal pressure, a decompressive laparotomy is necessary.

Wound Sepsis

Sepsis is a critical problem in the treatment of burns and an ever-present threat after the burn shock phase. Decreased level of consciousness and lethargy are early signs of sepsis. Initially, burn wounds are relatively pathogen free unless they are contaminated with potentially infectious material, such as dirt or polluted water. However, dead tissue and exudate provide a fertile field for bacterial growth. Early colonization of the wound surface by a preponderance of gram-positive organisms (primarily staphylococci) remains the chief cause of wound infection. Gram-negative organisms, particularly *Pseudomonas aeruginosa,* are ubiquitous and may cause invasive burn wound infections (Norbury, Herndon, Tanksley, et al., 2016). Early surgical excision of eschar together with placement of autograft reduces the incidence of sepsis.

Therapeutic Management

Emergency Care

The initial management of the burn patient begins at the scene of injury. The priority is to stop the burning process (see Emergency Treatment box). The child should then be transported immediately to the nearest medical facility for treatment and evaluation. The child and the family are usually extremely frightened and anxious; sensitivity to their emotional state and reassurance should be provided during the transport process.

EMERGENCY TREATMENT

Burns

Minor Burns

Stop the burning process:
- Remove burned clothing and jewelry.
- Apply cool water to the burn or hold the burned area under cool running water.
- Do not use ice.

Do not disturb any blisters that form unless the injury is from a chemical substance.
Do not apply anything to the burn.
Cover with a clean cloth if risk of damage or contamination.

Major Burns

Stop the burning process:
- Flame burns—smother the fire.
- Place victim in the horizontal position.
- Roll victim in a blanket or similar object; avoid covering the head.
- Remove burned clothing and jewelry.

Assess for an adequate airway and breathing.
If a child is not breathing, begin mouth-to-mouth resuscitation.
Cover the burn with a clean cloth.
Keep victim warm.
Begin intravenous fluids and oxygen therapy as prescribed.
Transport to medical aid.

Stop the burning process. The chief aim of rescue in flame burns is to smother the fire, not fan it. Children tend to panic and run, which spreads the flames and makes assistance more difficult. The burned child should be placed in a horizontal position and rolled in a blanket, rug, or similar article, with care taken not to cover the head and face because of the danger of inhalation of toxic fumes. If nothing is available, the victim should lie down and roll over slowly to extinguish the flames. Remaining in the vertical position may cause the hair to ignite or inhalation of flames, heat, or smoke.

Major burns should not be cooled for long periods of time. Heat is rapidly lost from burned areas, and additional cooling leads to a drop in core body temperature and potential circulatory collapse. Wet

dressings also promote vasoconstriction because of cooling, resulting in impaired circulation to the burned area and increased tissue damage. Chemical burns require continuous flushing with large amounts of water before transport to a medical facility. The use of neutralizing agents on the skin is contraindicated because heat from a chemical reaction is initiated and further injury may result. If the chemical is in a powder form, adding water may spread the caustic agent. The powder should be brushed off, if possible, before flushing the area.

Burned clothing is removed to prevent further damage from smoldering fabric and hot beads of melted synthetic materials. Jewelry is removed to eliminate the transfer of heat from the metal and constriction resulting from edema formation. This also provides access to the burn and prevents painful removal later.

Assess the victim's condition. As soon as the flames are extinguished, the child is assessed. Airway, breathing, and circulation are the primary concerns. Cardiopulmonary complications may result from inhalation of toxic fumes and smoke, exposure to electric current, hypovolemia, and shock. Emergency measures are instituted as appropriate.

Cover the burn. The burn should be covered with a clean dry cloth to prevent hypothermia, decrease pain by eliminating air contact, and prevent contamination. No attempt should be made to treat the burn. Application of topical ointments, oils, or other home remedies is contraindicated.

Transport the child to medical aid. The child with an extensive burn is not given anything by mouth to avoid aspiration in the presence of upper airway edema. The child is transported to the nearest medical facility. If this cannot be accomplished within a relatively short period, IV access should be established, if possible, with a large-bore catheter. Oxygen is administered, if available, at 100%. A report of the initial assessment, suspected inhalation injury, associated trauma, and any interventions implemented is given to the medical facility assuming care of the child.

Provide reassurance. Providing reassurance and psychologic support to both the family and the child helps immeasurably during the period of postburn crisis. Reducing anxiety conserves energy that the family and child will need to cope with the physiologic and emotional stress of a burn.

Minor Burns

Treatment of burns classified as minor usually can be managed adequately on an outpatient basis when it is determined that the parent can be relied on to carry out instructions for care and observation. Patients with less than optimum circumstances may require close follow-up to ensure adherence with treatment.

Cleanse the burn with a mild soap and tepid water. Debridement of the burn includes removal of any embedded debris, chemicals, and devitalized tissue. Removal of intact blisters remains controversial (Smith, 2000). Some authorities argue that blisters provide a barrier against infection; others maintain that blister fluid is an effective medium for the growth of microorganisms. However, blisters should be broken if the burn is due to a chemical agent to control absorption or if the blisters are large enough that the buildup of fluid will cause pressure resulting in increased pain.

Most practitioners favor covering the burn with an antimicrobial ointment to reduce the risk of infection and to provide some form of pain relief. The dressing consists of nonadherent fine-mesh gauze placed over the ointment and a light wrap of gauze dressing that avoids interference with movement. This helps keep the burn clean and protects it from trauma. The caregiver is instructed to wash the burn, reapply the dressing, and return the child to the office or clinic as directed for burn wound observation. The frequency of dressing changes may vary from once a day to every other day or longer depending on the burn wound classification and dressing used. If there is a high probability of infection or other complications or if there is doubt about the ability to carry out instructions, the caregiver may be directed to bring the patient in more often for dressing changes and inspection. Another option is to have a nurse make a home visit to inspect the burn and perform the dressing change. Frequent removal of the dressing is an effective mode of debridement. Soaking the dressing in tepid water or normal saline before removal helps loosen the dressing and debris as well as reduces discomfort. Burns of the face are usually treated by an open method. Wash and debride the burn in the same manner and apply a thin film of antimicrobial ointment without a dressing. This is repeated at least twice a day.

Obtain a tetanus history on admission. Administer tetanus prophylaxis if there is no history of immunization or if more than 5 years have passed since the last immunization. A mild analgesic (such as acetaminophen) is usually sufficient to relieve discomfort; the antipyretic effect of the drug also alleviates the sensation of heat.

Most minor burns heal without difficulty. Hospitalization may be indicated if the burn margin becomes erythematous or grossly purulent or if the child develops evidence of a systemic reaction, such as fever or tachycardia. Evaluate the child for functional impairment. Instruct the caregiver in the exercise and ambulation program. After healing, an evaluation of scar maturation and range of motion will indicate any need for further therapy.

Major Burns

When a child with extensive burns is admitted to the hospital for treatment, various assessments are conducted and therapies initiated. Of these, the priority concerns include the establishment and maintenance of an adequate airway, initiation of fluid administration, and evaluation and treatment of the burn. Although the order of implementation may vary from institution to institution and the condition of the child, a number of procedures and activities are generally initiated on admission. Some are carried out simultaneously (Box 31.4).

QUALITY PATIENT OUTCOMES: Acute Management of Burns

- Stable body temperature
- Adequate fluid replacement and urinary output
- Adequate nutrition and reduction of metabolic losses
- No evidence of acute complications
- Pain controlled
- Evidence of wound healing
- No evidence of contractures
- Adequate emotional support

Establishment of adequate airway. The priority is airway maintenance. The inhalation of noxious agents or respiratory burns is suggested when there is a history of injury in an enclosed space; edema of the oral and nasal membranes; burn injury to the face, nares, and upper torso; hyperemia; and blisters or evidence of trauma to the upper respiratory passages. When respiratory involvement is suspected or evident, 100% oxygen is administered and blood gas values, including carbon monoxide levels, are determined.

If the child exhibits changes in sensorium, air hunger, or other signs of respiratory distress, an endotracheal tube is inserted to maintain the airway. When severe edema of the face and neck is anticipated, intubation is performed before swelling makes intubation difficult or impossible. Controlled intubation is preferred to an emergency intubation. Intubation allows for the delivery of humidified oxygen, the removal of secretions from respiratory passages, and the provision of ventilatory support. When full-thickness burns encircle the chest, constricting

BOX 31.4 Major Burn Management

- Ascertain the adequacy of the airway and provide oxygen, intubation, and ventilatory support as indicated.
- Assess breathing rate and depth. Note any use of accessary muscles, nasal flaring, or grunting, which may indicate respiratory compromise.
- Insert a large-bore intravenous (IV) line, preferably through unburned skin, to deliver fluids at a sufficiently rapid rate to effect resuscitation.
- Remove clothing and jewelry and examine for secondary trauma.
- Evaluate the burn wound and determine the extent and depth of injury.
- Obtain an admission weight.
- Calculate fluid requirements and establish the appropriate regimen.
- Obtain baseline laboratory studies.
- Provide IV medication for control of pain and anxiety only after adequate oxygenation is ensured and fluid resuscitation is initiated.
- Insert a nasogastric tube to empty stomach contents and maintain gastric decompression.
- Insert an indwelling Foley catheter to obtain specimens and monitor hourly output.
- Perform escharotomy or fasciotomy to the chest and extremities for constricting circumferential eschar, elevated compartment pressures, or impaired circulation.
- Apply topical antimicrobials and dressings to the burn wounds.
- Obtain a history regarding the injury and other pertinent data.
- Administer appropriate tetanus prophylaxis.
- Prophylactic antibiotic administration is not recommended.

eschar (dead tissue) may limit chest wall excursion, and ventilation of the child becomes more difficult. Young children are particularly at risk because of the pliability of the skeletal structure. Escharotomy of the chest, where the eschar is incised through to the fatty tissue, relieves this constriction and improves ventilation.

Fluid replacement therapy. The objectives of fluid therapy are to (1) compensate for water and sodium lost to traumatized areas and interstitial spaces; (2) reestablish sodium balance; (3) restore circulating volume; (4) provide adequate perfusion; (5) correct acidosis; and (6) improve renal function.

Fluid replacement is required during the first 24 hours because of fluid shifts that occur after the burn. Various formulas are used to calculate fluid needs, and the one adopted depends on practitioner preference. Crystalloid solutions are used during this initial phase of therapy. Parameters (such as urinary output volume, vital signs [especially heart rate], adequacy of capillary filling, and state of sensorium) determine adequacy of fluid resuscitation.

After the initial 24-hour period, theoretically there is a capillary seal, and capillary permeability is restored. Colloid solutions (such as albumin or fresh-frozen plasma) are useful in maintaining plasma volume. However, children with burns usually require fluids in excess of their calculated maintenance and replacement volume. Reasons for this may include underestimation of burn size (particularly in pediatric patients), delay in the initiation of fluid resuscitation, pulmonary injury that sequesters resuscitation fluid in the lung, and electrical injury with greater tissue destruction than that which is visible. Irreversible burn shock that persists despite aggressive fluid resuscitation remains a significant cause of death in the immediate postburn period. Fluid balance may continue to be a problem throughout the course of treatment, especially during periods in which there may be considerable evaporative loss from the burn.

Nutrition. The enhanced metabolic requirements and catabolism in severe burns make nutritional needs of paramount importance and often difficult to satisfy. To avoid protein breakdown, the diet must provide sufficient calories to meet the increased metabolic needs and enough protein. Hypoglycemia can result from the stress of the burn because the liver glycogen stores are rapidly depleted.

A high-protein, high-calorie diet is encouraged. Many children have poor appetites and are unable to meet energy requirements solely by oral feeding. Oral feedings are encouraged unless the child is intubated or paralytic ileus develops. Most children with burns in excess of 25% TBSA require supplementation with enteral feedings. Early and continued nutritional support is an important part of therapy for seriously burned patients. Children who require enteral supplementation must be monitored for adequacy of feeds, feeding intolerance, and tube malposition. The nurse should also monitor and report any abdominal distention, diarrhea, or electrolyte and metabolic deviations. If nutritional requirements cannot be met entirely by the enteral route, parenteral hyperalimentation is used to supplement intake. However, enteral feedings increase blood flow in the intestinal tract, preserve gastrointestinal function, and minimize bacterial translocation by decreasing mucosal atrophy of the intestines. These factors make enteral feeding the preferred route of nutritional support (Clark, Imran, Madni, et al., 2017).

To facilitate growth and proliferation of epithelial cells, administration of vitamins A and C is begun early in the post-burn period. Zinc is also supplemented because of its important role in burn healing and epithelialization.

Medication. Antibiotics are usually not administered prophylactically. The administration of systemic antibiotics to control wound colonization is not indicated because decreased circulation to the burned area prevents delivery of the medication to areas of deepest burn injury. The most reliable indicator of developing wound infection is changes in the appearance of the wound (Greenhalgh, 2017). Appropriate antibiotics are instituted to treat the specific identified organism. Remember, otitis media can also be a source of fever in the pediatric patient.

