There are numerous theories regarding the etiology of SIDS, but the cause remains unknown. One hypothesis is that SIDS is related to brainstem abnormalities in the neurologic regulation of cardiorespiratory control. This maldevelopment affects arousal and physiologic responses to a life-threatening challenge during sleep (Hauck, Carlin, Moon, et al., 2020). Abnormalities include prolonged sleep apnea, increased frequency of brief inspiratory pauses, excessive periodic breathing, and impaired arousal responsiveness to increased carbon dioxide or decreased oxygen. However, *sleep apnea is not the cause of SIDS.* The vast majority of infants with apnea do not die, and only a minority of SIDS victims have documented apparent life-threatening events (ALTEs) (see the Apparent Life-Threatening Event section later in the chapter). Further, the findings of numerous studies indicate that no association exists between SIDS and any childhood vaccine.

A **genetic predisposition** to SIDS has been suspected as a potential cause. Differences in genes pertinent to immune system functioning and the development of the autonomic nervous system have been discovered in infants who died of SIDS compared with typical infants (Hauck, Carlin, Moon, et al., 2020). Several "triple-risk factor" models have been proposed to explain the etiology of SIDS. The proposed risk factors include an underlying infant vulnerability such as a brain abnormality, a critical incident in the fetal developmental period or in early neonatal life, and an exogenous stressor such as prone sleep positioning (Moon, 2016).

Risk Factors for Sudden Infant Death Syndrome

Maternal smoking during pregnancy is a major modifiable risk factor for SIDS. The incidence of SIDS is approximately three times greater among infants whose mothers smoked during pregnancy, and risk of death is progressively greater as daily cigarette use increases (Hauck, Carlin, Moon, et al., 2020). The effects of smoking by the father and other household members are more difficult to interpret because they are highly correlated with maternal smoking. There appears to be a small independent effect of paternal smoking, but data on other household members have been inconsistent. It is also difficult to assess the independent effect of infant exposure to environmental tobacco smoke because parental smoking behaviors during and after pregnancy are also highly correlated. However, an increased risk for SIDS has been found in infants exposed only to postnatal maternal environmental tobacco smoke (Hauck, Carlin, Moon, et al., 2020).

Co-sleeping, or an infant sharing a bed with an adult or older child on a noninfant bed, is associated with SIDS. Current studies and guidelines state that there is a significant increase in the risk of SIDS among infants who bed-shared compared with infants who slept alone and recommend that parents avoid bed-sharing (Das, Sankar, Agarwal, et al., 2014; Moon, 2016). The findings of a retrospective analysis of infant deaths showed a twofold increase of accidental suffocation or strangulation when infants were sleeping on a sofa compared to other locations. This is likely due to sharing the sleeping area with another person (Rechtman, Colvin, Blair, et al., 2014).

Prone sleeping may cause oropharyngeal obstruction or affect thermal balance or arousal state. Rebreathing of carbon dioxide by infants due to sleeping in the prone position is also a possible cause of SIDS. Infants sleeping prone and on soft bedding may be unable to move their heads to the side, thus increasing the risk of suffocation and lethal rebreathing. Therefore the side-lying position is no longer recommended for infants sleeping at home, daycare, or hospitals (unless medically indicated). Further, most preterm infants being discharged from the hospital should be placed in a supine sleeping position unless special factors predispose them to airway obstruction.

Another potential cause of SIDS has been a **prolonged Q-T interval** or other cardiac arrhythmias (Hauck, Carlin, Moon, et al., 2020). Recently cardiac ion channelopathies, which occur as a result of gene mutations and may result in lethal arrhythmias, have been proposed as a possible risk factor for SIDS (Hauck, Carlin, Moon, et al., 2020).

Soft bedding (waterbeds, sheepskins, beanbags, pillows, and quilts) should be avoided for infant sleeping surfaces. Bedding items, such as stuffed animals and toys, should be removed from the crib while the infant

is asleep. Head covering by a blanket has also been found to be a risk factor for SIDS, thus supporting the recommendation to avoid extra bed linens and other items (Hauck, Carlin, Moon, et al., 2020). Further, crib bumper pads should not be used (American Academy of Pediatrics, 2016).

Protective Factors for Sudden Infant Death Syndrome

The findings of a meta-analysis indicate that SIDS rates may be reduced by up to 45% for infants who are breastfed and that this protective effect increases with exclusive breastfeeding (Hunt & Hauck, 2016). Pacifier use has also been associated with a lower risk of SIDS. Although it is uncertain if this is a direct effect of the pacifier itself or from associated infant or parental behavior, there is increasing evidence that pacifier use even with dislodgment can increase the arousability of infants during sleep. There has been some concern about recommending pacifiers for reducing the risk of SIDS out of fear this may interfere with breastfeeding. The findings of rigorous studies have failed to show an association between pacifier use and breastfeeding duration (Hauck, Carlin, Moon, et al., 2020).

The American Academy of Pediatrics, Task Force on Sudden Infant Death Syndrome (2016) recommends that *all infants* be placed to sleep in the **supine (on the back) position**. They also recommend that medically stable preterm infants and infants diagnosed with gastroesophageal reflux (GER) be placed in a supine sleep position unless they have a specific upper airway disorder that places them at greater risk of death than the risk of death from SIDS. Further, in the new Safe to Sleep recommendations, the American Academy of Pediatrics recommends that infants share a bedroom with parents but not the same sleeping surface, preferably until the infant is 1 year old but at least for the first 6 months. Roomsharing decreases the risk of SIDS by as much as 50% (American Academy of Pediatrics, Task Force on Sudden Infant Death Syndrome, 2016).

Since the 1994 Back to Sleep campaign began advocating for nonprone sleeping for infants, an increased incidence of positional plagiocephaly has been observed (see discussion later in the chapter). Therefore it is recommended that an infant's head position be alternated during sleep time to prevent plagiocephaly. Infants should also be placed prone in "tummy time" during awake periods for 10 to 15 minutes, three times a day, to prevent positional plagiocephaly and to encourage development of upper shoulder girdle strength (Hauck, Carlin, Moon, et al., 2020). Updated childhood immunization status has also been shown to be protective against SIDS.

Although the cause of SIDS is unknown, autopsies reveal consistent pathologic findings, such as pulmonary edema and intrathoracic hemorrhages that confirm the diagnosis. Consequently, autopsies should be performed on all infants suspected of dying of SIDS, and findings should be shared with the parents as soon as possible after the death. Postmortem findings in SIDS and accidental suffocation or intentional suffocation, such as in Munchausen syndrome by proxy (see Chapter 13, Child Maltreatment), are practically the same. Individuals with less experience and training in performing autopsies, such as coroners instead of medical examiners, may not correctly identify some deaths as SIDS. Therefore mortality statistics can vary in different regions.

Infant Risk Factors

Certain groups of infants are at increased risk for SIDS:

- Low birth weight or preterm birth (<37 weeks)
- Low Apgar scores
- Recent viral illness
- Siblings of two or more SIDS victims
- Male gender
- Infants of American Indian or African American ethnicity

No diagnostic tests exist to predict which infants, including those in the above-listed groups, will die of SIDS. The next-born siblings of firstborn infants who died of any noninfectious natural cause are at significantly increased risk for infant death from the same cause, including SIDS. The increased risk for recurrent SIDS in families is consistent with genetic risk factors interacting with environmental risk factors (Hauck, Carlin, Moon, et al., 2020). Home monitoring is not recommended for this group of children, but it is often used by practitioners and may even be requested by parents. There is no evidence that home apnea monitoring prevents SIDS (Hauck, Carlin, Moon, et al., 2020).

Nursing Care Management

Nurses have a vital role in preventing SIDS by educating families about the risk of prone sleeping in infants from birth to 6 months of age. This education should include the use of appropriate bedding surfaces, the association between SIDS and maternal smoking, and the dangers of co-sleeping on noninfant surfaces with adults or other children. In addition, nurses have an important role in modeling behaviors for parents that decrease the risk of SIDS, such as placing infants in a supine sleeping position while in the hospital. Unfortunately, research shows that some nurses still place healthy infants in a side-lying position in the hospital due to a belief in safety concerns if the infant is placed supine (Patton, Stiltner, Wright, et al., 2015). However, research shows that establishing current, evidence-based hospital policies, as well as providing education for both nurses and parents, can change practice (Naugler & DiCarlo, 2018).

Role modeling safe sleep practices and providing education to parents is imperative before hospital discharge because limited opportunities exist for parents to receive information about caring for their infant (Naugler & DiCarlo, 2018). Nurses must be proactive in further decreasing the incidence of SIDS through providing education during postpartum discharge planning, newborn discharge teaching, follow-up home visits, well-baby clinic visits, and immunization visits. Further, nurses must continue to take every opportunity to advocate for infants by providing information for parents and caretakers about the modifiable risk factors for SIDS that can be implemented to prevent its occurrence across all sectors of the population.

Care of the Family of a Sudden Infant Death Syndrome Infant

Loss of a child from SIDS presents several crises for the infant's parents. In addition to grief and mourning the death of their child, the parents must face a tragedy that was sudden, unexpected, and unexplained. This discussion focuses primarily on the objectives of care for families experiencing SIDS rather than on the process of grief and mourning, which is explored in Chapter 17.

The first people to arrive at the scene may be the police and emergency medical service personnel. They should handle the situation by (1) asking few questions; (2) giving no indication of wrongdoing, abuse, or neglect; (3) making sensitive judgments concerning any resuscitation efforts for the child; and (4) comforting the family members as much as possible. A compassionate, sensitive approach to the family may help minimize some of the overwhelming guilt and anguish that commonly follow this type of loss.

The medical examiner or coroner may go to the home or place of death and make the death pronouncement. Until then, the sleep environment should remain as it was when the infant was initially found. If the infant is not pronounced dead at the scene, he or she may be transported to the emergency department to be pronounced dead by a physician. Usually there is no attempt at resuscitation in the emergency department. While they are in the emergency department, the parents should be asked only factual questions, such as when they found the infant, how he or she looked, and whom they called for help. The nurse avoids any remarks that may suggest responsibility, such as "Why didn't you go in earlier?" or "Didn't you hear the infant cry out?" It is the coroner's responsibility

to document findings at the scene rather than have parents recount the experience in the emergency department. Parents may also express feelings of guilt about administering cardiopulmonary resuscitation (CPR) correctly or the timing of CPR in relation to finding the infant.

The physician should initiate the discussion of an autopsy, often with the nurse being present to support the family. The physician or medical examiner, depending on the circumstances, should emphasize that a diagnosis cannot be confirmed until the postmortem examination is completed. Instructions about the autopsy and funeral arrangements may need to be repeated or put in writing. If the mother was breastfeeding, she will need information about abrupt discontinuation of lactation. The nurse or physician should contact the primary care practitioner for the infant and the mother to avoid any miscommunications or telephone calls later inquiring about the child's health status.

Parents experiencing perinatal death perceive health care workers' responses as having a significant impact on their grieving process. A family-centered approach that involves the sociocultural context and unique needs of the family is essential for perinatal bereavement care (Flenady, Boyle, Koopmans, et al., 2014). Health care workers require adequate training and support in order to deliver appropriate care and prevent burnout (Flenady et al., 2014).

An important aspect of compassionate care for parents is allowing them to say goodbye to their child. These are the parents' last moments with their child, and they should be as quiet, meaningful, peaceful, and undisturbed as possible. Encourage parents to hold their infant before leaving the emergency department. Because the parents will be leaving the hospital without their infant, it may be helpful to accompany them to the car or arrange for someone to take them home. A debriefing session may help health care workers who cared for the family to cope with troubling emotions.

When the parents return home, a competent, qualified professional should visit them as soon after the death as possible. They should receive printed material that contains excellent information about SIDS (available from several national organizations[c]). During the initial visit, help the parents gain an intellectual understanding of the condition. The nursing objectives are to assess what the parents have been told about SIDS; what they think happened; and how they explained this to the infant's siblings, family members, and friends. One question that the nurse will never be able to answer and therefore should not attempt to is, "Why did this happen to our baby?" or "Who is responsible for this tragedy?" These and other questions may linger in the parents' minds for months or even years.