Some form of sedation and analgesia is required in the care of the burned child. There is no consensus for practice guidelines for procedural sedation and analgesia for pediatric patients across burn centers. Choice of the agent should depend on efficacy and safety of the agent as well as consideration of the age of the child, burn depth, extent and location, and length of the procedure (Fagin & Palmieri, 2017). The unstable circulatory status and edema formation preclude intramuscular or subcutaneous administration of these medications for effectiveness. Opioids, such as fentanyl (Sublimaze) and morphine, midazolam (Versed), propofol, ketamine, and dexmedetomidine, are the most commonly used agents. Dosage monitoring is important because tolerance to opioids may develop.

The use of short-acting anesthetic agents, such as propofol (Diprivan) and nitrous oxide, has proven beneficial in eliminating procedural pain. Pharyngeal reflexes remain intact, thus ensuring a patent airway. Propofol is an IV sedative hypnotic agent that produces sedation in less than 1 minute and lasts only a few minutes. For any conscious or unconscious sedation, the child must be monitored continuously during the procedure (see Chapter 20, Preoperative Care, and Chapter 5).

Management of the burn wound. After the initial period of burn shock and the restoration of fluid balance, the primary concern is the burn itself. The objectives of burn management include prevention of infection, removal of devitalized tissue, and closure of the burn. The application of dressings and topical antimicrobial therapy reduce pain by minimizing the exposure to air.

Primary excision. In children with large, full-thickness burns, excision is performed as soon as the patient is hemodynamically stable after initial resuscitation. Because the burn wound precipitates an

exaggerated physiologic response, many complications do not resolve until the eschar is excised and the wound is closed. Early excision of the burn is an effective therapy to reduce the incidence of infection and the threat of sepsis, thus decreasing mortality (Rowan et al., 2015).

Debridement. Partial-thickness burns require debridement of devitalized tissue to promote healing. Debridement is painful and requires analgesia and a sedative before the procedure. IV analgesics are most effective when they are administered just before the onset of procedural pain. Early usage of appropriate sedation for burn wound care allows for early aggressive wound debridement (Fagin & Palmieri, 2017). Medications given for pain need to be readily available during this procedure and may need to be titrated up during the procedure.

Hydrotherapy is used to cleanse the burn and involves either showering (spraying off the burn) or immersion (soaking in a tub) at least once a day. Immersion hydrotherapy is becoming less common and is being replaced by shower hydrotherapy. The water acts to loosen and remove sloughing tissue, exudate, and topical medications. Any loose tissue is carefully trimmed away before the burn is redressed. Hydrotherapy helps cleanse not only the burn, but also the entire body and aids in maintenance of range of motion.

Topical agents. Methods used for managing the burn include:

- **Open**—involves applying the topical antibacterial cream or ointment directly to the wound without use of gauze or any type of covering. This process may be repeated throughout the day, two to three times, as ordered. Burns of the face and ears are often treated by an open method type of wound care.
- **Semiocclusive/occlusive (closed)**—the wound care agent is prepared on some type of sterile gauze or comes prepackaged. When this method is used, during application all edges of the wound should be covered completely. Once this is completed the area is usually covered with an overwrapped layer of gauze (secondary dressing) and then held in place or secured. Some prepackaged long-acting prepared dressings are not changed daily.

These methods of care provide burn wound coverage and use some type of topical agent. Topical agents do not eliminate organisms from the burn but can effectively inhibit bacterial growth. To be effective, a topical application must be nontoxic, capable of diffusing through eschar, harmless to viable tissue, inexpensive, and easy to apply. A variety of specific agents are available; examples include bacitracin, silver sulfadiazine (Silvadene), and mafenide acetate (Sulfamylon). Some topical agents are packaged and prepared on fine-mesh gauze that allows ease of application. The gauze provides necessary protection for the burn, is nonadherent, maximizes patient comfort, increases rate of healing, decreases the need for frequent dressing changes, and is cost effective. Examples include a flexible low-adherent polyester layer coated with silver (Acticoat Flex 3 or Flex 7), a silicone foam dressing with silver (Mepilex Ag), and a wound contact layer consisting of a polyamide net coated with soft silicone (Mepitel). Assessment of the dressing, drainage (if any), and other complications is still completed daily.

Temporary skin substitutes. Permanent coverage of extensive burns is a prolonged process that requires repeated operative procedures using general anesthesia for atraumatic care in debridement and grafting. Early closure shortens the period of metabolic stress and decreases the likelihood of burn wound sepsis. In the acute phase, temporary skin substitutes cover and protect the burn from contamination, reduce fluid and protein loss, increase the rate of epithelialization, reduce pain, and facilitate movement of joints to retain range of motion.

Allograft (homograft) skin is obtained from human cadavers that are screened for communicable diseases. Allograft is particularly useful as a temporary skin covering of surgically excised deep partial- and full-thickness burns and extensive burns when available donor sites are limited. Severe immunosuppression occurs in massively burned children, and the allograft becomes adherent. The allograft can remain in place until suitable donor sites become available. Typically, rejection is seen approximately 14 to 21 days after application (Rezaei, Beiraghi-Toosi, Ahmadabadi, et al., 2017). The availability of tissue banks and a supply of suitable donors limit the use of allografts.

Xenograft from a variety of species, most notably pigs, is commercially available. Porcine xenograft will adhere to a clean superficial burn and provide excellent pain control while the burn heals (Vloemans, Hermans, van der Wal, et al., 2014). Porcine xenograft dressings are replaced daily or every 2 to 3 days. They are particularly effective in children with partial-thickness scald burns of the hands and face because they allow relatively pain-free movement, which can reduce contracture formation.

When applied early to superficial partial-thickness burns, skin substitutes stimulate epithelial growth and faster wound healing. However, they must be applied to clean burns. If the dressing covers areas of heavy microbial contamination, infection occurs beneath the dressing. In the case of partial-thickness burns, such infection may convert the burn to a full-thickness injury.

Synthetic skin coverings are available for the management of partial-thickness burns and donor sites. Ideally, the dressing should provide the properties of human skin, including adherence, elasticity, durability, and hemostasis. Synthetic skin coverings are readily available and are composed of a variety of materials that are usually permeable to air, vapor, and fluids.

Since these dressings do not contain antimicrobial properties, it is important that the burn is free of debris before the dressing is applied. Body temperature elevation or evidence of purulence, erythema, or cellulitis around the wound edges may indicate that the burn has become infected beneath the dressing. If this occurs, prompt discontinuation of the synthetic dressing is indicated. Examples include a pertrolatum dressing (Xeroform), a hydrocolloid dressing (DuoDERM), and transparent adhesive films (OpSite and Tegaderm). All synthetic dressings are reputed to hasten burn wound healing and reduce discomfort.

Permanent skin coverings. Permanent coverage of deep partial- and full-thickness burns is usually accomplished with a split-thickness skin graft (autograft). The graft consists of the epidermis and a portion of the dermis removed from the donor site of an intact area of skin by a special instrument called a dermatome (Fig. 31.19). With extensive burns, it is often difficult to find enough viable skin to cover the burns;

Fig. 31.19 Removal of split-thickness skin graft with a dermatome.

Fig. 31.20 Sheet graft.

Fig. 31.21 Mesh graft.

therefore available donor sites and special techniques are used. Split-thickness skin grafts may be sheet graft or mesh graft.

Sheet graft. A sheet of skin removed from the donor site is placed intact over the recipient site and sutured in place; this is used in areas where cosmetic results are most visible—for example, the face (Fig. 31.20).

Mesh graft. A sheet of skin is removed from the donor site and passed through a mesher, which produces tiny slits in the skin before application that allow the skin to cover 1.5 to 9 times the area of the sheet graft; this results in a less desirable cosmetic, but functional outcome (Fig. 31.21).

The donor site is dressed with synthetic wound coverings until the dressing separates at 10 to 14 days when the wound is healed. Dressings are not changed on donor sites to avoid damage to newly healed, delicate epithelium. Healed donor sites are available for reharvesting in patients with extensive burns and limited undamaged skin, but the quality of skin is decreased when multiple grafts are taken.

Dermal replacements. The development of products that replace or allow the dermis to regenerate has produced significant improvement in burn wound healing and decreased scar formation. Integra (artificial skin) is a two-layer membrane made of collagen (a fibrous protein from animal tendons and cartilage) and silicone. Applied over the burn following excision, the outer silicone layer is later peeled off after the dermis is formed. The application of artificial skin does not replace the grafting procedure but prepares the burn wound to accept an ultrathin autograft.

AlloDerm is another product that is used similarly to artificial skin. It is made from human cadaveric tissue that is processed to remove cells that can lead to tissue rejection. The resulting acellular tissue contains epithelial elements that provide a foundation for new tissue regeneration. With dermal replacements, advantages include faster healing of the burn wound when integrity of the dermis is restored, faster healing of donor sites with the use of ultrathin grafts, and restoration of sweat glands and hair follicles. A disadvantage is its high cost.

Cultured epithelium. When burns are extensive and donor sites for split-thickness skin grafting are limited, it is possible to culture cells from a full-thickness skin biopsy and produce coherent sheets that can be applied to clean, excised full-thickness burns. Epithelial cell culture grafts offer the possibility of an unlimited source of autografts in patients with extensive burns. Cultured epithelial autografts (CEAs) are effective in early wound closure. The child's own skin is fractionated and cultured in a porcine media to form a thin epithelial layer that is applied to the burn. This technique offers an improved rate of survival in patients with extensive burns and limited donor sites.

Application of skin cells. New technologies are emerging for skin repair of the burn patient. ReCell is one such device that processes a solution of the patient's harvested skin cells using minimal donor site skin. The device produces an autologous skin cell suspension that the burn surgeon then sprays onto the open wound in surgery to repair skin texture and color (Holmes, Molnar, Carter, et al., 2018).

Nursing Care Management

Because the care of burned children encompasses a broad range of skills, nursing care has been divided into segments that correspond with the major phases of burn treatment. The **acute phase**, also referred to as the *emergent* or *resuscitative phase,* involves the first 24 to 48 hours. The **management phase** extends from the completion of adequate resuscitation through burn coverage. The **rehabilitative phase** begins when the majority of the burns have healed and rehabilitation has become the predominant focus of the care plan. This phase continues until all reconstructive procedures and corrective measures are accomplished (often a period of months or years).

Acute Phase

The primary emphasis during the emergent phase is the treatment of burn shock and the management of pulmonary status. Monitoring vital signs, urine output, fluid infusion, and respiratory parameters are ongoing activities in the hours immediately after injury. IV infusion is begun immediately and is regulated to maintain an hourly urinary output of at least 0.5 to 1 ml/kg in children weighing less than 30 kg (66 pounds) or 30 ml/h in children weighing more than 30 kg (American Burn Association, 2016). Urinary output, vital signs, laboratory data, and objective signs of adequate hydration guide the rate of fluid administration.

Children who are hospitalized with burns require constant observation and assessment for complications. Alterations in electrolyte balance produce clinical symptoms of confusion, weakness, cardiac irregularities, and seizures. Changes in respiratory function and gas exchange are reflected clinically by restlessness, irritability, increased work of breathing, and alterations in blood gas values. The loss of protective function of the skin exposes burned children to increased risk of hypothermia. Edema formation and circulatory impairment result in the loss of sensation and deep, throbbing pain.

Burn centers maintain a pictorial record of the burns to record progress and for legal purposes (if nonaccidental trauma is suspected). Burn wounds are treated according to the protocol of the specific burn

! NURSING ALERT

Evaluate the burned extremity and check the pulse every hour. If unable to palpate, use a Doppler (an ultrasonic pulse probe that can detect blood flow) to ascertain loss of circulation and pulse. If the pulse is lost, escharotomy may be necessary to relieve the edema causing pressure on blood vessels to restore adequate circulation.

center. The burn team monitors infection control procedures and ensures that staff and visitors comply with established protocols to prevent cross-contamination in the burn unit.

Throughout the acute phase of care, the psychosocial needs of the child and his or her family are carefully considered. The child is frightened, uncomfortable, and often confused. The child may be isolated from familiar persons and surroundings; the overwhelming physical needs at this time are the primary focus of the staff and parents.

Management and Rehabilitative Phases

After the patient's condition is stabilized, the management phase begins. The interprofessional team concentrates on preventing burn wound infections, closing the burn as quickly as possible, and managing the numerous complications. Although the rehabilitative phase begins when permanent burn wound closure has been achieved, rehabilitation issues are identified on admission and are included in the care plan throughout the hospital course.

! NURSING ALERT

In a pediatric burn patient, a decreased level of consciousness, increased restlessness, and lethargy are some of the first signs of overwhelming sepsis and may indicate inadequate hydration. A decrease in blood pressure is considered a late sign in a pediatric patient with sepsis. Assessment of capillary refill and pulses are another important indicator of the adequacy of hydration. With inadequate hydration, a spiking fever and diminished bowel sounds accompanied by paralytic ileus are noted and progressively increase over 48 to 72 hours, after which the temperature falls to subnormal limits. At this time the wound deteriorates, the white blood cell count is depressed, and septic shock becomes manifest.

Comfort Management

The severe pain of the burn and resultant therapies, the anxiety generated by these experiences, sleep deprivation, itching related to burn wound healing, and the conscious and unconscious interpretations of traumatic events contribute to the psychologic behaviors commonly observed in children with burns. It is always difficult to deal with a child in pain, and inflicting pain on a helpless child is contrary to the empathic nature of nursing. Interventions to promote comfort may include medications (as previously mentioned), relaxation techniques, distraction therapy, behavioral techniques, operant conditioning (e.g., tokens, star chart), and family participation (Fagin & Palmieri, 2017).

Children need age-appropriate explanations before all procedures. When children appear to accept pain with little or no response, psychologic consultation may be needed. Consistency in caregivers is important. If this is not possible, a carefully developed, interprofessional care plan is necessary to provide consistency.

Care of the Burn Wound

The nurse has a major responsibility for cleansing, debriding, and applying topical agents and dressings to the burn. Pain medication should be administered so that the peak effect of the drug coincides with the procedure. Children who understand the procedure to be performed and have some perceived control demonstrate less maladaptive behavior. Children also respond well to participating in decisions (see Atraumatic Care box).

ATRAUMATIC CARE

Reducing the Stress of Burn Care Procedures

- Have all materials ready before beginning the procedure.
- Administer appropriate analgesics and sedatives.
- Remind the child of the impending procedure to allow sufficient time to prepare.
- Allow the child to test and approve the temperature of the water.
- Allow the child to select the area of the body on which to begin.
- Allow the child to request a short rest period during the procedure.
- Allow the child to remove the dressings if desired.
- Provide something constructive for the child to do during the procedure (e.g., holding a package of dressings or a roll of gauze).
- Inform the child when the procedure is near completion.
- Praise the child for cooperation.

Outer dressings are removed first. Any dressings that have adhered to the burn can be easily removed by applying tepid water or normal saline. Loose or easily detached tissue is debrided during the cleansing process. In dressing the burn, it is important that all areas be clean, that medication is amply applied, and that no two burned surfaces touch each other (e.g., fingers or toes, ears touching the side of the head). If they are touching, the burned surfaces will heal together, causing deformity or dysfunction.

Topical agents may be applied directly to the burn with a tongue blade or gloved hand as well as using impregnated fine-mesh gauze or prepackaged products. All dressings applied circumferentially should be wrapped in a distal-to-proximal manner. The dressing is applied with sufficient tension to remain in place but not so tightly as to impair circulation or limit motion. Elastic net is then applied to secure the dressing in place. A stable dressing is especially important when the child is ambulatory.

Standard Precautions, including the use of personal protective equipment as indicated, should be followed when caring for patients with burns. Frequent hand and forearm washing is the single most important element of the infection control program. Strict policies for cleaning the environment and patient care equipment should be implemented to minimize the risk of cross-contamination. All visitors and members of other departments should be oriented to the infection control policies, including the importance of hand and forearm washing and use of protective garb. Visitors should be screened for infection and contagious diseases before patient contact.

Prevention of Complications

Acute care. The maintenance of body temperature is important to children with burns. Core body temperature is supported when energy is conserved with an environmental temperature of 28°C to 33°C (82.4°F to 91.4°F). Large areas of the body should not be exposed simultaneously during dressing changes. Warmed solutions, linens, occlusive dressings, heat shields, radiant warmers, and warming blankets assist in preventing hypothermia.

The chief danger during acute care is infection: wound infection, generalized sepsis, or bacterial pneumonia. Accurate and ongoing assessments of all parameters that provide clues to the early diagnosis and treatment of infection are essential. Symptoms of sepsis include a decreased level of consciousness, a rising or falling white blood cell count, hyperthermia progressing to hypothermia, increasing fluid

Fig. 31.22 Extensive scars from a flame burn. (Courtesy The Paul and Carol David Foundation Burn Institute, Akron, OH.)

Fig. 31.23 Child in an elasticized (Jobst) garment and "airplane" splints.

requirements, hypoactive or absent bowel sounds, a rising or falling blood glucose level, tachycardia, tachypnea, and thrombocytopenia. Infection delays the progress of burn wound healing.

Children are reluctant to move if movement causes pain, and they are likely to assume a position of comfort. Unfortunately, the most comfortable position often encourages the formation of contractures and loss of function. Ongoing efforts to prevent contractures include maintaining proper body alignment, positioning and splinting the involved extremities in extension, providing active and passive physical therapy, and encouraging spontaneous movement when feasible. Frequent position changes are important to promote adequate bronchopulmonary hygiene and capillary perfusion to common pressure areas. Low–air loss beds are beneficial for morbidly obese children or children with posterior grafts. Special attention should be given to areas at risk for increased pressure, such as the posterior scalp, heels, sacrum, and areas exposed to mechanical irritation from splints and dressings.

Long-term care. When the burn heals, the rehabilitative phase of care begins. Scar formation becomes a major problem as the burn heals (Fig. 31.22). Contractile properties of the scar tissue can result in disabling contractures, deformity, and disfigurement.

Uniform pressure applied to the scar decreases the blood supply. When pressure is removed, blood supply to the scar is immediately increased; therefore periods without pressure should be brief to avoid nourishment of the hypertrophic tissue. Continuous pressure to areas of scarring can be achieved by elastic tubular bandages or commercially available pressure garments. Because these custom-made garments are often worn for months, revisions may be required as the child grows. It is much easier to prevent scarring and contracture of the burn than to resolve an existing problem. Splints and appliances may also be needed until wound maturation is achieved (Fig. 31.23).

Scar tissue has certain significant properties, particularly for growing children. Intense itching may occur in healing burn wounds and scar tissue until the scar is no longer active. Itching is usually treated with a variety of medications; hydroxyzine and diphenhydramine are examples of two such medications.

Frequently apply a moisturizer such as Aveeno Baby, Alpha Keri, Vaseline Intensive Care, or cocoa butter. Other brands with the word "ultra-healing" in their title that are fragrance-free and do not contain alcohol can be used. Massage therapy during the application of moisturizers is also beneficial to stretch scar tissue and aid in contracture prevention. Scar tissue has no sweat glands, and children with extensive scarring may experience difficulty during hot weather. Caregivers should be alerted to this possibility and be prepared to institute alternate methods of cooling when necessary.

Scar tissue does not grow and expand as does normal tissue, which may create difficulties, especially in functional areas such as on the hands and over joints. Additional surgery is sometimes required to allow independent functioning in daily activities, to improve cosmetic appearance, or to restore anatomic integrity.

The nursing activities in the rehabilitative phase of treatment focus on the child's and family's adaptation to the burn and their ability to reintegrate into the community. The psychologic pain and sequelae of severe burn injury are as intense as the physical trauma. The impact of severe burns taxes the coping mechanisms at all ages. Very young children, who suffer acutely from separation anxiety, and adolescents, who are developing an identity, are probably the most affected psychologically. Toddlers cannot understand why the parents they love and who protect them can leave them in such a frightening and unfamiliar place. Adolescents, in the process of achieving independence from the family, find themselves in a dependent role with a damaged body. Being different from others, especially at a time when conformity with peers is so important may be difficult to accept.

Anticipation of the return to school can be overwhelming and frightening. It is essential that health care professionals recognize the importance of preparing teachers and classmates for the child's return. Teachers need to be provided with information to assist the child and family and to promote the child's optimal adjustment. Hospital-sponsored school reentry programs use a variety of methods to provide education and information about the implications of the injury, the garments and appliances, and the need for support and acceptance. Telephone calls, videotapes, information packets, and visits by members of the health care team offer opportunities to help with reintegration into the school environment—a focal point of the child's life.

Psychosocial Support of the Child

Children should begin early to do as much for themselves as possible and to be active participants in their care. Loss of control and perceived helplessness may result in acting-out behaviors. During illness, children can regress to a previous developmental level that allows them to deal with stress. As children begin to participate in their care, they gain

confidence and self-esteem. Fears and anxieties diminish with accomplishment and self-confidence. If the child demonstrates nonadherence in the rehabilitative phase, a behavior modification program can be initiated to promote or reward the child's accomplishments in care.

Play is a normal part of a young child's life. This normalcy becomes disrupted and compromised when a burn injury occurs and various treatments and therapies are necessary. In the hospital, a child life specialist can be of assistance in decreasing distress, fear, and sometimes pain during procedures or care. Having a child life specialist assess the child and introduce distraction techniques and play therapy can be instrumental throughout hospitalization (Fagin & Palmieri, 2017).

Children need to know that their injury and the treatments are not punishment for real or imagined transgressions and that the nurse understands their fear, anger, and discomfort. They also need human touch. This is often difficult to arrange for the child with massive burns. Stroking areas of unburned skin is comforting. Even older children enjoy sitting on the parent's or caregiver's lap and being cuddled and hugged. This can be a reward or a comfort in times of stress, but most of all it should be kept in mind that it is a natural part of childhood.

Psychosocial Support of the Family

Recognizing and respecting each family's strengths, differences, and methods of coping allow the nurse to respond to their unique needs by implementing a family-centered approach to care. In the acute phase, most of the attention is focused on the child, and the parents or caregivers may feel powerless and ineffectual. Parents or caregivers may feel overwhelming guilt, whether or not this guilt is justified. They feel responsible for the injury. These feelings may impede the child's rehabilitation. Parents or caregivers may indulge the child and allow nonadherent behaviors that affect physical and emotional recovery. They need to be informed of the child's progress and helped to cope with their feelings while providing support to their child. The nurse can help them understand that it is not selfish to look after themselves and their own needs in order to meet their child's needs. It is important to recognize the parents' or caregivers' need to grieve the change in their child's normal appearance as part of the grieving process. Definitive professional help may be needed for those whose response to the injury is severe or whose response to stress is manifested in destructive behavior.

The parents or caregivers are members of the interprofessional team and participate in the development of the care plan. It is important to facilitate their input; to consider all aspects of the physical, emotional, social, and cultural factors affecting the child and family; and to establish a realistic home therapy program. The family's willingness to assume responsibility for care and their ability to implement the therapeutic regimen are assessed. Home, school, and other environmental factors are explored; financial concerns and available community resources are discussed; and a specific care plan for the child, with an anticipated follow-up program, is developed.

Prevention of Burn Injury

The best intervention is to prevent burns from occurring. Hot liquids in the kitchen and bathroom most commonly injure infants and toddlers. Hot liquids should be kept out of reach; tablecloths and dangling appliance cords are often pulled by toddlers, who spill hot grease and liquids on themselves. Electrical cords and outlets represent a potential risk to small children, who may chew on accessible cords and insert objects into outlets.

The Consumer Product Safety Commission recommends a reduction of water heater thermostats to a maximum of 48.9° C (120° F). The "dial-down" recommendation has been suggested by utility companies, burn treatment centers, medical personnel, and others interested in public safety. However, many water heaters continue to remain set at levels well above the safe level. Small children are especially at risk for scald injuries from hot tap water because of their decreased reaction time and agility, their curiosity, and the thermal sensitivity of their skin. Third degree burns can develop within 5 seconds at a temperature of 140° F and within 2 seconds at 148° F. When bathing a child the caregiver should never leave the child unattended. Always test the water before placing the child into the tub or shower.

BOX 31.5 Microwave Safety

- Do not let small children operate the microwave.
- Place microwave ovens at a safe height (but higher than children's faces) and within easy reach to avoid spills.
- Never leave a young child alone while food is heating in the microwave.
- For food heated in containers, puncture plastic wrap, use vented lids, or wait 1 minute before removing a sealed covering; then lift the covering from the corner farthest away from face or arm.
- Never heat baby formula or milk in a plastic bottle liner because it may burst.
- Before adding a cold liquid to a liquid that has been heated in the microwave, insert a spoon to prevent bubbling over of the hot liquid.
- Stir food well or let it stand for 1 minute before tasting it so the heat can distribute evenly.

The increased use of microwave ovens has resulted in burn injuries from the extremely hot internal temperatures generated in heated items. Baby formula, jelly-filled pastries, noodles, and hot liquids or dishes may result in cutaneous scalds or the ingestion of overheated liquids. Caregivers should use caution when removing items from the microwave oven and should always mix and test the food before giving it to children (Box 31.5).

As children mature, risk-taking behaviors increase. Matches and lighters are dangerous in the hands of children. Adults must remember to keep potentially hazardous items out of the reach of children; a lighter, like a match, is a tool for adult use.

Education related to fire safety and survival should begin with very young children. They can practice "stop, drop, and roll" to extinguish a fire. The fire escape route, including a safe meeting place away from the home in case of fire, also should be practiced. A working smoke alarm greatly reduces the chance of dying in a home fire. Additional information on burn care and prevention can be obtained from the American Burn Association[b] and the National Safety Council.[c]

Community activities are also helpful in supporting burn survivors and preventing burns. Aluminum Cans for Burned Children is an exemplary effort based at The Paul and Carol David Foundation Burn Institute in Akron, Ohio.[d] Activities funded by Aluminum Cans for Burned Children include a burn survivors support group, Burn Camp, and meetings of Juvenile Firestoppers (for children with fire-setting behavior). Adult weekend retreats and school and family education sessions are a part of this program. The burn center and fire department provide the personnel to present programs.

SUNBURN

Sunburn is a common skin injury caused by overexposure to UV light waves—either sunlight or artificial light in the UV range. The sun emits a continuous spectrum of visible and nonvisible light rays that range in length from very short to very long. The shorter, higher frequency waves are more damaging than longer wavelengths, but much of the light is filtered out as it travels through the atmosphere. Of the light that does filter through, **ultraviolet A (UVA) waves** are the longest and cause only minimum burning, but they play a significant role in photosensitive and photoallergic reactions. They are also responsible for premature aging of the skin and potentiate the effects of **ultraviolet B (UVB) waves**, which are shorter and responsible for tanning, burning, and most of the harmful effects attributed to sunlight, especially skin cancer.