When the unexpected death of a child occurs, it is common for one parent to blame the other. Parents may also experience guilt over the child's death. For example, they may feel that if they had checked on the child earlier, he or she might still be alive. It is important that the nurse assist parents in working through these feelings to prevent marital disruption in addition to the loss of the loved child.

Some parents are able to discuss their feelings openly, and the nurse should support this coping skill. However, others may be reluctant to express their grief, and the nurse can encourage the expression of emotions by asking about crying and feeling sad, angry, or guilty. During their interaction, the nurse can help the parents to explore their typical coping strategies and, if these are ineffectual, to investigate new approaches. For example, one parent may refrain from discussing the death for fear of upsetting the other parent, but each may need to hear how the other feels.

Ideally, the number of visits and plans for subsequent intervention need to be flexible. Parents facing the question of having a subsequent child will need support. Both the birth of a subsequent child and the survival of that child, especially past the age of death of the previous child, are important transitional stages for parents.

POSITIONAL PLAGIOCEPHALY

Since the Back to Sleep campaign that advocated nonprone sleeping for infants to prevent SIDS began in 1994, an increase in the incidence of positional plagiocephaly has been reported (Myers et al., 2020). Approximately 20% of infants have this type of skull deformity that is most prevalent between 2 and 4 months of age (van Wijk, van Vlimmeren, Groothuis-Oudshoorn, et al., 2014). The term **plagiocephaly** connotes an oblique or asymmetric head. Positional plagiocephaly, deformational plagiocephaly, or nonsynostotic plagiocephaly implies an acquired skull deformity that occurs as a result of cranial molding during infancy, usually as a result of lying in the supine position (van Wijk et al., 2014). Because infants' sutures are not yet fused, the skull is pliable, so when infants are placed on their backs to sleep, the posterior occiput flattens over time (Fig. 10.4A).

Fig. 10.4 A, Plagiocephaly. B, Helmet used to correct plagiocephaly. (Courtesy Dr. Gerardo Cabrera-Meza, Department of Neonatology, Baylor College of Medicine, Houston, TX.)

A typical bald spot develops over the area, which is usually transient. Prolonged pressure on one side of the skull can result in that side becoming misshapen. Mild facial asymmetry may also develop. The sternocleidomastoid muscle may tighten on the preferential side, resulting in a condition called torticollis. Congenital or acquired torticollis may also cause plagiocephaly. Other causes of deformational plagiocephaly include certain craniofacial syndromes. This discussion focuses only on positional plagiocephaly (PP) caused by supine sleeping position.

Therapeutic Management

Prevention of PP should begin shortly after birth by placing the infant to sleep supine and alternating the infant's head position nightly, avoiding prolonged placement in car safety seats and swings, and using prone positioning or "tummy time" for approximately 10 to 15 minutes, three times per day, while the infant is awake (Myers et al., 2020).

The watch and wait method of treatment for torticollis and plagiocephaly is not recommended (Myers et al., 2020). Repositioning and physical therapy (RPPT), which includes providing counseling and teaching for parents as to positional changes and tummy time for their child, is recommended. A referral to physical therapy may be needed in the case of congenital torticollis. RPPT is the optimal treatment choice for patients younger than 4 months of age who have mild to moderately severe PP. The earliest types of behavioral modifications can be as simple as increasing tummy time or repositioning the infant's crib such that everything interesting in the room is on the side opposite the plagiocephaly (Myers et al., 2020).

Molding therapy (helmet therapy) is the use of an orthotic helmet to promote the resolution of cranial asymmetry while the infant's head is still rapidly growing (Myers et al., 2020) (see Fig. 10.4B). Orthotic helmets do not actively mold the skull; instead, they protect the areas that are flattened and allow the child to "grow into" the flat spots. Studies have shown that helmet therapy alone achieves correction three times faster and better than repositioning alone. This therapy is still debated, however, due to its expense, time requirements, and side effects (irritation, rashes, and pressure sores). The findings of recent studies suggest that combined treatment with helmet therapy and physical therapy is the most beneficial for the management of infants older than 4 months of age who are severely affected or with worsening of mild or moderate plagiocephaly who have been trialed on physical therapy. Infants with severe plagiocephaly should be considered for helmet therapy at any age (Myers et al., 2020).

Nursing Care Management

Minor skull deformation is not considered significant, but parents should learn to prevent plagiocephaly by altering the infant's head position during sleep. Infants should be placed prone on a firm surface during awake time (tummy time) for at least 10 to 15 minutes, three times a day (Myers et al., 2020), which prevents plagiocephaly and facilitates development of upper shoulder girdle strength. The latter helps in the progressive development of movements such as rolling over and starting to rise up on all fours that are precursors to crawling and eventually walking. Despite the perceived increase in the incidence of positional plagiocephaly, the supine sleeping position is still recommended because it has led to a significant decrease in loss of infant lives from SIDS. When a nurse or parent notices plagiocephaly, a consultation with the primary practitioner is recommended to evaluate the head shape and ascertain the need for early intervention.

Nurses in well-child care settings are in a unique position to assess parents' ability to follow guidelines for preventing plagiocephaly by observing them alternating head placement for sleeping, demonstrating sternocleidomastoid muscle exercises (as appropriate to the condition), and implementing tummy time for infants during awake periods. Most important, nurses should continue to encourage parents to place the infant in a supine sleep position despite the development of plagiocephaly. Nurses can also assist parents in the proper use of a skull-molding helmet and reassure them of the high rate of success with the helmet. Allowing parents to verbalize concerns and feelings related to the health status of their child, as well as the provision of current best practice, is an important nursing function.

APPARENT LIFE-THREATENING EVENT

An **apparent life-threatening event (ALTE)**, formerly referred to as an *aborted SIDS death* or a *near-miss SIDS,* generally refers to an event that is sudden and frightening to the observer in which the infant exhibits a combination of apnea; change in color (e.g., pallor, cyanosis, redness); change in muscle tone (usually hypotonia); and choking, gagging, or coughing that usually involves a significant intervention such as CPR provided by the caregiver who witnesses the event (Carolan, 2016). The definition of ALTE may include apnea, but ALTE may occur without apnea (Carolan, 2016). In 2016 the American Academy of Pediatrics released a clinical practice guideline that recommended the replacement of the term *ALTE* with a new term, *brief resolved unexplained event (BRUE)*. The American Academy of Pediatrics defines BRUE as an event observed in infants younger than 1 year of age during which an observer reports a sudden, brief (less than 1 minute), but then resolved episode that includes at least one of the following: (1) cyanosis or pallor; (2) absent, decreased, or irregular breathing; (3) marked change in muscle tone (hypertonia or hypotonia); or (4) altered responsiveness. Per the guidelines, a BRUE can be diagnosed only when there is no explanation for a qualifying event after completion of a through history and physical examination (Carolan, 2016).

It is erroneous to characterize ALTE as a near-miss SIDS incident. A history of an unexplained ALTE occurs in 5% to 9% of SIDS victims, and the risk of SIDS appears to be higher with two or more unexplained events, but no definite incidence rates are available. Compared with healthy control infants, the risk for SIDS may be as much as three to five times greater in infants having experienced an ALTE.

Results from the Collaborative Home Infant Monitoring Evaluation (CHIME) study showed that apnea and bradycardia occurred at conventional and extreme alarm thresholds in all groups of infants studied: siblings of SIDS infants, infants with ALTEs, symptomatic (of apnea and bradycardia) and asymptomatic preterm infants weighing less than 1750 g (3.8 pounds) at birth, and healthy term infants. Many infants experience apnea and bradycardia in each of these groups yet do not die (Hauck, Carlin, Moon, et al., 2020).

Diagnostic Evaluation

An essential component of the diagnostic process includes a detailed description of the event, including who witnessed it, where the infant was during the event, and what, if any, activities were involved (e.g., during or after a feeding, riding in a car seat restraint, presence of siblings or any minor children, what clothing the infant was wearing). In addition, a prenatal and postnatal history must be obtained. A short period of observation in the emergency department may be appropriate to monitor the infant's respiratory pattern and response to feeding. Further, a careful evaluation of late-preterm and preterm infants in the car seat restraint is essential. Upper airway occlusion and subsequent apnea and cyanosis may occur if the infant is not positioned properly. Reported diagnoses in infants with ALTE include (1) neurologic events such as seizures (30% of cases seen); (2) GI problems, including GER (50%); (3) respiratory conditions (20%); (4) cardiac conditions (5%); (5) metabolic or endocrine conditions (<5%); or (6) other problems such as child abuse (Aminiahidashti, 2015).

If an underlying diagnosis cannot be established, home monitoring may be recommended. The most commonly used monitoring is continuous recording of cardiorespiratory patterns (cardiopneumogram or pneumocardiogram). Four-channel pneumocardiograms (or multichannel pneumograms) monitor heart rate, respirations (chest impedance), nasal airflow, and oxygen saturation. A more sophisticated test, polysomnography (sleep study), also records brain waves, eye and body movements, esophageal manometry, and end-tidal carbon dioxide measurements. However, none of these tests can predict risk. Some children with normal results may still have subsequent apneic episodes.

Therapeutic Management

The treatment of an infant with an ALTE depends on the underlying condition. Several diagnostic tests may be carried out to determine the cause of the ALTE; however, a cause may not be determined in up to 50% of cases. Further, testing for seizures, GER, or sepsis is not recommended unless signs were present on the physical examination and history. However, testing for a urinary tract infection is recommended (Aminiahidashti, 2015).

Nursing Care Management

The diagnosis of an ALTE causes great anxiety and concern in parents, and the institution of home monitoring presents additional physical and emotional burdens. Parents of infants on home apnea monitors report experiencing emotional distress, especially depression and hostility, during the first few weeks after hospital discharge. For parents of a SIDS victim who have a new infant on home apnea monitoring, the anxiety is compounded by the uncertainty of the future of the living child and grief for the lost child. Home apnea monitoring may offer some predictability and control over the current child's survival through the period of uncertainty.

If home monitoring is required, the nurse can be a major source of support to the family in terms of education about the equipment, education regarding observation of the infant's status, and instructions regarding immediate intervention during apneic episodes, including CPR. To help the family cope with the numerous procedures they must learn, adequate preparation before discharge and written instructions are essential. In the first few weeks after discharge, parents may benefit from having a practitioner readily available to answer questions regarding false alarms and for other technical assistance.

Several types of home monitors are available and are set up by either a home monitor equipment company or home health staff. Nurses, especially those involved in the care at home, must become familiar with the equipment, including its advantages and disadvantages. Safety is a major concern because monitors can cause electrical burns and electrocution. The following precautions are recommended:

- Remove leads from infant when not attached to the monitor.
- Unplug the power cord from the electrical outlet when the cord is not plugged into the monitor.
- Use safety covers on electrical outlets to discourage children from inserting objects into sockets.

Additional home use instructions should focus on troubleshooting the monitor alarms. Parents should be encouraged to always look at the infant first if an alarm goes off and ensure that the infant is breathing, then determine the cause of the alarm. Parents also need information about traveling or running errands with an infant on an apnea monitor, what to do in case of power failure, and whom to contact if the monitor alarm goes off continuously but the infant appears well. Siblings should be supervised when near the infant and taught that the monitor is not a toy. Other safety practices include informing local utility and rescue squads (fire and/or emergency services) of the home monitoring in case of an emergency, especially if the family lives in a remote, rural area. Telephone numbers for these services should be posted in the home or set up as speed dial on certain phones if a universal 911 system is not available. Instructions for infant CPR should also be posted in a central location of the house. Parents are encouraged to tell visitors and other family members about the location of these instructions. If a cellular phone is the main house phone, make sure it stays in a central location for all family members to access in an emergency.