Numerous factors influence the amount of UVB exposure. Maximum exposure occurs at midday (10 AM to 3 PM), when the distance from the sun to a given spot on the Earth is shortest. Solar intensity varies with the seasons, time zones, and altitude. Exposure is greater at higher altitudes and near the equator and less when the sky is hazy (although the effect is easily underestimated). Window glass effectively screens out UVB but not UVA rays. Fresh snow, water, and sand reflect UV rays, especially when the sun is directly overhead.

Excessive or long-term exposure to the sun and UV rays permanently damages the skin. Ninety percent of skin cancers occur in areas of the skin that are exposed to UV rays, and rates of skin cancers are higher in parts of the world where sunlight is more intense.

Nursing Care Management

Treatment involves stopping the burning process, decreasing the inflammatory response, and rehydrating the skin. Local application of cool tap water soaks or immersion in a tepid-water bath (temperature slightly below 36.7°C [98°F]) for 20 minutes or until the skin is cool limits tissue destruction and relieves the discomfort. After the cool applications, aloe gel or a bland oil-in-water moisturizing lotion can be applied. Partial-thickness burns are treated in the same way as those from any heat source (see earlier discussion on burns).

Protection from sunburn is the major goal of management, and the harmful effects of the sun on the delicate skin of infants and children are currently receiving increased attention. To protect skin exposed to the sun for extended periods, skin should be covered with clothing, and sun protection agents approved by the US Food and Drug Administration should be applied. Two types of products are available for sun protection: (1) **topical sunscreens**, which partially absorb UV light; and (2) **sun blockers**, which block out UV rays by reflecting sunlight. The most frequently recommended sun blockers are zinc oxide and titanium dioxide ointments.

Sunscreens are products containing a **sun protection factor (SPF)** based on evaluation of effectiveness against UV rays. Most sunscreens have an SPF ranging from 2 to more than 30; the higher the number, the greater the protection. For example, if an individual normally burns in 10 minutes without a sunscreen, use of a sunscreen with SPF 15 allows them to remain in the sun 15 times 10, or 150 minutes (2½ hours) before acquiring the same degree of burns. The most effective sunscreens against UVB are ***p-aminobenzoic acid (PABA)*** and **PABA-esters**. However, many individuals are allergic to PABA, and sunscreens without PABA are encouraged to prevent these reactions in children.

Sunscreens are applied evenly to all exposed areas, with special attention to skin folds and areas that might become exposed as clothing shifts. Avoid eye contact. Parents are directed to read labels of sunscreen products carefully for the SPF and follow manufacturer's directions for application.

! NURSING ALERT

Sunscreens are not recommended for infants younger than 6 months old. However, infants younger than 6 months old may have sunscreen applied over small areas of skin (such as the back of hands) that may not be adequately covered by clothing when they are in the sun. Infants should be kept out of the sun or physically shaded from it. Fabric with a tight weave, such as cotton, offers good protection.

Individuals who work in the community, such as teachers, daycare workers, coaches, and youth group leaders, and relatives should all be made aware of sun safety for children. Sunscreens must be applied *liberally to exposed skin and reapplied often.*

COLD INJURY

In cold injuries the nature of the heat-regulating mechanisms of the body is such that the inner portion of the body, or core, produces heat, and the periphery, or outer area, conserves or dissipates heat. When the body attempts to conserve heat, the outer tissues are subjected to low temperatures, and local trauma may result.

Chilblain, redness and swelling of the skin, occurs when extremities, usually the hands, are exposed intermittently to temperatures of 1.1°C to 15.5°C (30°F to 60° F). The response may vary but is characterized by intense vasodilation that increases the temperature of involved tissues above that of unaffected tissue and produces edematous, reddish blue patches that itch and burn. As warming takes place, the sensations become more intense, but ordinarily they subside in a few days.

Frostbite is the term used to describe tissue damage caused when excessive heat loss to local tissues allows ice crystals to form in tissues. The frostbitten part appears white or blanched, feels solid, and is without sensation. Rapid rewarming is associated with less tissue necrosis than slow thawing. It restores blood flow and shortens the period of cellular damage. Rewarming produces a flush (sometimes deep purple) and a return of sensation, which is extremely painful. Large blisters may appear in 24 to 48 hours after rewarming and begin to reabsorb within 5 to 10 days, followed by the formation of a hard black eschar.

Nursing Care Management

Treatment involves rapid rewarming of the affected areas. Rewarming is accomplished by immersing the part in well-agitated water at 37.8°C to 42.2°C (100°F to 108°F). Discomfort is managed with analgesics and sedatives. Care of blistered skin is similar to that described for burns. Superficial injury often heals without incident. It is seldom possible to estimate the extent of tissue loss until new skin layers are revealed after the eschar layer separates. Treatment of the wound is comparable to burn wound care. In extreme cases amputation may be necessary.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A 16-year-old male is admitted with burns on both arms and face after trying to light a gas grill. He had put gasoline on it because it would not light. The nurse notes that the patient has superficial partial thickness burns on both lower front arms and the top of the hands. He has superficial burns on both sides of his face, specifically on the cheeks. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.** Using the Rule of Nines, the nurse calculates the patient has burns on approximately _____1_____ of his total body surface area. The nurse is aware that with superficial partial thickness burns, _____2_____ are intact and the wound should heal in approximately _____3_____ with possible scarring.

Options for 1	Options for 2	Options for 3
3%	bony structures	3-4 days
5 ½ %	muscle structures	5-7 days
10 ½ %	dermal elements	7-14 days
22%	fascia elements	14-21 days
6 ½%	nerve structures	30 days

2. A 9-month-old girl is in the pediatrician office because of a diaper rash that is getting worse. The child has no fever, is bottle fed and is in the 50% for weight and height for age. On examination the nurse notes a soiled diaper with a strong ammonia odor. The skin is beefy red with numerous maculopapular lesions across the front. The lesions extend into the skin folds and across the upper thighs. The child's axillary temperature is 98.9° F, pulse = 80 beats/min, respirations = 28/min. Which of the following would the nurse discuss with the mother? **For each nursing action, use an X to indicate whether it was Effective (helped to meet expected quality patient outcomes), Ineffective (did not help to meet expected quality patient outcomes), or Unrelated (not related to the quality patient outcomes).**

Nursing Action	Effective	Ineffective	Unrelated
"Change the diaper as soon as it becomes wet or soiled."			
"Use a hair dryer or heat lamp to dry the area."			
"Use a superabsorbent disposable diaper if you can."			
"Keep the skin dry."			
"Wash the area often as possible using a wipe."			
"Diapers that are unscented can be purchased."			
"Apply ointment such as zinc oxide or petrolatum to the skin."			
"Avoid removing the skin barrier cream with each diaper change."			

3. A school nurse is seeing several children who have evidence of pediculosis capitis. Most of these children are coming from one first grade class. Children have been evaluated by carefully assessing the scalp by spreading the hair to look for lice and observing for nits or eggs that adhere to the hair shafts close to the scalp. These children were treated with a lice treatment and recommended to treat the scalp again in 10 days. The nurse is working with the teacher to educate parents on how to prevent pediculosis. What are the **most appropriate** responses for the nurse to provide to help prevent another outbreak? **Select all that apply.**

A. Inspect the child for head lice on a regular basis once an outbreak occurs.
B. Seal non-washable items in plastic bags for 2 months before using again.
C. Keep clothing items such as hats and scarves in separate cubicles at school.
D. Treat infected children monthly with a lice treatment during the school year.
E. Teach children not to share hats, scarves, hair accessories, combs or brushes.
F. Machine wash all washable clothing, towels and linens in water hotter than 130° F.

4. A 9-year-old boy in the emergency department for a "skin rash." His boy scout troop was camping three weeks ago. The mother noted a large red raised lesion on his ankle when he returned from camp, but the child did not complain about it. The nurse completes a history and physical assessment and notes the following. Which assessment findings **require follow-up** by the nurse? **Select all that apply.**

A. Fatigue
B. Headache
C. Temperature 100.4° F
D. Cough for past week
E. Pulse = 88 beats/minute
F. Respirations = 20/minute
G. Blood pressure = 100/66 mmHg
H. Spleen 1 cm below left costal margin
I. Small, red, annular lesions on the lower legs and arms
J. Inguinal and axillar lymph nodes 1 cm in circumference

Clinical Judgment and Next-Generation NCLEX® Examination-Style Questions Answer Key

CHAPTER 1 PERSPECTIVES OF PEDIATRIC NURSING

1. C, D
2. A, C, E, G
3.

CJMM Skill	Nursing Process	Match the Nursing Process Skill With CJMM Skill
1. Recognize Cues	Analysis	**2 or 3**
2. Analyze Cues	Planning	**4**
3. Prioritize Hypotheses	Implementation	**5**
4. Generate Solutions	Evaluation	**6**
5. Take Action	Assessment	**1**
6. Evaluate Outcomes		

4.

Nursing Action	Indicated	Contraindicated	Non-Essential
Eating preferences and attitudes related to food are established by family influences and culture.	X		
Breastfeeding provides micronutrients and immunologic properties.	X		
Most children establish lifelong eating habits by 18 months of age.		X	
Because of the stress of returning to work, most mothers use this as a time to stop breastfeeding.		X	
During adolescence, parental influence diminishes, and adolescents make food choices related to peer acceptability and sociability.			X
Chronic illness can cause a young child to not want to eat.		X	

CHAPTER 2 SOCIAL, CULTURAL, RELIGIOUS, AND FAMILY INFLUENCES ON CHILD HEALTH PROMOTION

1.

Options for 1	Options for 2	Options for 3 and 4
Stage I	**Autonomy**	**Marital**
Stage II	Trust	Sibling
Stage III	Identity	**Career**
Stage IV	Fear	Home
Stage V	Growth	Retirement
Stage VI	Height	Insurance

2.

Nursing Action: Quality Patient Outcomes	Indicated	Contraindicated	Non-Essential
Realize that parenting roles are learned behaviors and the mother is not prepared to take the child home.			X
The family strengths and unique functional style can be a resource for the nurse.	X		
Parenting styles are all the same, and the mother should be forced to listen to the discharge plan.		X	
Despite difficulty trying to meet with the mother, a sense of purpose to care for this child at home can promote a successful discharge.	X		
This must be a single family, and counseling should be contacted to work with the mother.		X	

3. A, B, C, D, E
4. A, C, E

CHAPTER 3 DEVELOPMENTAL AND GENETIC INFLUENCES ON CHILD HEALTH PROMOTION

1. C, E
2. B, C, D
3.

History and Assessment	Indicated	Contraindicated	Non-Essential
Family history should include information going back at least three generations.	X		
Family history should include environmental assessment, including neighbors and friends.		X	
Assessment should focus only on the infant's ability to move the arms and legs.		X	
Assessment should evaluate for Turner syndrome since girls have a prepubertal growth spurt and then mostly stop growing.			X
Awareness of parents' feelings of guilt about causing the disorder is important for the nurse to consider.	X		

4.

Options for 1	Options for 2	Options for 3
Chromosome analysis	**risk factors**	etiology
Family health history	medical records	**inheritance patterns**
Ultrasound	severity	rate of occurrence
Metabolic screening	birth defects	
Anorexia	platelets	
Fever	weight	

CHAPTER 4 COMMUNICATION AND PHYSICAL ASSESSMENT OF THE CHILD AND FAMILY

1. A, B, D
2.

Options for 1	Options for 2
20%	radial arterial
30%	radial venous
40%	dorsal arterial
50%	popliteal venous
60%	**brachial arterial**

3.

Nursing Action: Approach to Physical Examination	Effective	Ineffective	Unrelated
With toddlers, restraints help keep the child still, and requesting a parent's assistance is inappropriate.		X	
An infant's physical examination is always done head to toe, similar to that for an adult.		X	
When examining a preschooler, giving a choice of which body parts to examine first may be helpful in gaining the child's cooperation.	X		
Giving explanations about body systems can make adolescents nervous due to their egocentricities.			X
With an adolescent, it is best to have a parent present during the examination.		X	
The parent's knowledge of stethoscopes can help with cooperation during the examination			X

4.

Nursing Action	Indicated	Contraindicated	Non-Essential
Understand the difference in measurement for children who can stand alone and for those who must lie recumbent.	X		
Use a stadiometer to measure infant length.		X	
Two measurers are required for a recumbent child.			X
Reposition the child and repeat the procedure. Measure at least twice (ideally three times). Average the measurements for the final value.	X		
Demonstrate competency when measuring the growth of infants, children, and adolescents. Refresher sessions should be taken when a lack of standardization occurs.	X		
Understand the difference in body mass index (BMI) in children versus adults.			X

CHAPTER 5 PAIN ASSESSMENT AND MANAGEMENT IN CHILDREN

1.

Nursing Action	Indicated	Contraindicated	Non-Essential
"Infants don't feel pain as adults do because their pain receptors are not fully developed yet."		X	
"Although we try to give the baby medicine before pain is felt, we watch very closely and use different techniques to help relieve the pain."	X		
"The nurse gives pain medication to all hospitalized patients before the infant really feels the pain."			X
"We assess pain using a pain assessment tool for children of all ages and give the medicine as needed."		X	
"We wait until the infant cries or is fussy, and then we know that pain is being experienced."		X	

2. A, G, I, J

3.

Pain Assessment Scale	Patient and Type of Pain Experienced	Correct Pain Scale
1. CRIES: **C**rying, **R**equiring increased oxygen, **I**nability to console, **E**xpression, and **S**leeplessness	2-year-old with Down syndrome in recovery from morning surgery	**2**
2. FLACC Pain Assessment Tool: **F**acial expression, **L**eg movement, **A**ctivity, **C**ry, and **C**onsolability	Newborn in intensive care for low birth weight and born to an addicted mother	**1**
3. Non-Communicating Children's Pain Checklist (NCCPC): Parent and health care giver questionnaire assessing acute and chronic pain	17-year-old admitted for sickle cell crisis	**7**
4. Neonatal Pain, Agitation, and Sedation Scale (NPASS): For infants from 3 to 6 months old	5-year-old with leukemia undergoing a lumbar puncture	**5**
5. Wong-Baker FACES Pain Rating Scale		
6. Premature Infant Pain Profile (PIPP)		
7. Visual Analogue Scale		

4.

Options for 1	Options for 2	Options for 3
intermittent	**bolus**	increasing
continuous	triple	changing
as needed	half	stopping
prn	full	**tapering**
one-time	continuous	adjusting
daily	daily	holding

CHAPTER 6 CHILDHOOD COMMUNICABLE AND INFECTIOUS DISEASES

1.

Standard Precautions	History and Assessment Findings	Type of Precaution to Implement
1. Transfusion-Based Precautions	15-year-old returning from summer in India who presents with symptoms of tuberculosis	**2**
2. Airborne Precautions	3-year-old who has a respiratory illness with cough	**5**
3. Standard Precautions	5-year-old admitted with fever and productive cough; bacterial pneumonia confirmed by lab and x-ray	**4**
4. Droplet Precautions	7-year-old admitted for tonsillectomy	**3**
5. Respiratory Hygiene / Cough Etiquette		
6. No precautions needed		

2.

Options for 1	Options for 2	Options for 3
A Virus	subcutaneously	dorsogluteal
B Virus	intravenously	**vastus lateralis**
Tetanus	**intramuscularly**	pectoral
Infection	intrathecally	subclavicular

3. A, D, E, G, H, I

4. A, C, E

CHAPTER 7 HEALTH PROMOTION OF THE NEWBORN AND FAMILY

1. A, B, D, E, F
2.

Nursing Action: Early Discharge Newborn Care	Topic	Appropriate Nursing Education Action
1. The newborn should be fed every 1.5-3 hours.	Wet Diapers	**8**
2. This could occur within 24 hours of birth and hemolysis or ABO/Rh problem suspected.	Position of Sleep	**6**
3. The newborn should be fed 1-2 oz every 4-6 hours.	Umbilical Cord	**5**
4. Wash with warm water and check for bleeding.	Stools	**9**
5. Keep it above the diaper line, allow to dry, and check for drainage.	Breastfeeding	**1**
6. Place the newborn on his back.	Pathologic Jaundice	**2**
7. The newborn should have 4-5 wakeful periods a day.		
8. The newborn should have 6-10 wakeful periods a day after 14 days of age.		
9. The newborn should have 2-3 stools a day if breastfeeding.		

3. A, C, E
4.

Health Teaching	Indicated	Contraindicated	Non-Essential
Human immunodeficiency virus (HIV) is rarely transmitted to the newborn through maternal milk.		**X**	
In such infants, antiretroviral medication will be started within 12 hours of birth.			**X**
Breastfeeding will be avoided completely in mothers with high-risk behaviors.		**X**	
Breastfeeding will be withheld until HIV status (maternal) is determined.	**X**		

CHAPTER 8 HEALTH PROBLEMS OF NEWBORNS

1.

Options for 1	Options for 2
oral	mouth
rectal	ear
axillary	**rectum**
temporal	nose

2.

Nursing Action	Indicated	Contraindicated	Non-Essential
Review the medical history to assess what laboratory studies were performed after birth.	**X**		
Encourage frequent breastfeeding.	**X**		
Switch to formula feeding for 72 hours.		**X**	
Teach mother how to swaddle the newborn.			**X**
Administer intravenous (IV) immunoglobulin.		**X**	

3. B, C, D, E
4. B, C, E, F, G

CHAPTER 9 HEALTH PROMOTION OF THE INFANT AND FAMILY

1. B, D, E
2.

Health Teaching	Indicated	Contraindicated	Non-Essential
The infant will be taking a vitamin D supplement daily.	**X**		
The infant will be receiving a fluoride supplement.		**X**	
The infant will be receiving an iron supplement.		**X**	
The infant's head will be covered when breastfeeding.			**X**
Breast milk can be stored in the refrigerator for up to 5 days.	**X**		

3.

Options for 1	Options for 2	Options for 3
obesity	1-2 days	**food allergies**
iron-deficiency anemia	10-12 days	infection
rickets	**4-7 days**	growth delay
infant botulism	14 days	urinary tract infection

4.

Nursing Education	Potential Injury	Appropriate Nursing Action to Promote Safety
1. Keep buttons, beads, or other small objects out of infant's reach.	Falls	**2**
2. Restrain in a highchair.	Aspiration	**1**
3. Know the local poison control number.	Suffocation	**5**
4. Keep out of reach of water faucets.	Poisoning	**3**
5. Keep latex balloons out of reach.	Burns	**4**
6. Keep bathroom doors closed.		
7. Keep large objects that could be overturned off furniture.		

CHAPTER 10 HEALTH PROBLEMS OF INFANTS

1. A, B, D, E
2.

Options for 1	Options for 2
diarrhea	goat's milk
eczema	**soy milk or a hydrolyzed formula**
sneezing	whole milk
urticaria	evaporated milk
fever	milk
swelling	eggs

3. B, C, D, F
4.

Nursing Action: Health Teaching	Indicated	Contraindicated	Non-Essential
Reassure the mother that she is correct in keeping the infant on his side.		**X**	
Discuss with the mother that keeping the infant in bed with her can actually increase the risk of sudden infant death syndrome (SIDS).	**X**		
Advise the mother that the waterbed is a type of "soft bedding" and the infant should not sleep on the waterbed.	**X**		
Discuss with the mother that a warm bath before bedtime can help minimize risk.			**X**
Advise the mother to keep stuffed animals and toys in the crib to provide comfort.		**X**	

CHAPTER 11 HEALTH PROMOTION OF THE TODDLER AND FAMILY

1. A, B, D, E
2. A, C, D
3.

Health Teaching	Indicated	Contraindicated	Non-Essential
Avoid placing large food portions on the toddler's plate.	**X**		
Allow the child to graze on snacks during the day.		**X**	
Insist that the child sit at the table until all persons have completed their meals.		**X**	
Allow the child to make certain food choices (within reasonable limits).	**X**		
Provide meals at the same time of day as much as possible so that the toddler has a sense of consistency.	**X**		
Offer the child oranges or apples each day.			**X**
Make the child eat all of the food provided and use disciplinary actions if the plate is not cleaned.		**X**	

4.

Options for 1	Options for 2
rear-facing	until the child is 2 years of age
front seat	**for as long as possible**
forward-facing	until the child can sit in the front seat
booster that is front facing	until the child weighs 50 pounds

CHAPTER 12 HEALTH PROMOTION OF THE PRESCHOOLER AND FAMILY

1. A, B, E
2.

Health Teaching	Indicated	Contraindicated	Non-Essential
Most preschoolers weigh between 10 and 12 kilograms.		**X**	
The legs of a preschooler, rather than the trunk, increase in length, which may make him look thinner.	**X**		
Preschoolers usually keep that pot-bellied appearance until about 6 years old.		**X**	
Most preschoolers gain ½ to 1 pound per year.		**X**	
Most preschoolers do not like to get their weight and height checked.			**X**

3.

Options for 1	Options for 2	Options for 3
understand	**prejudice**	**perspective**
wonder	change	likeness
question	colors	family
fear	hardship	status
realize	temperature	parents

4. C, D, E

CHAPTER 13 HEALTH PROBLEMS OF TODDLERS AND PRESCHOOLERS

1. A, D, E
2. A, C, E, F
3.

Options for 1	Options for 2
surveillance	**1 month**
treatment	1 week
chelation	6 months
nutrition	6 weeks
iron supplements	1 year

4. A, C, E

CHAPTER 14 FAMILY-CENTERED CARE OF THE SCHOOL-AGE CHILD AND ADOLESCENT

1.

Health Teaching	Indicated	Contraindicated	Non-Essential
"Children this age are able to see things from another's point of view, and it is important to keep communication open with your son."	X		
"He may be having difficulty making judgments about his surroundings and may need further evaluation."		X	
"It would be helpful to sit beside him and watch a favorite movie to show support."			X
"School-age children often use their past experiences to evaluate their present situation, and moving to a new school is a tough adjustment for him."	X		

2. B, D, F
3.

Sex Education Nursing Action	Effective	Ineffective	Unrelated
Separate the boys and girls into same-sex groups with a leader of the same sex.	X		
Answer questions in a matter-of-fact way that is honest and appropriate to the children's level of understanding.	X		
Use vernacular or slang terms to describe human physiologic functions.		X	
Avoid discussing sexually transmitted infections in this age-group.		X	
Discuss what it is like to have your first boyfriend or girlfriend.			X
Discuss common myths and misconceptions associated with sex and the reproductive process.	X		

4.

Options for 1	Options for 2
peer pressure	bullying
physical awkwardness	clumsiness
parents' lack of supervision	feeling small
wanting to impress the opposite sex	**risk-taking behaviors**
hormones	feeling invincible
underdeveloped skeletal muscles	showing off

CHAPTER 15 HEALTH PROMOTION OF THE ADOLESCENT AND FAMILY

1.

Options for 1	Options for 2
facial hair	muscle
height	**breast**
testicular enlargement	penile
ejaculation	testicular
axillary hair	larynx
voice changes	neck

2. B, C, D, F
3. A, B, C
4. B, D, F

CHAPTER 16 HEALTH PROBLEMS OF SCHOOL-AGE CHILDREN AND ADOLESCENTS

1. dry eyes, decreased night vision, headaches, depression, mood swings
2. A, D, E, F
3.

Option 1	Option 2	Option 3	Option 4
Abstinence	>99% effective	Irregular menstrual bleeding	Not recommended for women >90 kg
Calendar methods	Regulates menses	Latex sensitivity may occur	Risk of perforation
Oral contraceptives	Prevents ovarian cancers	**High failure rate unless combined with condom**	May cause headaches
Progestin	**Easy to use, minimal side effects**	May cause nausea	May cause dysmenorrhea
Cervical cap	Prevents endometriosis	May cause vaginitis	**Requires fitting by medical personnel, minimal sexually transmitted infection (STI) protection**

4.

Option 1	Option 2	Option 3
Neisseria gonorrhoeae	*Neisseria gonorrhoeae*	**Neisseria gonorrhoeae**
Chlamydia trachomatis	*Chlamydia trachomatis*	*Chlamydia trachomatis*
Treponema pallidum	*Treponema pallidum*	*Treponema pallidum*
Human papillomavirus (HPV)	**Human papillomavirus (HPV)**	Human papillomavirus (HPV)
Trichomonas vaginalis	*Trichomonas vaginalis*	*Trichomonas vaginalis*

CHAPTER 17 FAMILY-CENTERED CARE OF THE CHILD WITH SPECIAL NEEDS

1.

Health Teaching	Indicated	Contrain-dicated	Non-Essential
"'Giving in' is not a detriment to your child when he or she has a disability and limitations."		X	
"When parents establish reasonable limits, children are likely to develop independence that is appropriate for their age and achievement equal to their limitations."	X		
"It is best to wait to explain any procedure to the child until they are at the health care setting or just before the procedure to avoid unduly upsetting your child."		X	
"I recommend talking to other mothers in your neighborhood about how they parent their children."			X
"It is important to realize that it would be unfair to the siblings to expect similar rules to apply to all children in the family."		X	

2. A, C, F
3. A, B, E, F

4.

Nursing Action	Potential Communication Problems	Appropriate Nursing Action for Potential Communication Problem
1. Listen to the mother's perception of the seriousness or severity of the illness.	Lack of support from family and friends	**7**
2. Provide an opportunity for the mother to discuss her concerns and worries.	Nurse unaware of the mother's understanding of the child	**1**
3. Acknowledge that language constraints may make it necessary for the health care team to make some decisions.	Lack of support from health care providers	**2**
4. Ask the mother how her extended family feels about the child's illness.		
5. Tell the mother not to talk to anyone else about her concerns.		
6. Explore alternative medicines and therapies.		
7. Explore the mother's support network to find others that can help.		

CHAPTER 18 IMPACT OF COGNITIVE OR SENSORY IMPAIRMENT ON THE CHILD AND FAMILY

1. A, C, F, G, H
2. A, B, C, D
3.

Health Teaching	Indicated	Contra-indicated	Non-Essential
"It is unfortunate that you waited so long to have children; most children with Down syndrome are born to older women."		**X**	
"When feeding your infant, use a small, straight-handled spoon to push food to the side and back of the mouth."	**X**		
"Parents like you believe that the experience of having this special child makes them stronger and more accepting of others."			**X**
"As your child gets older, it has been found that school is detrimental to the child with Down syndrome due to lack of one-on-one teaching."		**X**	
"I am going to listen closely to your child's heart because congenital heart problems can occur in a child with Down syndrome."	**X**		

4.