! NURSING ALERT

If the infant is apneic, gently stimulate the trunk by patting or rubbing it. Call loudly for help even if alone. If the infant is prone, turn to the supine position and flick the heels of the feet. If there is still no response, immediately begin cardiopulmonary respiration (CPR) starting with chest compressions. After approximately 2 minutes of CPR, activate the emergency medical service—"Call 911"—and then resume CPR until emergency responders arrive or the infant starts breathing. Never vigorously shake the child. No more than 10 to 15 seconds is spent on stimulation before implementing CPR (American Heart Association, 2015).

Caregivers need detailed information regarding proper attachment of the electrodes to the infant's chest with impedance monitors that detect chest movement. The electrodes are placed in the midaxillary line at a space one or two fingerbreadths below the nipple. For home use, electrodes attached to a belt that is placed around the child's trunk are preferred (Fig. 10.5). The belt is positioned so that the electrodes contact the skin in the same area. Monitors may have memory chips that allow for event recording, which can be an effective tool in evaluating the use of the monitor, events immediately before and after the ALTE, and reported frequency of alarms. Monitors are effective only if they are used. They do not prevent death but alert the caregiver to the ALTE in time to intervene. The need to use the monitor and to respond appropriately to alarms must be stressed. Noncompliance can result in the infant's death.

Many of the stresses observed during the home monitoring period are characteristic of families with chronically ill children. The child with an apnea or cardiorespiratory monitor may have additional health care needs such as a gastrostomy, tracheostomy, and multiple medications or treatments that exacerbate the parents' stress. Parents report increased stress, including concern for the child's survival, fear

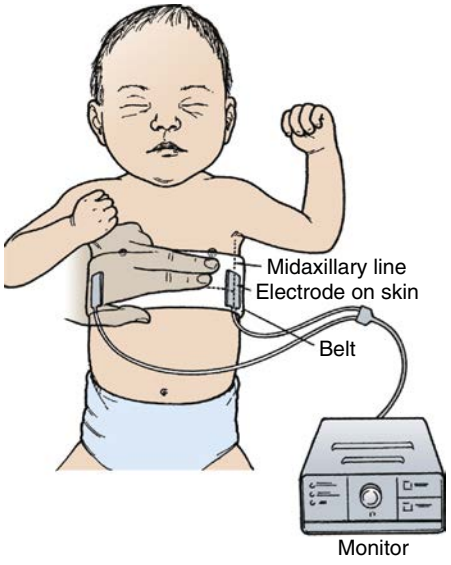

Fig. 10.5 Electrode placement for apnea monitoring. In small infants, one fingerbreadth may be used.

of incompetence in assuming home responsibility, inadequate respite care, lack of time for other children and spouse, social isolation from friends and extended family, constant work, and fatigue. To deal with these potential stressors, nurses need to use the same interventions as those discussed for children with chronic illness and be aware of the need for referral when difficulties are suspected.

To lessen the continuous responsibility of monitoring, other family members, such as grandparents and other immediate family members, should be taught how to assess the infant for responsiveness, manipulate the equipment, read and interpret the signals, and administer CPR (if needed). They are encouraged to stay with the infant for regular periods to allow the parents respite. Support groups of other families who have successfully completed monitoring can also be of benefit. Because reliable babysitters are difficult to locate, support group members and nursing students may be potential sources of qualified caregivers.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. An 11-month-old infant being seen in the emergency department is experiencing difficulty breathing. The mother states the 5-year-old brother had given the infant peanuts while riding in the back of the car without the mother knowing it. On examination the nurse notices the symptoms listed below. Which of these findings is an indication of a possible anaphylactic reaction? **Select all that apply.**
   A. Wheezing
   B. Flushing
   C. Headache
   D. Trouble breathing
   E. Urticaria
   F. Temperature of 98.2 F (36.8 C)
   G. Decreased bowel signs

2. A 9-month-old full-term infant is being seen in the clinic and the mother states she thinks the infant has cow's milk allergy. She thinks this because her mother told her that she had it when she was an infant. **Choose the most likely options for the information missing from the statements below by selecting from the list of options provided.**
   The nurse is aware that common signs and symptoms of cow's milk allergy involving the gastrointestinal track include _____1_____. An infant with a cow's milk allergy is placed on _____2_____ to prevent further problems.

Options for 1	Options for 2
diarrhea	goat's milk
eczema	soy milk or a hydrolyzed formula
sneezing	whole milk
urticaria	evaporated milk
fever	milk
swelling	eggs

3. The nurse is examining a 7-month-old female full-term infant and notices the diaper is soiled and the perianal area is extremely red with satellite pustules on the surrounding skin. The child's vital signs include a temperature of 98.2 F (26. C), pulse of 100 beats/min and respirations of 30 breaths/min. The mother states the infant is eating well. The mother states the rash occurred after she changed the brand of diapers she was using. The child is alert and responsive to the nurse's voice. Based on the assessment findings, what priority actions would the nurse recommend to the mother at this time? **Select all that apply.**
   A. Using a hair dryer blow warm air on rash area
   B. Apply a skin barrier paste such as zinc oxide.
   C. Keep skin surface irritants such as urine and stool off skin.
   D. Expose skin to air.
   E. Use only cloth diapers.
   F. Educate the mother on how to treat the rash

4. The mother of a 2-month-old male who was premature is extremely concerned about Sudden Infant Death Syndrome (SIDS). She tells the nurse she has read that preterm infants with lower Apgar scores who have older siblings are more at risk. She also states that she believes that keeping the infant in bed with her allows her to watch him more closely. She states she puts him on his side and her waterbed allows him to easily fall asleep. **Use an X for the health teaching below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Nursing Action: Health Teaching	Indicated	Contraindicated	Non-Essential
Reassure the mother that she is correct in keeping the infant on his side.			
Discuss with the mother that keeping the infant in bed with her can actually increase the risk of SIDS.			
Advise the mother that the waterbed is a type of "soft bedding" and the infant should not sleep on the waterbed.			
Discuss with the mother that a warm bath before bedtime can help minimize risk.			
Advise the mother to keep stuffed animals and toys in the crib to provide comfort.

PROMOTING OPTIMAL GROWTH AND DEVELOPMENT

The term *terrible twos* has often been used to describe the toddler years, the period from 12 to 36 months old. It is a time of intense exploration of the environment as children attempt to find out how things work; what the word "no" means; and the power of temper tantrums, negativism, and obstinacy. "Getting into things" is their way of learning about their world, especially relationships. Successful mastery of the tasks of this age requires a strong foundation of trust during infancy and frequently necessitates guidance from others when parents and toddlers face the struggles of toilet training, limit setting, and sibling rivalry. Nurses who understand the dynamics of growth and development of toddlers can help families deal effectively with the tasks of this age.

BIOLOGIC DEVELOPMENT

Proportional Changes

Physical growth slows considerably during toddlerhood. The average weight gain is 1.8 to 2.7 kg (4 to 6 pounds) per year. The average weight at 2 years old is 12 kg (26.5 pounds). The birth weight is quadrupled by 2½ years old. The rate of increase in height also slows. The usual increment is an additional 7.5 cm (3 inches) per year and occurs mainly in elongation of the legs rather than the trunk. The average height of a 2-year-old child is 86.6 cm (34 inches). In general, adult height is about twice the 2-year-old child's height. Accurate measurement of height and weight during the toddler years should reveal a steady growth curve that is steplike rather than linear (straight), which is characteristic of the growth spurts during the early childhood years.

The rate of increase in head circumference slows somewhat by the end of infancy, and head circumference is usually equal to chest circumference by 1 to 2 years old. The usual total increase in head circumference during the second year is 2.5 cm (1 inch). Then the rate of increase slows until at age 5 years the increase is less than 1.25 cm (0.5 inch) per year. The anterior fontanel closes between 12 and 18 months old.

Chest circumference continues to increase in size and exceeds head circumference during the toddler years. The chest's shape also changes as the transverse, or lateral, diameter exceeds the anteroposterior diameter. After the second year, the chest circumference exceeds the abdominal measurement, which in addition to the growth of the lower extremities makes the child appear taller and leaner. However, toddlers retain a squat, "pot-bellied" appearance because of their less developed abdominal musculature and short legs. The legs retain a slightly bowed or curved appearance during the second year from the weight of the relatively large trunk.

Sensory Changes

Visual acuity of 20/40 is considered acceptable during the toddler years. Full binocular vision is well developed, and any evidence of persistent strabismus requires professional attention as early as possible to prevent amblyopia. Depth perception continues to develop, but because of toddlers' lack of motor coordination, falls from heights continue to be a persistent danger.

The senses of hearing, smell, taste, and touch become increasingly well developed, coordinated with each other, and associated with other experiences. All senses are used to explore the environment. Toddlers visually inspect an object by turning it over; they may taste it, smell it, and touch it several times before they are satisfied with their investigation. They shake it to see if it makes noise and vigorously test its durability.

Another example of the integrated function of the senses is toddlers' development of specific taste and texture preferences. Toddlers are much less likely than infants to try new foods because of their appearance, texture, or smell, not just their taste.

Maturation of Systems

Most of the physiologic systems are relatively mature by the end of toddlerhood. By the end of the first year, all brain cells are present but continue to increase in size. Myelination of the spinal cord is almost complete by 2 years old, which parallels the completion of most of the gross motor skills. Brain growth is 75% completed by the end of 2 years.

The volume of the respiratory tract and growth of associated structures continue to increase during early childhood, lessening some of the factors that predisposed children to frequent and serious infections during infancy. The internal structures of the ear and throat continue to be short and straight, and the lymphoid tissue of the tonsils and adenoids continues to be large. As a result, otitis media, tonsillitis, and upper respiratory tract infections are common. The respiratory and heart rates slow, and the blood pressure increases. Respirations continue to be abdominal.

The digestive processes are fairly complete by the beginning of toddlerhood. The acidity of the gastric contents continues to increase and has a protective function because it can destroy many types of bacteria. Stomach capacity increases to allow for the usual schedule of three meals a day.

One of the more prominent changes of the gastrointestinal system is the voluntary control of elimination. With complete myelination of the spinal cord, control of the anal and urethral sphincters is gradually achieved. The physiologic ability to control the sphincters probably occurs somewhere between 18 and 24 months old. Bladder capacity also increases considerably. By 14 to 18 months old, children can retain urine for up to 2 hours or longer.

Under conditions of moderate variation in temperature, the toddler rarely has the difficulties of young infants in maintaining body temperature. The capillaries can conserve core body temperature by constricting in response to cold and dilating in response to heat.

The defense mechanisms of the skin and blood, particularly phagocytosis, are much more efficient in toddlers than in infants. The production of antibodies is well established. However, many young children demonstrate a sudden increase in colds and minor infections when entering daycare or preschool because of their exposure to new pathogens.

Rapid growth in neurobehavioral organization contributes to greater regularity of sleep–wake cycles, the diminishing of crying and unexplained fussiness, and the enhanced predictability in mood. Valuable stimulants of early brain development include the various interactions (talking, singing, and playing) between the toddler and caregivers. Adequate nutrition; protection from environmental toxins, such as lead, various drugs, and stress; and promotion of good health care all contribute to healthy brain growth.

Gross and Fine Motor Development

The major gross motor skill during the toddler years is the development of locomotion. By 12 to 13 months old, toddlers walk alone using a wide stance for extra balance, and by 18 months old, they try to run but fall easily. At 2 years old, toddlers can walk up and down stairs, and by 2½ years old, they can jump using both feet, stand on one foot for a second or two, and manage a few steps on tiptoe. By the end of the second year, they can stand on one foot, walk on tiptoe, and climb stairs with alternate footing.

Fine motor development is demonstrated in increasingly skillful manual dexterity. For example, by 12 months old, toddlers can grasp a very small object. At 15 months old, they can drop a raisin into a narrow-necked bottle. Casting or throwing objects and retrieving them become almost obsessive activities at about 15 months old. By 18 months old, toddlers can throw a ball overhand without losing their balance. Mastery of gross and fine motor skills is evident in all phases of toddlers' activity, such as play, dressing, language comprehension, response to discipline, social interaction, and propensity for injuries. Activities occur less in isolation and more in conjunction with other physical and mental abilities to produce a purposeful result. For example, the toddler walks to reach a new location, releases a toy to pick it up or to choose a new one, and scribbles to look at the image produced. The possibilities of the exploration, investigation, and manipulation of the environment—and its hazards—are endless.

PSYCHOSOCIAL DEVELOPMENT

Toddlers are faced with the mastery of several important tasks. If the need for basic trust has been satisfied, they are ready to give up dependence for control, independence, and autonomy. Some of the specific tasks to be dealt with include:

- Differentiation of self from others, particularly the mother
- Toleration of separation from parent
- Ability to withstand delayed gratification
- Control over bodily functions
- Acquisition of socially acceptable behavior
- Verbal means of communication
- Ability to interact with others in a less egocentric manner

Mastery of these goals is only begun during late infancy and the toddler years; tasks such as developing interpersonal relationships with others may not be completed until adolescence. However, crucial foundations for successful completion of such developmental tasks are laid during these early formative years.

Developing a Sense of Autonomy (Erikson)

According to Erikson (1963), the developmental task of toddlerhood is acquiring a sense of autonomy while overcoming a sense of doubt and shame. As infants gain trust in the predictability and reliability of their parents, environment, and interactions with others, they begin to discover that their behavior is their own and that it has a predictable, reliable effect on others. Although they are aware of their will and control over others, they are confronted with the conflict of exerting autonomy and relinquishing the much-enjoyed dependence on others. Exerting their will has definite negative consequences, whereas retaining dependent, submissive behavior is generally rewarded with affection and approval. On the other hand, continued dependency creates a sense of doubt regarding their potential capacity to control their actions. This doubt is compounded by a sense of shame for feeling this urge to revolt against others' will and a fear that they will exceed their own capacity for manipulating the environment. Skillful monitoring and balance of controls by parents allows a growing rate of realistic successes and the emergence of autonomy.

Just as infants have the social modalities of grasping and biting, toddlers have the newly gained modality of holding on and letting go. Holding on and letting go are evident in how the toddler uses the hands, mouth, eyes, and eventually the sphincters, when toilet training is begun. Children constantly express these social modalities in play activities, such as throwing objects; taking objects out of boxes, drawers, or cabinets; holding on tighter when someone says, "No; don't touch"; and refusing to eat certain foods as taste preferences become strong.

Several characteristics, especially **negativism** and **ritualism**, are typical of toddlers in their quest for autonomy. As toddlers attempt to express their will, they often act with negativism, giving a negative response to requests. The words "no" or "me do" can be their sole vocabulary. Emotions become strongly expressed, usually in rapid mood swings. One minute, toddlers can be engrossed in an activity, and the next minute they might be angry because they are unable to manipulate a toy or open a door. If scolded for doing something wrong, they can have a temper tantrum and almost instantaneously pull at the parent's legs to be picked up and comforted. Understanding and coping with these swift changes is often difficult for parents. Many parents find the negativism exasperating and, instead of dealing constructively

with it, give in to it, which further threatens children in their search for learning acceptable methods of interacting with others (see the Temper Tantrums and Negativism sections later in the chapter).

In contrast to negativism, which frequently disrupts the environment, ritualism, the need to maintain sameness and reliability, provides a sense of comfort. Toddlers can venture out with security when they know that familiar people, places, and routines still exist. One can easily understand why any change in the daily routine represents such a threat to these children. Without comfortable rituals, they have little opportunity to exert autonomy. Consequently, dependency and regression occur (see the Regression section later in the chapter).

Erikson focuses on the development of the **ego**, which may be thought of as reason or common sense, during this phase of psychosocial development. The child struggles to deal with the impulses of the **id**, tolerate frustration, and learn socially acceptable ways of interacting with the environment. The ego becomes evident as children develop the ability to tolerate delayed gratification.

Toddlers also have a rudimentary beginning of the **superego**, or conscience, which is the incorporation of the morals of society and the process of acculturation. With the development of the ego, children further differentiate themselves from others and expand their sense of trust in self. But as they begin to develop awareness of their own will and capacity to achieve, they also become aware of their ability to fail. This ever-present awareness of potential failure creates doubt and shame. Successful mastery of the task of autonomy necessitates opportunities for self-mastery while withstanding the frustration of necessary limit setting and delayed gratification. Opportunities for self-mastery are present in appropriate play activities, toilet training, the crisis of sibling rivalry, and successful interactions with significant others.

COGNITIVE DEVELOPMENT: SENSORIMOTOR AND PREOPERATIONAL PHASE (PIAGET)

The period from 12 to 24 months old is a continuation of the final two stages of the sensorimotor phase. During this time, the cognitive processes develop rapidly and at times seem similar to those of mature thinking. However, reasoning skills are still primitive and need to be understood to effectively deal with the typical behaviors of a child of this age.

In the fifth stage of the sensorimotor phase, **tertiary circular reactions** (13 to 18 months old), the child uses active experimentation to achieve previously unattainable goals. Newly acquired physical skills are increasingly important for the function they serve rather than for the acts themselves. The child incorporates the old learning of secondary circular reactions with new skills and applies the combined knowledge to new situations, with emphasis on the results of the experimentation. In this way, there is the beginning of rational judgment and intellectual reasoning. During this stage, the child further differentiates self from objects. This is evident in the child's increasing ability to venture away from his or her parents and to tolerate longer periods of separation.

Awareness of a **causal relationship** between two events is apparent. After flipping a light switch, toddlers are aware that a reciprocal response occurs. However, they are not able to transfer that knowledge to new situations. Therefore every time they see what appears to be a light switch, they must reinvestigate its function. Such behavior demonstrates the beginning of categorizing data into distinct classes and subclasses. Innumerable examples of this type of behavior occur as toddlers continuously explore the same object each time it appears in a new place.

Because classification of objects is still basic, the appearance of an object indicates its function. For example, if the child's toys are stored in a paper bag or large container, the toddler does not perceive a difference between the toy receptacle and the garbage pail or laundry basket. If allowed to turn over the toy receptacle, the child will just as quickly do the same to other similar containers because, in the child's mind, there is no difference. Expecting the child to judge which receptacles are permissible to explore and which are not is inappropriate for this age-group. Instead, the forbidden object, such as the garbage pail, should be placed out of reach. This has significant implications for prevention of accidents and accidental ingestion of injurious agents.

The discovery of objects as objects leads to the awareness of their **spatial relationships**. Children can recognize different shapes and their relationships to each other. For example, they can fit slightly smaller boxes into each other (nesting) and can place a round object into a hole even if the board is turned around, upside down, or reversed. Children are also aware of space and the relationship of their bodies to dimensions, such as height. They will stretch, stand on a low stair or stool, and pull a string to reach an object.

Object permanence has also advanced. Although they still cannot find an object that has been invisibly displaced and is no longer visible or moved from under one pillow to another without their seeing the change, toddlers are increasingly aware of the existence of objects behind closed doors, in drawers, and under tables. Parents are usually acutely aware of this developmental achievement and find high places and locked cabinets the only places that are inaccessible to toddlers.

During ages 19 to 24 months, the child is in the final sensorimotor stage, invention of new means through mental combinations. This stage completes the more primitive, autistic thought processes of infancy and prepares the way for more complex mental operations that occur during the phase of preoperational thought. One of the most dramatic achievements of this stage is in the area of object permanence. Toddlers will now actively search for an object in several potential hiding places. In addition, they can infer a cause when only experiencing the effect. They can infer that an object was hidden in any number of places even if they only saw the original hiding place.

Imitation displays deeper meaning and understanding. There is greater symbolization to imitation. Children are acutely aware of others' actions and attempt to copy them in gestures and in words. **Domestic mimicry** (imitating household activities) and sex-role behavior become increasingly common during this period and during the second year. Identification with the parent of the same gender becomes apparent by the second year and represents the child's intellectual ability to differentiate different models of behavior and to imitate them appropriately (Fig. 11.1).

Fig. 11.1 Domestic mimicry is common during toddlerhood.

BOX 11.1 Characteristics of Preoperational Thought

Egocentrism: Inability to envision situations from perspectives other than one's own

Example: If a person is positioned between the toddler and another child, the toddler (who is facing the person) will explain that both children can see the middle person's face. The young child is unable to realize that the other person views the middle person from a different perspective, the back.

Implication: Avoid moralizing about "why" something is wrong if it requires an understanding of someone else's feelings or opinion. Telling a child to stop hitting because hitting hurts the other person is often ineffective because, to the aggressor, it feels good to hit someone else. Instead, emphasize that hitting is not allowed.

Transductive reasoning: Reasoning from the particular to the particular

Example: Child refuses to eat a food because something previously eaten did not taste good.

Implication: Accept child's reasoning; offer refused food at different time.

Global organization: Reasoning that changing any one part of the whole changes the entire whole

Example: Child refuses to sleep in his or her room because location of bed has changed.

Implication: Accept child's reasoning; use same bed position or introduce change slowly.

Centration: Focusing on one aspect rather than considering all possible alternatives

Example: Child refuses to eat a food because of its color even though its taste and smell are acceptable.

Implication: Accept child's reasoning.

Animism: Attributing lifelike qualities to inanimate objects

Example: Child scolds stairs for making child fall down.

Implication: Join child in the "scolding." Keep frightening objects out of view.

Irreversibility: Inability to undo or reverse the actions initiated physically

Example: When told to stop doing something (such as talking), child is unable to think of a positive activity.

Implication: State requests or instructions positively (e.g., "Be quiet.").

Magical thinking: Believing that thoughts are all-powerful and can cause events

Examples: Child wishes someone died; then if the person dies, child feels at fault because of the "bad" thought that made the death happen. Calling children "bad" because they did something wrong makes them feel as if they are bad.

Implication: Clarify that thoughts do not make things happen and that child is not responsible.

- Use "I" messages rather than "you" messages to communicate thoughts, feelings, expectations, or beliefs without imposing blame or criticism. Emphasize that the act, not the child, is bad.

Inability to conserve: Inability to understand the idea that a mass can be changed in size, shape, volume, or length without losing or adding to the original mass (instead, children judge what they see by the immediate perceptual clues given to them)

Example: If two lines of equal length are presented in such a way that one appears longer than the other, child will state that one line is longer even if child measures both lines with a ruler or yardstick and finds that each has the same length.

Implication: Change the most obvious perceptual clue to reorient child's view of what is seen.

- Give medicine in a small medicine cup rather than a large cup because the child will imagine that the large vessel contains more liquid. If child refuses the medicine in the small cup, pour it into a large cup because the liquid will appear to be less in a tall, wide container.
- Give a large, flat cookie rather than a thick, small one or do the reverse with meat or cheese; child will usually eat larger size of favorite food and smaller size of less favorite food.

The concept of time is still embryonic, but children have some sense of timing in terms of anticipation, memory, and a limited ability to wait. They may listen to the command, "Just a minute," and behave appropriately. However, their sense of timing is exaggerated—1 minute can seem like an hour. Toddlers' limited attention spans also indicate their sense of immediacy and concern for the present.

Preoperational Phase (Piaget)

At approximately 2 years old, children enter the preconceptual phase of cognitive development, which lasts until about 4 years old. The preconceptual phase is a subdivision of the preoperational phase, which spans ages 2 to 7 years. The preconceptual phase is primarily one of transition that bridges the purely self-satisfying behavior of infancy and the rudimentary socialized behavior of latency. **Preoperational thinking** implies that children cannot think in terms of operations—the ability to manipulate objects in relation to each other in a logical fashion. Rather, toddlers think primarily based on their perception of an event. Problem solving is based on what they see or hear directly rather than on what they recall about objects and events (Box 11.1).

Within the second year, the child increasingly uses language symbolically and is concerned with the "why" and "how" of things. For example, a pencil is "something to write with," and food is "something to eat." However, such **mental symbolization** is closely associated with prelogical reasoning. For instance, a needle is "something that hurts." Such painful experiences take on new significance because memory is associated with the specific event, and fears are likely to develop, such as resistance to people who wear uniform scrubs or rooms that look like the practitioner's office. Because of the vulnerability of these early years, it is essential to prepare children for any new experience, whether it is a new babysitter or a visit to the dentist.