Options for 1	Options for 2
antibiotics	**thimerosal**
vitamins	arsenic
vaccines	penicillin
milk	hormones
fruit juices	amoxicillin

CHAPTER 19 THE CHILD WHO IS HOSPITALIZED

1.

Health Teaching	Indicated	Contrain-dicated	Non-Essential
"Separation anxiety may be seen in your child by refusing to eat, having trouble sleeping, crying quietly for you when gone, or withdrawing from others."	X		
"Separation anxiety comes in stages: denial, despair, and detachment."		X	
"Loss of peer group contact may pose a severe emotional threat because of loss of group status and loss of group acceptance."		X	
"Your child may need and desire parental guidance or support from other adult figures as she returns to school."			X
"Young children can react 'negatively' to their parents during hospitalization; they may cling to you to ensure your continued presence."	X		

2. B, C, D, G
3. A, B, C, E, G, H
4. A, B, D, E

CHAPTER 20 PEDIATRIC NURSING INTERVENTIONS AND SKILLS

1. A, B, C, E, F
2.

Options for 1	Options for 2
5 ml	deltoid
2 ml	**dorsogluteal**
1 ml	ventrogluteal
8 ml	vastus lateralis

3. A, C, E, F
4.

Nursing Action	Indicated	Contrain-dicated	Non-Essential
An 18-gauge catheter needs to be inserted.		X	
A blunt plastic cannula needs to be used because it prevents the need for steel needles.	X		
An injection port site is used to deliver medications.	X		
An opaque covering of the intravenous (IV) site needs to be used.		X	
Music should be played in the background when performing the insertion.			X
A padded board should be placed below the hand where the catheter is inserted.		X	
Fingers are left unoccluded by tape or dressing to assess circulation.	X		

CHAPTER 21 THE CHILD WITH RESPIRATORY DYSFUNCTION

1. A, B, C, D, F
2. A, B, D, E
3.

Options for 1	Options for 2	Options for 3
Acute laryngotracheobronchitis	fungal	flashlight
Acute tracheitis	protozoic	**tongue depressor**
Acute epiglottitis	**bacterial**	microscope
Acute spasmodic laryngitis	idiopathic	otoscope light

4. A, B, D, E

CHAPTER 22 THE CHILD WITH GASTROINTESTINAL DYSFUNCTION

1.

Home Care Instruction	Indicated	Contrain-dicated	Non-Essential
Keep on clear liquids and toast for 24 hours.		X	
Offer a regular diet as child's appetite warrants.	X		
Sterilize the infant's eating utensils before each meal.			X
Give a BRAT diet (bananas, rice, applesauce, and toast) for 24 hours, then a soft diet as tolerated.		X	
Find out what the infant's favorite food is.			X
Give chicken or beef broth for 24 hours, then resume a soft diet.		X	

2.

Options for 1	Options for 2	Options for 3
Sugar	Yogurt	**Iron-deficiency anemia**
Meat	Corn on the cob	Bleeding
Gluten	Lettuce and tomato salad	Asthma
Salt	**Toast**	Hepatitis
Milk	Baked chicken	Pyloric stenosis
Eggs	Carrot sticks	Hoarseness and difficulty swallowing

3. A, E, F, G
4.

Options for 1	Options for 2	Options for 3	Options for 4
Hepatitis A	parenteral	**hepatitis A virus (HAV)**	Four
Hepatitis C	**fecal-oral**	hepatitis C virus (HCV)	**Two**
Hepatitis B	contaminated water	polio vaccine	Three
Hepatitis D	perinatal	hepatitis B virus (HBV)	One

CHAPTER 23 THE CHILD WITH CARDIOVASCULAR DYSFUNCTION

1. A, D
2.

1	2	3 and 4
Atrial septal defect (ASD)	Decreased pulmonary blood flow	**Abnormal opening between right and left ventricles = 3**
Coarctation of the aorta	**Resistance of blood flow in the left ventricle, causing decreased cardiac output**	Four defects of the heart disrupt blood flow
Heart failure	Increased pressure proximal to the defect and decreased pressure distal to the obstruction	**Valve fails to develop, leaving no communication from the right atrium to the right ventricle = 4**
Hypoplastic left heart syndrome	Blood flows from the left to right atrium, causing increased flow of blood to the right side of the heart	Local narrowing near the insertion of the ductus arteriosus

3. C, E
4. A, D, E, F, H, I

CHAPTER 24 THE CHILD WITH HEMATOLOGIC OR IMMUNOLOGIC DYSFUNCTION

1. A, B, C, E, H, I, J
2.

Health Teaching	Indicated	Contraindi-cated	Non-Essential
"We need to check your iron level to make sure you are not anemic."		X	
"I believe your disease is most common in those of Hispanic descent, although you are Mediterranean."		X	
"I would like to talk to you about the diagnosis and provide you with some information about beta thalassemia."	X		
"You look much younger than I would expect. I guess you are a late bloomer."			X
"I think a transfusion will be ordered because your hemoglobin level is 9.5."		X	

3. A, D, F, G
4.

Health Teaching	Indicated	Contraindicated	Non-Essential
"Your child should remain active to decrease joint problems, and most children with hemophilia can participate in the same activities as their peers."		X	
"Care should be taken to avoid bleeding of gums; softening the toothbrush in warm water before brushing or using a sponge-tipped disposable toothbrush may be helpful."	X		
"Signs of internal bleeding should be recognized, such as headache, slurred speech, loss of consciousness (from cerebral bleeding), and black, tarry stools (from gastrointestinal bleeding)."	X		
"If there is bleeding in a joint, elevation, ice, and rest should prevent the need for factor VIII replacement."		X	
"All of your son's teachers need to be aware of what to do if he gets a bloody nose."	X		
"Your child should drink a lot of fluids to decrease the possibility of dehydration."			X

CHAPTER 25 THE CHILD WITH CANCER

1. A, B, C, D, F
2.

Nursing Action	Indicated	Contraindicated	Non-Essential
Viscous lidocaine should be used to swish the mouth three times per day.		X	
Perform mouth care routinely before and after feeding.	X		
Lemon glycerin swabs are helpful because they remind children of lemon drops.		X	
Allowing the child to sleep 8 hours will help recovery.			X
Using a soft sponge–type toothbrush will decrease the tendency of gums to bleed.	X		
Sodium bicarbonate and salt water rinses can be used.	X		

3.

Options for 1	Options for 2	Options for 3
absolute red blood	subtracting	platelets
absolute platelet	**multiplying**	monocytes
absolute neutrophil	dividing	**neutrophils**
absolute white blood	adding	eosinophils

4. A, B, C, E

CHAPTER 26 THE CHILD WITH GENITOURINARY DYSFUNCTION

1. A, E
2.

Options for 1	Options for 2	Options for 3
post staphylococcal	**Group A beta-hemolytic streptococci**	Blood
post meningitis	Group B beta-hemolytic streptococci	**Urine**
post streptococcal	Group A beta-hemolytic staphylococcus	Radiographic
post pneumococcal	Group B beta-hemolytic staphylococcus	Ultrasound

3. B, C, D, F, G
4. B, C

CHAPTER 27 THE CHILD WITH CEREBRAL DYSFUNCTION

1. A, B, E, F, G
2.

Options for 1	Options for 2	Options for 3
Aplastic crisis	intubation	meningococcal
Bacterial meningitis	suctioning	**pneumococcal**
Acute chest syndrome	**isolation**	polio
Reye syndrome	vaccination	tetanus
COVID-19	blood transfusion	pertussis

3. A, E, F
4. A, B, E, F

CHAPTER 28 THE CHILD WITH ENDOCRINE DYSFUNCTION

1. C, D, E, F
2. B, D, E, F
3.

Options for 1	Options for 2	Options for 3
aplastic crisis	preparation of insulin	4-12 days
diabetes insipidus	**luteinizing hormone-releasing hormone**	2-3 weeks
diabetes mellitus	vasopressin injection	10-14 days
precocious puberty	vitamin D injection	3-5 weeks
Cushing syndrome	corticosteroid agent	**4-12 weeks**

4.

Nursing Action: Education	Indicated	Contraindicated	Non-Essential
When starting drug therapy, encourage staying in a quiet, unstimulating environment that promotes rest.	X		
Heat tolerance is a common symptom experienced by individuals with Graves' disease.	X		
Weight gain is a common symptom experienced by individuals with Graves' disease.		X	
Mood swings and irritability are common symptoms experienced by individuals with Graves' disease.	X		
Eating fruit and vegetables as part of a healthy diet is recommended for teenagers.			X

CHAPTER 29 THE CHILD WITH MUSCULOSKELETAL OR ARTICULAR DYSFUNCTION

1.

Nursing Action	Indicated	Contraindicated	Non-Essential
Monitor peripheral pulses and skin temperature changes.	X		
Use compression stockings or intermittent compression devices to decrease pooling.	X		
Reposition every 8 hours.		X	
Monitor intake and output closely.	X		
Place on a hard mattress to prevent movement.		X	
Encourage cough and deep breathing.	X		
Complete a dietary assessment.			X
Monitor vital signs.	X		

2.

Options for 1	Options for 2	Options for 3	Options for 4
bone fracture	days	**keep limb at heart level**	proximal to
severed nerve	**hours**	lower the limb	adjacent to
compartment syndrome	minutes	remove the cast	aligned with
bone contusion	seconds	turn patient on his side	alongside
bone rotation	weeks	provide pressure	**distal to**

3. B, C, D, G
4.

Health Teaching	Indicated	Contraindicated	Non-Essential
"Opioid medications should be given to your child whenever she complains of pain."		X	
"Relaxation techniques can be effective in decreasing her pain."	X		
"Make sure your child takes the prescribed medications on time."	X		
"Keeping your child in bed when she has extremity pain will prevent swelling."		X	
"Swimming can help strengthen your child's muscles and maintain mobility."	X		
"Your child can sleep in her sister's bedroom at night if she wishes."			X

CHAPTER 30 THE CHILD WITH NEUROMUSCULAR OR MUSCULAR DYSFUNCTION

1. A, E, F, G
2. A, B, C, D, F, G
3.

Options for 1	Options for 2	Options for 3
renal cyst	infection	Foley catheter placement
kidney stone	failure	**clean intermittent catheterization**
neuropathic bladder	strictures	sterile intermittent catheterization
rectal fissure	**distress**	suprapubic aspiration

4.

Health Teaching	Indicated	Contraindicated	Non-Essential
"DMD is inherited as an X-linked recessive trait and affects boys."			X
"Your child may need to have casts on his legs to help him walk."		X	
"You will learn stretching exercises and strength and muscle training to help your child."	X		
"You should call your health care provider if any respiratory symptoms occur."	X		
"Your child should be hospitalized when ambulation becomes impossible."		X	
"It is important for your child to remain as independent as possible."	X		
"Breathing exercises will help maintain his vital lung capacity."	X		

CHAPTER 31 THE CHILD WITH INTEGUMENTARY DYSFUNCTION

1.

Options for 1	Options for 2	Options for 3
3%	bony structures	3-4 days
5.5%	muscle structures	5-7 days
10.5%	**dermal elements**	7-14 days
22%	fascia elements	**14-21 days**
6.5%	nerve structures	30 days

2.

Nursing Action	Effective	Ineffective	Unrelated
"Change the diaper as soon as it becomes wet or soiled."	X		
"Use a hair dryer or heat lamp to dry the area."		X	
"Use a superabsorbent disposable diaper if you can."	X		
"Keep the skin dry."	X		
"Wash the area as often as possible using a wipe."		X	
"Diapers that are unscented can be purchased."			X
"Apply ointment such as zinc oxide or petrolatum to the skin."	X		
"Avoid removing the skin barrier cream with each diaper change."	X		

3. A, C, E, F
4. A, B, C, D, H, I, J

Next-Generation NCLEX® Examination-Style Unfolding Case Study Answer Key

CHAPTER 17 FAMILY-CENTERED CARE OF THE CHILD WITH SPECIAL NEEDS

Unfolding Case Study: Care at the End of Life

1. C, E, F, G, H, I
2.

Option 1	Option 2
1.0-2.0 mg/kg	**4 hours**
0.1-0.2 mg/kg	15 min
0.5-1.0 mg/kg	2 hours
0.1-1.0 mg/kg	6 hours
1.0-2.0 mg/kg	10 min

3. A, B, C, E, G
4.

Nursing Action	Potential Complication	Nursing Action for Complication
1. Administer morphine safely. Observe the patient for excessive sedation and respiratory depression.	To reduce unfounded fears.	**3**
2. Monitor for side effects of morphine: decreased respiratory rate, urinary retention, constipation, and pruritus.	To prevent unwanted side effects that may cause additional discomfort.	**2**
3. Educate parents on the safety and effectiveness of the pain-relieving medications.	To ensure optimal pain relief.	**4**
4. Reassess the pain level after administering pain medication. Assess within 1 hour of oral morphine and 30 minutes after intravenous (IV) administration.	To prevent adverse effects and overdose.	**1**
5. Recognize when pain is not well controlled on morphine.	To ensure satisfactory pain relief.	**5**
6. Provide appropriate bowel regimen and monitor urine output.		
7. Provide distraction and counseling to assure parents that everything possible is being done.		