SPIRITUAL DEVELOPMENT

Spiritual development in children is often discussed in terms of the child's developmental level because the evolution of spirituality often parallels cognitive development (Lima, do Nascimento, de Carvalho, et al., 2013). The child's family and environment strongly influence the child's perception of the world around him or her, and this often includes spirituality. Furthermore, family values, beliefs, customs, and expressions of these influence the child's perception of his or her spiritual self (Lima et al., 2013). Neuman (2011) proposes that Fowler's (1981) stages of faith be used to better understand children and spirituality; she provides an excellent overview of the stages of faith in childhood. The relationship between spirituality, illness in childhood, and nursing has been studied in the context of suffering, terminal illness such as cancer, and end-of-life care. In the past decade, there has been an increased interest in and focus on spiritual care in adults and children as further understanding of the influence of one's spirituality on health, illness, and well-being has progressed.

Toddlers learn about God through the words and the actions of those closest to them. They have only a vague idea of God and religious teachings because of their immature cognitive processes; however, if God is spoken about with reverence, young children associate God with something special. During this period, the assignment of

powerful religious symbols and images is strongly influenced by the way these symbols and images are presented, usually in the form of rituals, games, and songs (Lima et al., 2013). Toddlers are said to be in the intuitive-projective phase of Fowler's (1981) faith construct wherein thinking is largely based on fantasy and rather fluid in relation to reality and fantasy. God may be described as being around like air by the toddler because of the fluidity in dividing fantasy and reality (Neuman, 2011).

Toddlers begin to assimilate behaviors associated with the divine (folding hands in prayer). Routines such as saying prayers before meals or at bedtime can be important and comforting. Because toddlers tend to find solace in ritualistic behavior and routines, they incorporate routines associated with religious practices into their behavioral patterns without understanding all of the implications of the rituals until later. Near the end of toddlerhood, when children use preoperational thought, there is some advancement of their understanding of God. Religious teachings, such as reward or fear of punishment (heaven or hell) and moral development (see Chapter 3), may influence their behavior.

DEVELOPMENT OF BODY IMAGE

As in infancy, the development of body image closely parallels cognitive development. With increasing motor ability, toddlers recognize the usefulness of body parts and gradually learn their respective names. They also learn that certain parts of the body have various meanings; for example, during toilet training, the genitalia become significant, and cleanliness is emphasized. By 2 years old, toddlers recognize gender differences and refer to themselves by name and then by pronoun. Gender identity is developed by 3 years old. Also by this time, children begin to remember events with reference to their personal significance, forming an autobiographic memory that helps establish a continuous identity throughout life's events.

Once they begin preoperational thought, toddlers can use symbols to represent objects, but their thinking may lead to inaccuracies. For example, if someone who is pregnant is called "fat," they will describe all "fat" women as having babies. They begin to recognize words used to describe physical appearance, such as "pretty," "handsome," or "big boy." Such expressions eventually influence how children view their own bodies.

It is evident that body integrity is poorly understood and that intrusive experiences are threatening. For example, toddlers forcefully resist procedures such as examining their ears or mouths and having their axillary temperature taken. The procedure itself (e.g., taking vital signs) does not hurt the child, but it represents an intrusion into the child's personal space, which elicits a strong protest. Toddlers also have unclear body boundaries and may associate nonviable parts, such as feces, with essential body parts. This can be seen in a toddler who is upset by flushing the toilet and watching the stool disappear.

Nurses can assist parents in fostering a positive body image in their child by encouraging them to avoid negative labels, such as "skinny arms" or "chubby legs"; such self-perceptions are internalized and can last a lifetime. Body parts, especially those related to elimination and reproduction, should be called by their correct names. Respect for the body should be practiced.

DEVELOPMENT OF GENDER IDENTITY

Just as toddlers explore their environment, they also explore their bodies and find that touching certain body parts is pleasurable. Genital fondling (masturbation) can occur and involves manual stimulation, as well as posturing movements (especially in young girls) such as tightening of the thighs or mechanical pressure applied to the pubic or suprapubic area. Other demonstrations of pleasurable activities include rocking, swinging, and hugging people and toys. Parental reactions to toddlers' behavior influence the children's own attitudes and should be accepting rather than critical. If such acts are performed in public, parents should not condone or bring attention to the behavior but should teach the child that it is more acceptable to perform the behavior in private.

Children in this age-group are learning vocabulary associated with anatomy, elimination, and reproduction. Certain associations between words and functions become significant and can influence future sexual attitudes. For example, if parents refer to the genitalia as dirty, especially in the context of elimination, this association between "genitalia" and "dirty" may be transferred to sexual functions later in life. Sex-role differences become obvious to children and are evident in much of toddlers' imitative play. Although current research indicates that prenatal exposure to testosterone strongly influences the individual's gender identity, researchers also indicate that there are sensitive periods (e.g., puberty) that may also have an influence on the development of gender identity (Hines, Constantinescu, & Spencer, 2015: Stortelder, 2014). A sense of maleness or femaleness, or **gender identity**, begins by 24 months old when children can label their own and others' gender (Steensma, Kreukels, de Vries, et al., 2013). Early attitudes are formed about affectionate behaviors between adults from observing parental and other adult intimate or sensual activities (see also Chapters 12 and 14, Sex Education). The quality of relationships with parents is important to the child's capacity for sexual and emotional relationships later in life.

SOCIAL DEVELOPMENT

A major task of the toddler period is differentiation of the self from significant others, usually the mother. The differentiation process consists of two phases: **separation**, children's emergence from a symbiotic fusion with the mother; and **individuation**, those achievements that mark children's expression of their individual characteristics in the environment. Although the process begins during the latter half of infancy, the major achievements occur during the toddler years.

Toddlers have an increased understanding and awareness of object permanence and some ability to withstand delayed gratification and tolerate moderate frustration. As a result, toddlers react differently to strangers than do infants. The appearance of unfamiliar people does not represent such a significant threat to their attachment to their mothers. They have learned from experience that parents exist when physically absent. Repetition of events such as going to bed without the parents but waking to find them there again reinforces the reliability of such brief separations. Consequently, toddlers can venture away from their parents for brief periods because of the security of knowing that the parents will be there when they return. Verbal and visual reassurance from the parents gradually replaces some of the previous need to be physically close for comfort.

The separation-individuation phase of the toddler encompasses the phenomenon of **rapprochement**; as a toddler separates from the mother and begins to make sense of experiences in the environment, the child is drawn back to the mother for assistance in identifying the meaning of the experiences (Zimmer-Gembeck, Webb, Thomas, et al., 2015). Developmentally, the term *rapprochement* means that the child moves away and returns for reassurance. If the mother's response to the toddler is inappropriate, the toddler may experience insecurity and confusion.

Transitional objects, such as a favorite blanket or toy, provide security for children, especially when they are separated from their parents,

dealing with a new stress, or just fatigued (Fig. 11.2). Security objects often become so important to toddlers that they refuse to let them be taken away. Such behavior is normal; there is no need to discourage this tendency. During separations, such as daycare, hospitalization, or even staying overnight with a relative, transitional objects should be provided to minimize any fear or loneliness.

Learning to tolerate and master brief periods of separation are important developmental tasks for children in this age-group. In addition, it is a necessary component of parenting because brief periods of separation allow parents to restore their energy and patience and to minimize directing their irritations and frustrations at the children.

Language Development

The most striking characteristic of language development during early childhood is the increasing level of comprehension. Although the number of words acquired—from about 4 at 1 year old to approximately 300 at 2 years old—is notable, the ability to understand speech is much greater than the number of words the child can say. Bilingual children can also achieve their early linguistic milestones in each of the languages at the same time and produce a substantial number of semantically corresponding words in each of their two languages from the very first words or signs (Estes & Hay, 2015).

At 1 year old, children use one-word sentences or holophrases. The word "up" can mean "pick me up" or "look up there." For children, the one word conveys the meaning of a sentence, but to others, it may mean many things or nothing. At this age, about 25% of the vocalizations are intelligible. By 2 years old, children use multiword sentences by stringing together two or three words, such as the phrases "mama go bye-bye" or "all gone," and approximately 65% of the speech is understandable. By 3 years old, children put words together into simple sentences, begin to master grammatical rules, know their age and gender, and can count three objects correctly (Feigelman, 2016). Reading books together during this period provides an ideal setting for further language development. Language development among infants and toddlers is positively affected by adult-child conversations, including reading, storytelling, and interactive adult-child communication. Because of their immature symbolic, memory, and attentional skills, infants and toddlers cannot learn from traditional digital media as they do from interactions with caregivers, and they have difficulty transferring that knowledge to their three-dimensional experience (Barr, 2013). Emerging evidence shows that at 24 months of age, children can learn words from live video-chatting with a responsive adult or from an interactive touchscreen interface that scaffolds the child to choose the relevant answers (Kirkorian, Choi, & Pempek, 2016; Roseberry, Hirsh-Pasek, & Golinkoff, 2014). The American Academy of Pediatrics, Council on Communications and Media (2016) discourages the use of screen media other than video-chatting for children younger than 18 months. However, children 18 to 24 months of age can be introduced to digital media consisting of high-quality programming or apps, but these should be viewed together by parents and children. Allowing children to use media alone should be avoided.

Furthermore, educational programs have not been shown to increase cognitive skills in young children.

Gestures precede or accompany each of the language milestones up to 30 months old (putting phone to ear, pointing). After sufficient language development, gestures phase out, and the pace of word learning increases.

Fig. 11.2 Transitional objects, such as a warm and fuzzy stuffed animal, are sources of security to a toddler. (©2011 Photos.com, a division of Getty Images. All rights reserved.)

Personal-Social Behavior

One of the most dramatic aspects of development in the toddler is personal-social interaction. Personal-social behaviors are evident in such areas as dressing, feeding, playing, and establishing self-control. Parents frequently wonder why their manageable, docile, lovable infant has turned into a determined, strong-willed, volatile little tyrant. In addition, the tyrant of the terrible twos can swiftly and unpredictably revert to the adorable infant. All of this is part of growing up as toddlers acquire a more sophisticated awareness that others' feelings and desires can be different from their own. Through interactions with caregivers, children can explore these differences and their consequences.

Toddlers are developing skills of independence, which are evident in all areas of behavior. By 15 months old, children feed themselves, drink well from a covered cup, and manage a spoon with considerable spilling. By 2 years old, they use a spoon well, and by 3 years old, they may be using a fork. Between 2 and 3 years old, they eat with the family and like to help with chores such as setting the table or removing dishes from the dishwasher, but they lack table manners and may find it difficult to sit through the family's entire meal.

In dressing, toddlers also demonstrate strides in independence. The 15-month-old child helps by putting the arms or feet out for dressing and pulling off shoes and socks. The 18-month-old child removes gloves, helps with pullover shirts, and may be able to unzip. By 2 years old, toddlers remove most articles of clothing and put on socks, shoes, and pants without regard for right or left and back or front. Help is still needed to fasten clothes.

Toddlers also begin to develop concern for the feelings of others and develop an understanding of how adult expectations for behavior apply to specific situations (e.g., causing a sibling to cry while playing rough). As their understanding increases, they develop control. Age-appropriate discipline contributes to healthy social and emotional development. Positive reinforcement, redirection, and time-outs are appropriate for most toddlers. Social and emotional problems can develop in the youngest children. Early screening and intervention promote more positive outcomes as young children grow and develop.

Play

Play magnifies toddlers' physical and psychosocial development. Interaction with people becomes increasingly important. The solitary play of infancy progresses to **parallel play**; toddlers play alongside, not with, other children. Although sensorimotor play is still prominent, there is much less emphasis on the exclusive use of one sensory modality. The toddler inspects toys, talks to toys, tests toys' strength and durability, and invents several uses for toys.