5.

Nursing Action	Effective	Ineffective	Unrelated
Assure parents that the intravenous (IV) morphine dose can be the same dose they administer at home.		**X**	
Instruct parents to continue around-the-clock medications at home.	**X**		
Encourage parents to communicate any signs of pain; observe patient for nonverbal signs of pain.	**X**		
A home bowel regimen should be included in the discharge teaching.	**X**		
Instruct parents to talk to other family members about their feelings toward pain management.			**X**
Stress with the parents that escalating doses will not be needed and that tolerance to pain medications never occurs in children.		**X**	
Discuss appropriate nonpharmacologic options that can relieve pain.	**X**		

6. B, C, E, G

CHAPTER 21 THE CHILD WITH RESPIRATORY DYSFUNCTION

Unfolding Case Study: The Child With Acute Respiratory Tract Illness

1. A, B, C, D, E, F, G, H, J, K

2.

Options for 1	Options for 2	Options for 3
pneumonia	**Persistent dry, hacking cough worse at night, more productive in 2-3 days**	Inhaled corticosteroids, antibiotics
bronchiolitis	Retractions, labored respirations	Allergen and "triggers control"
emphysema	Poor feeding, inability to sleep, gastrointestinal symptoms	**Supplemental oxygen, fluid intake, suctioning as needed**
wheezing	Seizures, altered consciousness, inability to focus	Long-term antiinflammatory medications

3.

Options for 1	Options for 2	Options for 3
upper	skin	1-2
middle	**epithelial**	2-3
lower	blood	**5-8**
extreme	muscle	10-14
left	nasal	14-18
right	bone	21-24

4.

Nursing Action	Potential Complication	Nursing Action for Complication
1. Position infant for maximum ventilation and airway patency.	Inability to identify alterations in temperature, respiratory status, or circulation and need for additional interventions is missed	**2**
2. Monitor vital signs, including temperature and respiratory, cardiac, and oxygen status.	Nasal mucosal membrane drying	**3**
3. Provide humidified oxygen as indicated.	Fever	**6**
4. Suction airway (nares, mouth, nasopharynx) as indicated.	Bronchial constriction and decreased ventilation	**7**
5. Provide gentle chest percussion and chest physical therapy (CPT) as indicated.	Secretions causing lack of airway patency	**4**
6. Administer antipyretics as indicated.	Infection	**8**
7. Administer bronchodilators as indicated.	Spread of infection	**10**
8. Administer antibiotics if indicated.	Dehydration or fluid overload	**11**
9. Obtain specimens (e.g., secretions, blood) as indicated.		
10. Maintain appropriate precautions such as Standard Precautions, droplet isolation, and frequent hand washing.		
11. Monitor hydration status through strict intake and output and daily weights.		
12. Implement comfort measures such as allowing parent presence, parent holding infant, and comfort item such as favorite blanket or stuffed animal.		

5. A, C, E, F

6.

Health Teaching Evaluation	Indicated	Contraindicated	Non-Essential
Parents able to verbalize definition and characteristics of acute respiratory tract infection.	X		
Parents able to verbalize treatment, including medication and interventions that promote ventilation and airway clearance.	X		
Parents can identify discharge medications, including antipyretics, bronchodilators, and antibiotics as prescribed.	X		
Parents want to purchase a pulse oximeter before taking the infant home so they can constantly monitor the oxygen level.		X	
Parents feel that keeping the infant supine will assist with any nasal secretions the infant may have.		X	
Parents want to purchase another bed for the infant to keep her close to them at night.			X

Unfolding Case Study: The Child With Acute Asthma Exacerbation

7. B, C, D, F, G, H
8. A, C, E, G, H, I
9.

Nursing Action	Emergent	Not Emergent
Administer humidified oxygen to keep the oxygen saturation (SpO_2) above 90%.	X	
Administer methylprednisolone per the physician order.	X	
Administer albuterol per hospital protocol.	X	
Place the patient in a comfortable standing, sitting upright, or learning forward position.	X	
Discuss possible allergens in the home that might have triggered the attack.		X
Review how to use the metered-dose inhaler.		X

10.

Nursing Action	Potential Complication	Nursing Action to Prevent Complication
1. Allow patient to assume position of comfort.	To minimize drying of nasal mucous membranes.	**3**
2. Administer rescue medications (as prescribed) that can include inhalers, nebulization, and/or oral or intravenous (IV) steroids.	To prevent airway obstruction.	**1**
3. Administer humidified oxygen to maintain oxygen saturation (SaO_2) above 90%.	Decreased patient's awareness of factors that exacerbate asthma.	**5**
4. Assess patient's response to rescue medications.	To prevent constricted airways and decreased air exchange.	**2**
5. Assist patient in recognizing factors that trigger asthma symptoms.	Lack of awareness of need for more aggressive interventions.	**4**
6. Assure respirations will be easy and nonlabored at a rate within normal limits for age.		
7. Teach the patient how to use the peak expiratory flow meter (PEFM).		
8. Evaluate the use of the PEFM.		

11. A, D, E, F, H
12.

Options for 1	Options for 2	Options for 3	Options for 4
flow of air	5 seconds	**80%-100%**	4-5 weeks
flow of oxygen	10 seconds	50%-70%	**2-3 weeks**
flow of water	**1 second**	60%-80%	1-2 days

CHAPTER 22 THE CHILD WITH GASTROINTESTINAL DYSFUNCTION

Unfolding Case Study: The Child With Appendicitis

1. D, E, F, H, I
2.

Options for 1	Options for 2	Options for 3
Anemia	Blood pressure of 108/74	Ruptured kidney
Pain	Pulse of 80	**Acute abdomen**
Bleeding	**C-reactive protein (CRP)**	Influenza
Infection	Hemoglobin	Urinary tract infection
Heart failure	Platelets	Vomiting
Cancer	Serum sodium	Anxiety

3. A, C, D, F, H, I
4.

Nursing Action	Potential Postoperative Complication	Nursing Action for Postoperative Complication
1. Administer pain medications.	Inflammation at the wound site	**10**
2. Initiate intravenous (IV) fluids and assess intake and output (I&O).	Electrolyte imbalance	**6**
3. Assess temperature and report elevation.	Fluid deficit	**2**
4. Administer antiemetics.	Pain	**1**
5. Administer IV sodium heparin.	Nausea and vomiting	**4**
6. Draw blood as scheduled and evaluate results.	Infection	**8**
7. Report changes in vital signs, behavior, and level of consciousness.	Fever	**3**
8. Administer IV antibiotics.		
9. Administer a blood transfusion.		
10. Observe wound site.		

5.

Nursing Action	Effective	Ineffective	Unrelated
Exhibits no signs of infection.	**X**		
Pain is controlled.	**X**		
Referral is made to a physical therapist.			**X**
No complaints of nausea or vomiting and a regular diet is tolerated.	**X**		
No complaints of headaches.			**X**
Temperature remains in the normal range.	**X**		
Child spending all of the time in bed.		**X**	

6.

Health Teaching	Indicated	Contraindicated	Non-Essential
"Take your child's temperature if she feels warm and call the surgeon if she has a fever over 101°F."	**X**		
"Give ibuprofen every 6 hours for the next 5 days."		**X**	
"Sit beside her all day and watch her favorite movies."			**X**
"Inspect the surgical incision every day for increased redness, heat, or drainage; if present, call the surgeon immediately."	**X**		
Ask the parents, "What are your concerns regarding your daughter's care at home?"	**X**		
"Apply a topical antibiotic to the surgical wound for the next week."		**X**	

CHAPTER 23 THE CHILD WITH CARDIOVASCULAR DYSFUNCTION

Unfolding Case Study: The Child With Coarctation of the Aorta

1. A, B, D, E, G, I, J
2.

Options for 1	Options for 2	Options for 3 and 4
widening	increased	**bounding = 3**
absence	**decreased**	widening
narrowing	lack of	**weak or absent = 4**
crossing	absent	narrowing
absence	complex	unstable

3.

Nursing Action	Emergent	Not Emergent
Frequently assess and record heart rate, respiratory rate, blood pressure (BP), and any signs or symptoms of decreased cardiac output.	X	
Administer cardiac drugs on schedule. Assess and record any side effects or any signs and symptoms of toxicity. Follow hospital protocol for administration.	X	
Administer cool humidified oxygen to increase available oxygen during inspiration.	X	
Change the infant's position every 2 hours to prevent skin breakdown.		X
Keep accurate record of intake and output.	X	
Weigh infant on same scale at same time of day.		X
Maintain a 3-hour feeding schedule.		X
Restrict fluids if the intake and output is unbalanced.		X

4.

Nursing Action	Potential Complication	Nursing Action to Prevent Complication
1. Assess and record heart rate, respiratory rate, blood pressure (BP), and any signs or symptoms of altered cardiac output every 2 to 4 hours.	Decreased urinary output is a symptom of heart failure and could go unnoticed.	**3**
2. Administer cardiac drugs on schedule. Assess and record any side effects or any signs and symptoms of toxicity. Follow hospital protocol for administration.	Undetected changes in vital signs and infant's physical status that reflect altered cardiac output and high BP.	**1**
3. Keep accurate record of intake and output.	Excess water and salt because fluid retention commonly occurs with heart failure.	**5**
4. Weigh infant on same scale at same time of day as previously. Document results and compare to previous weight.	Dangers inherent in failure to administer cardiac drugs as prescribed and to perform careful assessment before administration.	**2**
5. Administer diuretics on schedule. Assess and record effectiveness and any side effects noted.		
6. Offer small, frequent feedings to infant's tolerance.		
7. Organize nursing care to allow infant uninterrupted rest.		

5. A, B, C, D, E, H, I

6.

Health Teaching	Indicated	Contraindicated	Non-Essential
Discuss the characteristics of coarctation of the aorta (COA) and the surgery done to repair the obstructive defect.	X		
Review the infant's daily care, including medication administration.	X		
Review signs and symptoms that could be of concern (fever, blue skin color, poor eating).	X		
Inform parents to purchase a pulse oximeter before taking the infant home so they can constantly monitor the oxygen level.		X	
Keep the infant supine at all times to assist with blood flow.		X	
Parents want to purchase another bed for the infant to keep her close to them at night.			X
Give parents the opportunity to express their fears and concerns.	X		

CHAPTER 24 THE CHILD WITH HEMATOLOGIC OR IMMUNOLOGIC DYSFUNCTION

Unfolding Case Study: The Child With Sickle Cell Anemia

1. C, E, F, G, J

2.

Options for 1	Options for 2
Aplastic crisis	High blood pressure
Sequestration crisis	**Ischemia**
Acute chest syndrome	Bleeding
Vasoocclusive crisis	Infection
Hyperhemolytic crisis	Diminished red blood cell production
Cerebral vascular accident	Decreased serum sodium

3. A, D, E

4.

Nursing Action	Potential Complication	Nursing Action for Complication
1. Discuss schedule of medication around the clock with parents.	Uncontrolled pain	**1**
2. Encourage high level of fluid intake.	Breakthrough pain	**3**
3. Recognize that various analgesics, including opioids, and medication schedules may need to be tried.	To avoid needless suffering because of unfounded fears	**4**
4. Reassure child and family that analgesics, including opioids, are medically indicated; that high doses may be needed; and that children rarely become addicted.	To prevent vasoconstriction that may enhance sickling with cold applications	**5**
5. Apply heat application or massage to affected area. Avoid applying cold compresses.	Dehydration	**2**
6. Provide protein shake with each meal.		
7. Weigh the child each morning with the same scale.		

5.

Options for 1	Options for 2	Options for 3	Options for 4
6	**0.4**	2.2	5 min
4	0.2	1.8	6 min
8	0.8	**1.4**	8 min
2	0.9	1.2	**10 min**

6.

Nursing Action	Effective	Ineffective	Unrelated
Administer morphine and ketorolac safely.	X		
Monitor for side effects of morphine; assess respiratory status closely and prevent constipation.	X		
Monitor for side effects of ketorolac; assess for bleeding (gastrointestinal [GI] or renal) closely.	X		
Educate parents on the safety and effectiveness of intravenous (IV) morphine and ketorolac when using them at home.		X	
Reassess the child's pain level once a shift after administering morphine and ketorolac.		X	
Read a children's book to the child while he is asleep.			X
Recognize that various analgesics and doses may need to be tried.	X		

CHAPTER 25 THE CHILD WITH CANCER

Unfolding Case Study: The Child With Acute Lymphoblastic Leukemia

1. A, C, D, E, H, I, J
2.

Option 1	Option 2	Option 3
Seizure	**Decreased production of red blood cells (RBCs)**	Lack of appetite and weight loss
Blindness	Increased production of plasma cells	Headache and seizure
Hemorrhage	Decreased production of central nervous system (CNS) fluid	Enlarged spleen
Hearing loss	Increased production of bilirubin	**Fever and infection**

3.

Options for 1	Options for 2	Options for 3
cardiac	**rapid**	production
cellular	slow	growth
metabolic	intermittent	**lysis**
neurologic	prolonged	mitosis

4.