Imitation is one of the most distinguishing characteristics of play and enriches children's opportunity to engage in fantasy. With less emphasis on gender-stereotyped toys, play objects such as dolls, carriages, dollhouses, dishes, cooking utensils, child-size furniture, trucks, and dress-up clothes are suitable for both genders (Fig. 11.3); however, boys may be more interested than girls in activities related to trucks, trailers, action figures, and building blocks; girls may prefer doll-related activities.

Increased locomotive skills make push–pull toys, straddle trucks or cycles, a small gym and slide, balls of various sizes, and riding toys appropriate for energetic toddlers. Finger paints, thick crayons, chalk, blackboard, paper, and puzzles with large, simple pieces use toddlers' developing fine motor skills. Interlocking blocks in various sizes (but large enough to avoid aspiration) and shapes provide hours of fun and, during later years, are useful objects for creative and imaginative play. The most educational toy is the one that fosters the interaction of an adult with a child in supportive, unconditional play. Parents and other providers are encouraged to allow children to play with a variety of toys that foster creative thinking (such as blocks, dolls, and clay), rather than passive toys that the child observes (battery-operated or mechanical). Active play time should be encouraged over the use of computer or video games. Toys should not be substitutes for the attention of devoted caregivers, but toys can enhance these interactions.

Certain aspects of play are related to emerging linguistic abilities. Talking is a form of play for toddlers, who enjoy musical toys such as "talking" dolls and animals and toy telephones. Children's television programs are appropriate for some children over 2 years old, who learn to associate words with visual images. However, total media time should be limited to 1 hour or less of quality programming per day. Parents are encouraged to allow the child to engage in unstructured playtime, which is considered much more beneficial than any electronic media exposure (American Academy of Pediatrics, Council on Communications and Media, 2016). Toddlers also enjoy "reading" stories from a picture book and imitating the sounds of animals.

Fig. 11.3 Young children enjoy dressing up. (©2011 Photos.com, a division of Getty Images. All rights reserved.)

Tactile play is also important for exploring toddlers. Water toys, a sandbox with a pail and shovel, finger paints, soap bubbles, and clay provide excellent opportunities for creative and manipulative recreation. Adults sometimes forget the fascination of feeling textures, such as slippery cream, mud, or pudding; catching air bubbles; squeezing and reshaping clay; or smearing paints. These types of unstructured activities are as important as educational play to allow children the freedom of expression.

Selection of appropriate toys must involve safety factors, especially in relation to size and sturdiness. The oral activity of toddlers puts them at risk for aspirating small objects and ingesting toxic substances. Parents need to be especially vigilant of toys played with in other children's homes and toys of older siblings. Toys are a potential source of serious bodily damage to toddlers, who may have the physical strength to manipulate them but not the knowledge to appreciate their danger. Ball pits have been associated with transmission of bacteria, often found to be contaminated with visible dirt, vomit, feces, or urine, providing a permissive environment for contamination (Oesterle, Wright, Fidler, et al., 2019). Ride-on toys (i.e., tricycles, wagons, scooters) and early exploratory toys (i.e., blocks, stacking toys, building sets) were the most common type of toy causing injury to children younger than 5 years old (Abraham, Gaw, Chounthirath, et al., 2015). Government agencies do not inspect and police all toys on the market. Therefore adults who purchase play equipment, supervise purchases, or allow children to use play equipment need to evaluate its safety, including toys that are gifts or those that are purchased by the children themselves. Adults should also be alert to notices of toys determined to be defective and recalled by the manufacturers. Parents and health care workers can obtain information on a variety of recalled products and can report potentially dangerous toys and child products to the US Consumer Product Safety Commission[a] or, in Canada, the Canadian Toy Testing Council.[b] Printable tips on toy safety are also available from Safe Kids Worldwide (http://www.safekids.org).

COPING WITH CONCERNS RELATED TO NORMAL GROWTH AND DEVELOPMENT

Table 11.1 summarizes the major features of growth and development for the age-groups of 15, 18, 24, and 30 months.

Toilet Training

One of the major tasks of toddlerhood is toilet training. Anticipatory guidance and clinical intervention for families surrounding toilet training should begin during routine well-child visits before the child's developmental readiness to toilet train. Preparation and education reveal and allay misconceptions; lead to the development of appropriate expectations; and provide information, guidance, and support to parents for managing this potentially frustrating process.

Voluntary control of the anal and urethral sphincters is achieved sometime after the child is walking, probably between 18 and 24 months old. However, complex psychophysiologic factors are required for readiness. The child must be able to recognize the urge to let go and hold on and be able to communicate this sensation to the parent. In addition, some motivation is probably involved in the desire to please the parent by holding on rather than pleasing oneself by letting go. Cultural beliefs may also affect the age at which children demonstrate readiness (Feigelman, 2016).

Trends in toilet training have changed, likely due to the availability of disposable diapers. In the 1920s, toilet training began around

TABLE 11.1 Growth and Development During the Toddler Years

Physical	Gross Motor	Fine Motor	Sensory	Language	Socialization
15 Months Old					
Steady growth in height and weight Head circumference, 48 cm (19 inches) Weight, 11 kg (24 pounds) Height, 78.7 cm (31 inches)	Walks without help (usually since 13 months old) Creeps up stairs Kneels without support Cannot walk around corners or stop suddenly without losing balance without support Cannot throw ball without falling	Constantly casting objects to floor Builds tower of two cubes Holds two cubes in one hand Releases a pellet into narrow-necked bottle Scribbles spontaneously Uses cup well but often rotates spoon before it reaches mouth	Able to identify geometric forms; places round object into appropriate hole Binocular vision well developed Displays an intense and prolonged interest in pictures	Uses expressive jargon Says four to six words, including names "Asks" for objects by pointing Understands simple commands May shake head to denote "no" Uses "no" even while agreeing to the request Uses common gestures, such as putting cup to mouth when empty	Tolerates some separation from parent Less likely to fear strangers Beginning to imitate parents, such as cleaning house (sweeping, dusting), folding clothes May discard bottle Kisses and hugs parents; may kiss pictures in a book Expresses emotions; has temper tantrums
18 Months Old					
Physiologic anorexia from decreased growth needs Anterior fontanel closed Physiologically able to control sphincters	Runs clumsily; falls often Walks up stairs with one hand held Pulls and pushes toys Jumps in place with both feet Seats self on chair Throws ball overhand without falling	Builds tower of three or four cubes Release, prehension, and reach well developed Turns two or three pages in a book at a time In a drawing, makes stroke imitatively Manages spoon without rotation		Says 10 or more words Points to common object, such as a shoe or ball, and to two or three body parts Forms word combinations Forms gesture–word combinations (points while naming) Forms gesture–gesture combinations	Great imitator (domestic mimicry) Takes off gloves, socks, and shoes and unzips zippers Temper tantrums may be more evident Beginning awareness of ownership ("my toy") May develop dependence on transitional objects, such as security blanket
24 Months Old					
Head circumference, 49-50 cm (19.5-20 inches) Chest circumference exceeds head circumference Lateral diameter of chest exceeds anteroposterior diameter Usual weight gain of 1.8-2.7 kg (4-6 pounds) per year Usual gain in height of 10-12.5 cm (4-5 inches) per year Adult height approximately double height at 2 years old Primary dentition of 16 teeth May demonstrate readiness for beginning daytime control of bowel and bladder	Goes up and down stairs alone with two feet on each step Runs fairly well, with wide stance Picks up object without falling Kicks ball forward without overbalancing	Builds tower of six or seven cubes Aligns two or more cubes like a train Turns pages of book one at a time In drawing, imitates vertical and circular strokes Turns doorknobs; unscrews lids	Accommodation well developed in geometric discrimination; able to insert square block into oblong space	Has a vocabulary of approximately 300 words Uses two- or three-word phrases Uses pronouns "I," "me," "you" Understands directional commands Gives first name; refers to self by name Verbalizes need for toileting, food, or drink Talks incessantly Able to remember and imitate arbitrary sequences of manual actions and gestures	Stage of parallel play Has sustained attention span Temper tantrums decreasing Pulls people to show them something Increased independence from parent Dresses self in simple clothing Develops visual recognition and verbal self-reference ("me big") Develops awareness that feelings and desires of others may be different and begins to explore implications and consequences
30 Months Old					
Birth weight quadrupled Primary dentition (20 teeth) completed May have daytime bowel and bladder control	Jumps with both feet Jumps from chair or step Stands on one foot momentarily Takes a few steps on tiptoe	Builds tower of eight cubes Adds chimney to train of cubes Good hand–finger coordination; holds crayon with fingers rather than fist In drawing, imitates vertical and horizontal strokes; makes two or more strokes for cross; draws circles		Gives first and last name Refers to self by appropriate pronoun Uses plurals Names one color	Separates more easily from parent In play, helps put things away; can carry breakable objects; pushes with good steering Begins to notice gender differences; knows own gender May attend to toilet needs without help except for wiping Emotions expand to include pride, shame, guilt, embarrassment

12 months old, which changed to at least 18 months old in the 1960s and is now initiated around 21 months old, with approximately half of children toilet trained by 36 months old (Rogers, 2013).

Three markers signal a child's readiness to toilet train: (1) being aware of the urge to void or stool, (2) interest in and/or motivation to use the toilet, and (3) being dry for at least 2 hours during the day (Kimball, 2016). According to some experts, physiologic and psychologic readiness is not complete until 24 to 30 months old (Rogers, 2013); however, parents should begin preparing their children for toilet training earlier than 30 months old. By this time, children have mastered most essential gross motor skills, can communicate intelligibly, are in less conflict with their parents in terms of self-assertion and negativism, and are aware of the ability to control the body and please their parents. There is no universal right age to begin toilet training or an absolute deadline to complete training. An important role for the nurse is to help parents identify the readiness signs in their children (see Nursing Care Guidelines box).[c] On average, girls are developmentally ready to begin toilet training before boys (Elder, 2016).

NURSING CARE GUIDELINES

Assessing Toilet Training Readiness

Physical Readiness

Voluntary control of anal and urethral sphincters, usually by 24 to 30 months old

Ability to stay dry for 2 hours; decreased number of wet diapers; waking dry from nap

Regular bowel movements

Gross motor skills of sitting, walking, and squatting

Fine motor skills to remove clothing

Mental Readiness

Recognizes urge to defecate or urinate

Verbal or nonverbal communicative skills to indicate when wet or has urge to defecate or urinate

Cognitive skills to imitate appropriate behavior and follow directions

Psychologic Readiness

Expresses willingness to please parent

Able to sit on toilet for 5 to 8 minutes without fussing or getting off

Curiosity about adults' or older sibling's toilet habits

Impatience with soiled or wet diapers; desire to be changed immediately

Parental Readiness

Recognizes child's level of readiness

Willing to invest the time required for toilet training

Absence of family stress or change, such as a divorce, moving, new sibling, or imminent vacation

Nighttime bladder control normally takes several months to years after daytime training begins. This is because the sleep cycle needs to mature so that the child can awake in time to urinate. Feigelman (2016) indicates that bedwetting is normal in girls up to 4 years old and in boys up to 5 years old. Few children have night wetting episodes after daytime dryness is totally achieved; however, children who do not have nighttime dryness by 6 years old are likely to require intervention.

[c]A helpful book is *The American Academy of Pediatrics Guide to Toilet Training,* 847-434-4000; http://shop.aap.org.

Bowel training is usually accomplished before bladder training because of its greater regularity and predictability. The sensation for defecation is stronger than that for urination and easier for children to recognize. A well-balanced diet that includes dietary fiber helps keep stool soft and supports the development and maintenance of regular bowel movements.

A number of techniques are helpful when initiating training, and cultural differences should be considered (see Cultural Considerations box). In the United States, some of the options recommended by practitioners include the Brazelton child-oriented approach, the American Academy of Pediatrics guidelines (which are similar to the Brazelton method), Dr. Spock's training method, and the intensive "toilet-training-in-a-day" (operant conditioning) approach by Azrin and Foxx (Wu, 2010). A systematic review by the Agency for Healthcare Research and Quality in 2006 concluded that the child-oriented method and the Azrin and Foxx methods were effective at toilet training healthy children (Kiddoo, 2012). The following discussion of toilet training methods includes suggestions from the child-oriented approach.

CULTURAL CONSIDERATIONS

Toilet Training

Cultural practices influence the timing, method, and significance of toilet training. For many families in China, the timing is liberal, the method is distinct, and the significance is low. Children are diapered during infancy. Once they are walking, they wear loose pants with a long slit between the legs, and they eliminate on the ground. This practice may continue until the child is 5 years old. In cold weather, a piece of cloth, like a "curtain," may be inserted. However, the Chinese have a concept that the buttocks are not susceptible to cold, so this is not a common practice.

Parents should begin the readiness phase of toilet training by teaching the child about how the body functions in relation to voiding and having a stool. Parents can talk about how adults and animals perform such functions on a routine basis. Toilet training should be as easy and simple as possible. Important considerations are the selection of the child's clothing and the potty chair or use of the toilet. A freestanding potty chair allows children a feeling of security (Fig. 11.4A). Planting the feet firmly on the floor also facilitates defecation. Another option is a portable seat attached to the regular toilet, which may ease the transition from potty chair to regular toilet. Placing a small bench under the feet helps stabilize the child's position. It is probably best to keep the potty in the bathroom and to let the child observe the excreta being flushed down the toilet to associate these activities with usual practices. If a potty chair is not available, having the child sit facing the toilet tank provides added support (see Fig. 11.4B). Practice sessions should be limited to 5 to 8 minutes, and a parent should stay with the child, practicing sanitary habits after every session. Children should be praised for cooperative behavior and successful evacuation. Dressing children in easily removed clothing; using training pants, "pull-on" diapers, or underwear; and encouraging imitation by watching others are other helpful suggestions.

When the child begins to experience regular daytime dryness, parents may experiment with underwear during the day. Daytime accidents are common, particularly during periods of intense activity. Young children become so engrossed in play activity that, if they are not reminded, they will wait until it is too late to reach the bathroom. Therefore frequent reminders and trips to the toilet are necessary. Parents often forget to plan ahead when their toddlers are being toilet trained; before trips outside the house, it is important to remind children to at least try to urinate to decrease the chance of needing to use the toilet while the car is stuck in traffic.

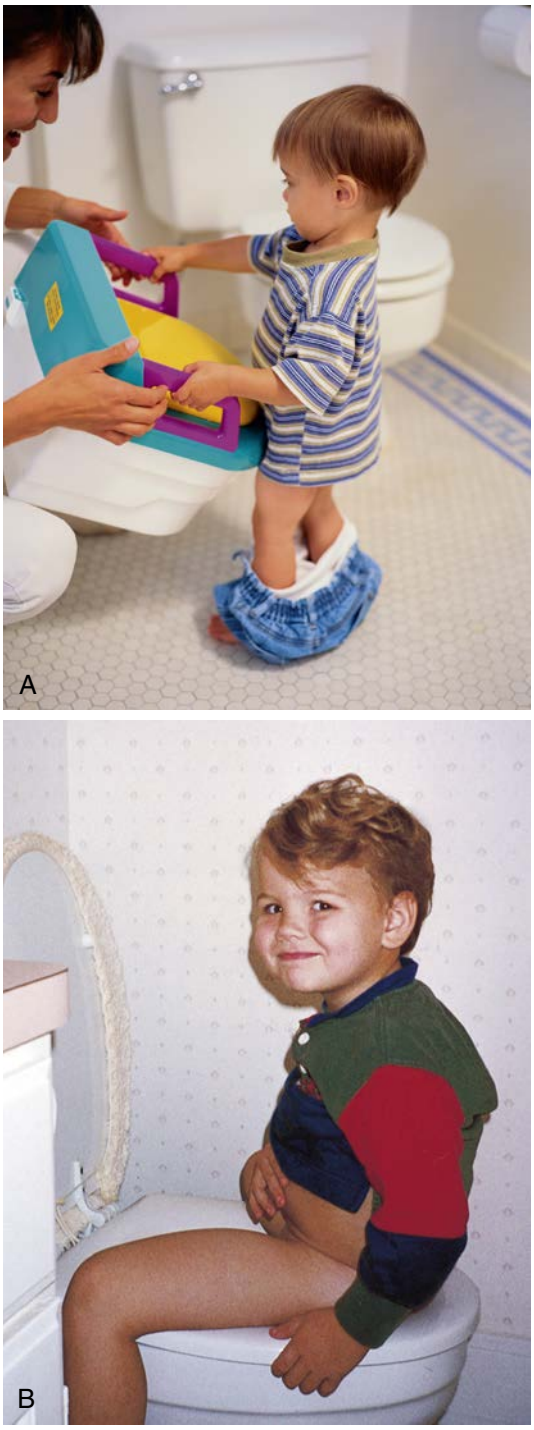

Fig. 11.4 A, Children may begin toilet training sitting on a small potty chair. B, Sitting in reverse fashion on a regular toilet provides additional security to a young child. (A, ©2011 Photos.com, a division of Getty Images. All rights reserved.)

As the child masters each step of toileting (discussion, undressing, going, wiping, dressing, flushing, and hand washing), he or she gains a sense of accomplishment that parents should reinforce. If the parent-child relationship becomes strained, both may need a break to focus on enjoyable activities together. Regression may coincide with a stressful family situation or the child being pushed too hard and too fast. Regression is a normal part of toilet training and does not mean failure but should be viewed as a temporary setback to a more comfortable place for the child.

Daycare providers also play a role in the support and education of parents regarding toilet training practices. It is important for parents to inform all caregivers of their individual family values and the child's specific needs when planning for training away from home. Ensuring consistency in care of toddlers and ensuring healthy practices in a sanitary environment allow for safe and effective toilet practices in all settings.

Sibling Rivalry

The term *sibling rivalry* refers to a natural jealousy and resentment toward a new child in the family or toward other children in the family when a parent turns his or her attention from them and interacts with their brother or sister.

The arrival of a new infant represents a crisis for even the best-prepared toddlers. They do not hate or resent the infant; rather, they hate the changes that this additional sibling produces, especially the separation from mother during the birth. The parents now share their love and attention with someone else, the usual routine is disrupted, and toddlers may lose their crib or room—all at a time when they thought they were in control of their world. Sibling rivalry tends to be most pronounced in firstborn children, who experience **dethronement** (loss of sole parental attention). It also seems to be most difficult for young children, particularly in terms of mother-child interaction.

Preparation of children for the birth of a sibling is individual but is dictated to some extent by age. For toddlers, time is a vague concept. A good time to start talking about the baby is when toddlers become aware of the pregnancy and the changes taking place in the home in anticipation of the new member. To avoid additional stresses when the newborn arrives, parents should perform anticipated changes, such as moving the toddler to a different room or bed, well in advance of the birth.

Toddlers need to have a realistic idea of what the newborn will be like. Telling them that a new playmate will come home soon sets up unrealistic expectations. Rather, parents should stress the activities that will take place when the baby arrives home, such as diapering, bottle-feeding or breastfeeding, bathing, and dressing. At the same time, parents should emphasize which routines will stay the same, such as reading stories or going to the park. If toddlers have had no contact with an infant, it is a good idea to introduce them to one, if feasible. Providing a doll with which toddlers can imitate parental behaviors is another excellent strategy. They can tend to the doll's needs (diapering, feeding) at the same time the parent is performing similar activities for the infant.

When the new baby arrives, toddlers keenly feel the changed focus of attention. Visitors may initiate problems when they inadvertently shower the infant with attention and presents while neglecting the older child. Parents can minimize this by alerting visitors to the toddler's needs, having small presents on hand for the toddler, and including the child in the visit as much as possible. The toddler can also help with the care of the newborn by getting diapers and doing other small tasks (Fig. 11.5).

How children exhibit jealousy is complex. Some will hit the infant, push the child off the mother's lap, or pull the bottle or breast from the infant's mouth. For this reason, infants must be protected by parental supervision of the interaction between the siblings. More often the expressions of hostility and resentment are more subtle and covert. Toddlers may verbally express a wish that the infant "go back inside mommy," or they will revert to more infantile forms of behavior, such as demanding a bottle, soiling their underpants, clinging for attention, using baby talk, or aggressively acting out toward others. The latter is particularly common in preschoolers, who may seem accepting of the new sibling at home but behave poorly in daycare or preschool.

Fig. 11.5 To minimize sibling rivalry, parents should include the toddler during caregiving activities.

This is a form of displacement that says, "I can't let my parents know how I feel, so I will tell you." Encouraging parents to explore how their older child is acting with other caregivers is an important aspect of intervention.

Temper Tantrums

Toddlers may assert their independence by violently objecting to discipline. They may lie down on the floor, kick their feet, and scream at the top of their lungs. Some have learned the effectiveness of holding their breath until the parent relents. Although holding one's breath may cause fainting from the lack of oxygen, the accumulation of carbon dioxide will stimulate the respiratory control center, resulting in no physical harm. Tantrums are an indication of the child's inability to control emotions; toddlers are particularly prone to tantrums because their strong drive for mastery and autonomy is frustrated by adult figures or lack of motor and cognitive skills.

The best approach to tapering temper tantrums requires consistency and developmentally appropriate expectations and rewards. Ensuring consistency among all caregivers in expectations, prioritizing what rules are important, and developing consequences that are reasonable for the child's level of development help manage the behavior. For example, a popular time for a tantrum is before bed. Active toddlers often have trouble slowing down and, when placed in bed, resist staying there. Parents can reinforce consistency and expectations by stating, "After this story, it is bedtime." Starting at 18 months old, time-outs work well for managing temper tantrums.

During tantrums, stay calm and ignore the behavior, provided the behavior is not injurious to the child, such as violently banging the head on the floor. Continue to be present to provide a feeling of control and security to the child when the tantrum has subsided. During periods of no tantrums, practice developmentally appropriate positive reinforcement.

Other suggestions for preventing tantrums include the following (El-Radhi, 2015):

- Offer the child options instead of an "all or none" position.
- Set clear boundaries and expectations with all caregivers.
- Ensure a consistent response to child's behavior by all caregivers.
- Praise the child for positive behavior when he or she is not having a tantrum or provide a reward system (i.e., sticker chart).

Temper tantrums are common during the toddler years and essentially represent normal developmental behaviors. However, temper tantrums can be signs of serious problems. Temper tantrums that occur past 5 years old, last longer than 15 minutes, or occur more than five times a day are considered abnormal and may indicate a serious problem (Eisbach, Cluxton-Keller, Harrison, et al., 2014). Nurses should be alert to situations that require further evaluation.

Negativism

One of the more difficult aspects of rearing children in this age-group is their persistent negative response to every request. The negativism is not an expression of being stubborn or insolent but a necessary assertion of self-control. One method of dealing with the negativism is to reduce the opportunities for a "no" answer. Asking the child, "Do you want to go to sleep now?" is an example of a question that will almost certainly be answered with an emphatic "no." Instead, tell the child that it is time to go to sleep and proceed accordingly. In their attempt to exert control, children like to make choices. When confronted with appropriate choices, such as "You may have a peanut butter and jelly sandwich or chicken noodle soup for lunch," they are more likely to choose one rather than automatically say no. However, if their response is negative, parents should make the choice for the child.

Nurses working with children and parents can assist parents in understanding this concept by role modeling. For example, when the nurse approaches the toddler to take vital signs, instead of asking, "Can I listen to your heart?" the nurse can say, "I am going to listen to your heart." Because of normal developmental behavior, toddlers first resist having their vital signs taken because it is an intrusion on their bodies. Second, toddlers are most likely going to answer "no," not because they necessarily fear the procedure itself but because of the tendency to answer all questions with a negative response. If the nurse asks the question and the toddler says, "No" but the nurse proceeds anyway, the toddler starts to mistrust the nurse's actions because they contradict his or her words.