Nursing Action	Effective	Ineffective	Unrelated
Explain the procedure to the patient and family and obtain informed consent.	X		
Monitor vital signs during the procedure (pulse rate, oxygen saturation, respirations, blood pressure).	X		
Administer a bolus of intravenous (IV) fluids before the procedure begins.		X	
Administer sedation during the procedure to provide optimal comfort and minimize pain.	X		
Provide comfort and reassure the patient and family throughout the procedure.	X		
Allow the child to watch a favorite show before the procedure.			X
Watch for signs of bleeding from the puncture site.	X		

5. B, C, D, E, F, H

6.

Nursing Action	Potential Complication	Nursing Action to Prevent Complication
1. Explain the disease course of treatment and adverse effects to the family.	Skin as an entry point for infection	**4**
2. Teach the patient and family ways to prevent infection through hand washing, bathing frequently, and not using cups and utensils used by another person.	Lack of recognition of infection	**3**
3. Teach the family how to recognize symptoms of infection such as fever, chills, cough, and sore throat and report these to the health care worker immediately.	Lack of understanding of leukemia treatment	**1**
4. Provide skin care to patient by keeping the skin and perianal area clean and apply mild lotion.	Mouth ulceration	**8**
5. Provide a high-protein and high-calorie diet.	Lack of knowledge on how to prevent infection in the home	**2**
6. Provide adequate hydration and encourage a high-fiber diet and stool softeners.	Bleeding	**7**
7. Educate family and patient on how to recognize and report abnormal bleeding through bruising and petechiae.		
8. Provide frequent mouth care and saline rinses and check for ulcers in the mouth and gum swelling.		
9. Instruct patient and family to avoid contact sports.		

CHAPTER 26 THE CHILD WITH GENITOURINARY DYSFUNCTION

Unfolding Case Study: The Child With Chronic Kidney Disease

1. A, B, C, D, E, G, I, M
2.

Nursing Action	Potential Complication	Nursing Action to Prevent Complication
1. Close monitoring of the patient's status. Follow clinical and laboratory findings. Blood studies include complete blood count (CBC), electrolytes, and kidney status.	Waste products accumulate	**2**
2. Observe for evidence of accumulated waste products.	Increased excretory kidney demands	**3**
3. Provide dietary instructions for foods that reduce excretory demands on kidneys and provide sufficient calories and protein for growth.	Changes in kidney status go unrecognized	**1**
4. Limit phosphorus, salt, and potassium as prescribed.	Growth failure unrecognized	**5**
5. Monitor growth closely since short stature is a significant side effect.	Accumulation of minerals	**4**
6. Monitor cardiovascular status, including blood pressure measurement.	Renal bone disease	**7**
7. Minimize renal bone disease by maintaining optimal calcium, phosphorus, and intact parathyroid hormone levels, and acid-base balance.		
8. Monitor for anemia. Child may require school accommodations and rest periods due to fatigue.		
9. Identify patient and family stressors that may accompany a diagnosis of chronic kidney disease (CKD).		

3. A, B, C, F, G, H
4. A, B, G, I, J, K
5. A, D, G
6. B, C, D, E, F

CHAPTER 27 THE CHILD WITH CEREBRAL DYSFUNCTION

Unfolding Case Study: The Child With Seizures

1. A, B, C, D, E, G, H
2.

Nursing Action	Potential Complication	Nursing Action to Prevent Complication
1. Monitor time (onset and duration), movements, and level of consciousness (LOC) during seizure.	Child experiences anxiety and fear.	**4**
2. If child is at risk of falling, ease child to floor. Prevent child from hitting head on objects. Do not attempt to restrain child or use force.	An accurate description of the seizure is not obtained.	**1**
3. During seizure, place child in a side-lying position on a flat surface such as floor. Do not put anything in child's mouth.	Parents unable to cope with the diagnosis and management of their son.	**5**
4. Stay with the child and reassure the child when awakening from seizure.	Physical harm occurs.	**2**
5. Involve child and parents in discussion of fears, anxieties, and resources and support options available to patient and family.	Aspiration can occur.	**3**
	Lack of description of the postictal state.	
	Further seizures occur.	

3. A, B, C, D, E
4.

Options for 1	Options for 2	Options for 3
simple partial seizure	blood pressure	intrathecal
complex partial seizure	seizure activity	intravenous
status epilepticus	**circulation, airway, and breathing (CAB)**	rectal
absence seizure	blood levels	**buccal**

5.

Nursing Action	Effective	Ineffective	Unrelated
Monitor circulation, airway, and breathing closely.	**X**		
Ensure antiepileptic drugs are being administered as directed.	**X**		
Monitor and record characteristics, onset, and duration of any new seizures, including motor effects, alterations in consciousness, and postictal state.	**X**		
Attempt to stop the seizure if one occurs again; keep the child upright.		**X**	
Do not place anything in child's mouth during the seizure.	**X**		
Place child in a side-lying position; suction the oral cavity and posterior oropharynx as needed.	**X**		
Closely monitor hemoglobin and platelet count.			**X**
Observe for hyperthermia, hypertension, and respiratory depression.	**X**		

6. B, D, E, F, G, H, I, J

CHAPTER 28 THE CHILD WITH ENDOCRINE DYSFUNCTION

Unfolding Case Study: The Child With Diabetes Mellitus

1. A, B, C, D, E
2.

Options for 1	Options for 2	Options for 3
Diabetes mellitus	platelets	insulin
Addison disease	hematocrit	**glucose**
Cushing syndrome	**blood glucose**	potassium
Hyperparathyroidism	**A1c level**	calcium
Pituitary hyperfunction	white blood cells	sodium

3. A, D, E, F

4.

Nursing Action	Potential Complication	Nursing Action for Complication
1. Obtain blood glucose level before meals and at bedtime.	Normal blood glucose level is not maintained.	**2**
2. Administer insulin as prescribed.	Appropriate dose of insulin is not administered.	**1**
3. Monitor urine glucose before each meal.	Appropriate type of insulin is not administered.	**6**
4. Use aseptic techniques when preparing and administering insulin.	Infection occurs.	**4**
5. Store insulin in the freezer to preserve the medication.	Absorption of insulin is impaired.	**7**
6. Understand the action of insulin: differences in composition, time of onset, and duration of action for the various preparations.		
7. Rotate insulin injection sites.		
8. Give less insulin before physical activity.		

5.

Nursing Action	Effective	Ineffective	Unrelated
Immediately administer cup of fruit juice or glass of nonfat or 1% milk.	**X**		
Check blood glucose after 15 minutes.	**X**		
Give a starch-protein snack.	**X**		
Start intravenous fluids with glucose.		**X**	
Provide information for the teacher on the child's diagnosis.			**X**
Give parents instructions on signs and symptoms of hypoglycemia versus hyperglycemia.	**X**		
Teach parents how to administer intramuscular glucagon if unresponsive, unconscious, or seizing.	**X**		
Place the child on a portable insulin infusion pump.		**X**	

6. B, C, E, F

  types of, 518b
Visually evoked potentials, 92
Vital signs
  neurologic examination of, 885–886
  postcatheterization, 736
  postoperative, 561t
Vitamin A, deficiency, 316
Vitamin A supplements, for measles, 153, 166
Vitamin C, for toddler, 351
Vitamin D
  deficiency, rickets, 201, 315
  for infant, 302
  therapy, for hypoparathyroidism, 946
  for toddler, 351
Vitamin D deficiency, 923b
Vitamin imbalances, in infants, 315–316
Vitamin K administration, in neonate, 195–196
Vitamin K deficiency bleeding (VKDB), 195–196, 262t
Vitamins
  excessive dose of, 316
  misuse of, 352
VKDB. *See* Vitamin K deficiency bleeding
VLDLs. *See* Very-low-density lipoproteins
VNS. *See* Vagus nerve stimulation
VOC. *See* Vasoocclusive crisis
Vocalization
  during crying, 298
  in infants, 287t–290t
Voice changes, in growth, 423
Voiding cystourethrography, 857t–858t
Voiding pressure study, 857t–858t
Volvulus, 714–715
Vomiting, 696–698
  bilious, 696
  in cancer, 826
  constipation and, 696
  cyclic, 696
  diagnostic evaluation of, 696
  etiology of, 696
  nursing care management for, 698
  from opioids, 127t–128t
  therapeutic management of, 696–698
von Willebrand disease (vWD), 799–800
Vulnerable child syndrome, 249
Vulva, 106–107
VUR. *See* Vesicoureteral reflux
vWD. *See* von Willebrand disease
VZV. *See* Varicella-zoster virus

W

Waldeyer tonsillar ring, 627
WAS. *See* Wiskott-Aldrich syndrome
Waste products, retention of, in chronic kidney disease, 876
Water balance, 680–681
  in infants, 681
Water depletion, 682t–684t
Water excess, 682t–684t
Water intoxication, 688
Water loss, insensible, 226, 226f, 681
  in high-risk neonate, 226–227
Water retention, in chronic kidney disease, 876
Weaning, 305
  flowsheet, for opioids, 132, 133f–134f
Weight, 79–80, 80f
  general trends in, 41, 41t
  in infant, 286
  related to gestational age, 179–181
Weight loss
  in adolescent, 459
  in neonates, 181
Werdnig-Hoffmann disease, 1024–1025, 1024b
Wet compresses, 1053
Wheelchair, 488
Wheeled go-carts, for cerebral palsy, 1009
Wheezes, 100
  assessment of, in respiratory function, 621b
Whey (lactalbumin), in human milk, 201
Whey-hydrolysate formulas, 203
Whey-to-casein ratio, in prepared formulas, 203
Whole-cell pertussis vaccine, 152
Whooping cough (pertussis), 643
Wilmington brace, 994
Wilms tumor, 844–846, 845b
Windup phenomenon, 135
Wiskott-Aldrich syndrome (WAS), 805, 808–809
Withdrawal Assessment Tool, 132, 133f–134f
Withdrawal symptoms, 132
Wong-Baker FACES Pain Rating Scale, 116t–117t, 117, 118f
Word-graphic rating scale, 116t–117t, 117–118
Work, adolescence and, 427
Work-based group care, 300
Working mothers, 27
Wounds, in children, 1048
  care for, 1052–1053, 1053b
  corticosteroid therapy for, 1051
  dressing for, 1050, 1051t
  healing of
    factors and, 1049, 1050t
    process of, 1048–1049
    types of, 1049, 1049f
  home care and family support and, 1054
  nursing care management for, 1052–1054, 1052b
  relief of symptoms of, 1053–1054
  systemic therapy for, 1052
  therapeutic management for, 1049–1052
  topical therapy for, 1050–1052, 1051b
Wrist restraint, 571

X

Xenograft, for burn wounds, 1081
Xiphoid, 98
X-linked dominant with reduced penetrance, 512
X-linked lymphopenic agammaglobulinemia, 808

Y

Yawn reflex, 185t
Yersinia enterocolitis, diarrhea due to, 689t–691t

Z

Zanamivir, for influenza, 629
Zika virus, 168
Zinc, deficiency in, 232
Zofran, 697
Zollinger-Ellison syndrome, 710

Celsius to Fahrenheit Temperature Conversions

°C	°F	°C	°F	°C	°F
35.0	95.0	37.0	98.6	39.0	102.2
35.2	95.4	37.2	99.0	39.2	102.6
35.4	95.7	37.4	99.3	39.4	102.9
35.6	96.1	37.6	99.7	39.6	103.3
35.8	96.4	37.8	100.0	39.8	103.6
36.0	**96.8**	**38.0**	**100.4**	**40.0**	**104.0**
36.2	97.2	38.2	100.8	40.2	104.4
36.4	97.5	38.4	101.1	40.4	104.7
36.6	97.9	38.6	101.5	40.6	105.1
36.8	98.2	38.8	101.8	40.8	105.4
				41.0	**105.8**

Conversion formulas:

$°F = (°C \times \frac{9}{5}) + 32$ or $(°C \times 1.8) + 32$.
$°C = (°F - 32) \times \frac{5}{9}$ or $(°F - 32) \times 0.556$.

Normal Heart Rates for Infants and Children

	RATE (beats/min)		
Age	Resting (Awake)	Resting (Sleeping)	Exercise (Fever)
Newborn	100-180	80-160	≤220
1 wk-3 mo	100-220	80-200	≤220
3 mo-2 yr	80-150	70-120	≤200
2-10 yr	70-110	60-90	≤200
10 yr-adult	55-90	50-90	≤200

From Gillette PC: Dysrhythmias. In Adams FH, Emmanoulides GC, Riemenschneider TA, editors: *Moss' heart disease In Infants, children, and adolescents,* ed 4, Baltimore, 1989, Williams & Wilkins.

Normal Temperatures in Children

	TEMPERATURE	
Age	°F	°C
3 mo	99.4	37.5
6 mo	99.5	37.5
1 yr	99.7	37.7
3 yr	99.0	37.2
5 yr	98.6	37.0
7 yr	98.3	36.8
9 yr	98.1	36.7
11 yr	98.0	36.7
13 yr	97.8	36.6

Modified from Lowrey GH: *Growth and development of children,* ed 8, St. Louis, 1986, Mosby.

Normal Respiratory Rates for Children

Age	Rate (breaths/min)
Newborn	35
1-11 mo	30
2 yr	25
4 yr	23
6 yr	21
8 yr	20
10 yr	19
12 yr	19
14 yr	18
16 yr	17
18 yr	16-18