Regression

The retreat from one's present pattern of functioning to past levels of behavior is referred to as **regression**. It usually occurs in instances of discomfort or stress when one attempts to conserve psychic energy by reverting to patterns of behavior that were successful in earlier stages of development. Regression is common in toddlers because almost any additional stress hinders their ability to master present developmental tasks. Any threat to their autonomy, such as illness, hospitalization, separation, disruption of established routines, or adjustment to a new sibling, represents a need to revert to earlier forms of behavior, such as increased dependency. This can include refusal to use the potty chair; temper tantrums; demand for the bottle or pacifier; and loss of newly learned motor, language, social, and cognitive skills.

At first, such regression appears acceptable and comfortable for children, but the loss of newly acquired achievements is frightening and threatening because children are aware of their helplessness. Parents become concerned about regressive behavior and frequently force the child to cope with an additional source of stress—the pressure to live up to expected standards. Brazelton (1999) suggests that these predictable times of regression, or **touchpoints**, are an opportunity to prepare parents for the next step in their child's development.

When regression does occur, the best approach is to ignore it while praising existing patterns of appropriate behavior. Regression is a child's way of saying, "I can't cope with this present stress and perfect this skill as well, but I will eventually if given patience and understanding." For this reason, it is advisable not to attempt new areas of learning when an additional crisis is present or expected, such as beginning toilet training shortly before a sibling is born or during a brief period of hospitalization.

PROMOTING OPTIMAL HEALTH DURING TODDLERHOOD

NUTRITION

During the period from 12 to 18 months old, the growth rate slows, decreasing the child's need for calories, protein, and fluid. However, the protein (13 g/day) and energy requirements are still relatively high to meet the demands for muscle tissue growth and high activity level. The need for minerals (such as iron, calcium, and phosphorus) may be difficult to meet, considering the characteristic food habits of children in this age-group. Parents may be tempted to rely on vitamin supplementation, rather than a well-balanced diet, to meet these requirements. Toddlers usually require three meals and two snacks per day; however, the portions consumed are generally smaller compared with those of older children.

The Feeding Infants and Toddlers Study (FITS) (Saavedra, Denning, Dattilo, et al., 2013) found that, in general, toddlers met or exceeded the requirements for daily energy and protein requirements. However, intake of a variety of foods was seen with advancing age in toddlers as their food preferences changed. FITS recommended that toddlers be fed a more balanced diet of vegetables, fruits, and whole grains.

At approximately 18 months old, most toddlers manifest this decreased nutritional need with a decreased appetite, a phenomenon known as **physiologic anorexia**. They become picky, fussy eaters with strong taste preferences. They may eat large amounts one day and almost nothing the next. Toddlers are increasingly aware of the nonnutritive function of food (i.e., the pleasure of eating, the social aspect of mealtime, and the control of refusing food). They are influenced by factors other than taste when choosing food. If a family member refuses to eat something, toddlers are likely to imitate that response. If the plate is overfilled, they are likely to push it away, overwhelmed by its size. If food does not appear or smell appetizing, they will probably not agree to try it. In essence, mealtime is more closely associated with psychologic components than with nutritional ones. Toddlers like to eat with their fingers and enjoy foods of different colors and shapes.

The **ritualism** of this age also dictates certain principles in feeding practices. Toddlers like to have the same dish, cup, or spoon every time they eat. They may reject a favorite food simply because it is served in a different dish. If one food touches another, they often refuse to eat it. Mixed foods, such as stews or casseroles, are rarely favorites. Because toddlers have unpredictable table manners, it is best to use plastic dishes and cups for both economic and safety reasons. For some children, a regular mealtime schedule also contributes to their desire and need for predictability and ritualism.

Developmentally, by 12 months old most children eat many of the same foods prepared for the rest of the family. Some may have mastered using a cup with occasional spilling, although most cannot use a spoon until 18 months old or later and generally prefer using their fingers.

Nutritional Counseling

The emphasis on preventing childhood obesity and subsequent cardiovascular disease in the United States has prompted a number of changes in dietary recommendations for children and adults alike. It is now recognized that lifetime eating habits may be established in early childhood, and health care workers are increasingly emphasizing the role of food selection choices, exercise, stress reduction, and other lifestyle choices (tobacco and alcohol use) on the quality of adult life and survival. Conditions such as obesity and cardiovascular disease can be prevented by encouraging healthy eating habits in toddlers and their families.

If food is used as a reward or sign of approval, a child may overeat for nonnutritive reasons. If food is forced and mealtime is consistently unpleasant, the usual pleasure associated with eating may not develop. Mealtimes should be enjoyable rather than times for discipline or family arguments. The social aspect of mealtime may be distracting for young children; therefore an earlier feeding hour may be appropriate. Young children are unable to sit through a long meal and become restless and disruptive. This is particularly common when children are brought to the table just after active play. Calling them in from play 15 minutes before mealtime allows them ample opportunity to get ready for eating while settling down their active minds and bodies.

The method of serving food also takes on more importance during this period. Toddlers need to have a sense of control and achievement in their abilities. Giving them large, adult-size portions can overwhelm them. In general, what is eaten is much more significant than how much is consumed. Toddlers usually restrict their food preference to four or five main foods and rarely try new foods; in some cases, a toddler may insist on one food such as mashed potatoes for lunch and dinner. Small amounts of meat and vegetables supply greater food value than a large consumption of bread or potato. Serving sizes need to be appropriate for age. Young children tend to like less spicy, bland food, although this is a culturally determined preference. Substitutions can be provided for foods that they do not enjoy, although parents need not cater to all of their desires. Frequent nutritious snacks can replace a meal. **Grazing** (i.e., nibbling and snacking) is a good way to ensure proper nutrition, provided that appropriate foods are offered.

To determine serving size for young children, use the following guidelines:

- A general guide to serving sizes for toddlers is 1 tablespoon of solid food per year of age, or one-fourth to one-third of the adult portion size.
- Use the tablespoon guide for easily measured foods, such as vegetables or rice.
- Use the fraction guide for bread or milk.

Mastication skills continue to mature, putting children at risk for choking; therefore large, round foods (e.g., hot dogs, grapes, peas, carrots, popcorn, fruit gel snacks) should be avoided until the child is able to chew them effectively. Active play while eating should be discouraged to prevent choking. Appetite and food preferences are sporadic. Often the interest in food parallels a growth spurt; thus periods of good eating are interspersed with phases of poor eating. If exposed to the same food every day, a young toddler does not learn how to manage the complex sensory information needed to eat new, more difficult foods (e.g., vegetables with a different texture vs. pureed, slippery fruits). To help prevent "food jags," it is recommended that parents present food in various physical forms. The child may need to progress to eating new foods in a stepwise fashion, such as visually tolerating the food, interacting with the food, smelling the food, touching the food, tasting the food, and then eating the food.

Many authorities consider this period of picky eating to be a developmental phase, and growth charts can be used to demonstrate growth

to parents who are often concerned (Parks, Shaikhkhalil, Groleau, et al., 2016). Parents should be encouraged to plan a nutritionally balanced week instead of day because of the way toddlers restrict food intake in their effort to exert control over their environment (Schwartz & Benuck, 2013).

Dietary Guidelines

Dietary guidelines are necessary to promote adequate energy and nutrient intake to support physical, emotional, psychologic, and cognitive development. New dietary guidelines have been developed to address the issue of childhood obesity, sedentary lifestyles, and increase in cardiovascular disease mortality in the United States.

The National Academies of Medicine (2017) has developed guidelines for nutritional intake that encompass the Recommended Dietary Allowances (RDAs) yet extend their scope to include additional parameters related to nutritional intake. The Dietary Reference Intakes (DRIs)[d] are composed of four categories. These include Estimated Average Requirements (EARs) for age and gender categories, Tolerable Upper Intake Levels (ULs) that are associated with a low risk of adverse effects, Adequate Intakes (AIs) of nutrients, and new standard RDAs. The guidelines present information about lifestyle factors that may affect nutrient function, such as caffeine intake and exercise, and about how the nutrient may be related to chronic disease. An important factor in the development of the DRIs that affects children, particularly infants from birth to 6 months old, is that the AIs are based on the nutrient intake of full-term, healthy, breastfed infants (by well-nourished mothers), which now represents the gold standard for infant nutrition in this age-group. In 2010 new DRIs for vitamin D and calcium were released by the Institute of Medicine.

The 2015–2020 Dietary Guidelines for Americans may also be used to encourage healthy dietary intakes and regular exercise designed to decrease obesity, cardiovascular risk factors, and subsequent cardiovascular disease, which is now known to occur in both young children and adults. As an example, the 2015–2020 Dietary Guidelines recommend a caloric intake for a moderately active boy, ages 2 to 3 years, of 1000 to 1400 calories per day. The emphasis in the Dietary Guidelines is on decreasing overall fat and sodium intakes, and increasing the amount of daily exercise to reduce the incidence of obesity and cardiovascular disease. The 2015–2020 Dietary Guidelines[e] are for children ages 2 years and older. They encourage a variety of fruits, vegetables, whole grains, and low-fat dairy and nonfat dairy products in addition to fish, beans, and lean meat.

Additional resources for dietary counseling include MyPlate[f], developed by the US Department of Agriculture to replace MyPyramid. This colorful plate shows the five main food groups (i.e., fruits, grains, vegetable, protein, and dairy) with the intended purpose of involving children and their families in making appropriate food choices for meals and decreasing the incidence of overweight and obesity in the United States. MyPlate provides an online interactive feature that allows the individual to select (click on) an individual food group and see choices for foods in that group. Approximate serving sizes are suggested, and vegetarian substitutions are also provided.

Nutrition during toddlerhood involves a transition as a young toddler is weaned off milk- or formula-based diets. Milk intake, the chief source of calcium and phosphorus, should average two or three servings (24 to 30 oz) a day. Consuming more than a quart of milk daily considerably limits the intake of solid foods, resulting in a deficiency of dietary iron and other nutrients. After 2 years of age, children can be given low-fat milk to reduce daily total fat to less than 30% of calories, saturated fatty acids to less than 10% of calories, and cholesterol to less than 300 mg. Other measures to reduce dietary fat include using lean meats, fat-modified products (e.g., low-fat cheese), and low-fat cooking. Because less fat in children's diets can also mean fewer calories and nutrients, caregivers must know what kinds of food to choose. However, trans fatty acids and saturated fats should be avoided.

Iron-fortified cereals and iron-rich foods are recommended for all children older than 6 months of age. Parents should be encouraged to provide an iron-rich diet that includes heme and nonheme iron sources (red meats, poultry, fish, green leafy vegetables, dried fruit, and beans) and limit whole-milk consumption. Iron supplementation may be necessary in some cases. Calcium and vitamin D are essential for healthy bone development. Adequate intake of calcium for children 1 to 3 years old is 500 mg per day. Whole milk, cheese, yogurt, legumes (beans), and vegetables (broccoli, collard greens, and kale) are good sources of calcium. Popular calcium-fortified foods include waffles, cereals and cereal bars, orange juice, and some white breads. Adequate vitamin D intake is essential to prevent rickets; it is now recommended that children and adolescents have an intake of at least 400 IU of vitamin D daily (US Department of Health and Human Services, 2016). Multivitamin preparations containing 400 IU of vitamin D (by tablet or liquid) are adequate if food intake is poor or exposure to sunlight is minimal; vitamin D–only preparations containing 400 IU are also available commercially. Sources of vitamin D include fish, fish oils, and egg yolks. Fortified cereals, dairy products, and meat are also good sources of zinc and vitamin E.

Juice should not be introduced into the diet of infants before 12 months of age unless clinically indicated. Toddlers should not be given juice from bottles or easily transportable covered cups that allow them to consume juice easily throughout the day. Toddlers should not be given juice at bedtime. The intake of juice should be limited to, at most, 4 ounces/day in toddlers 1 through 3 years of age (Heyman & Abrams, 2017). Fruit-flavored drinks advertised as juices may not actually contain 100% juice and should be avoided.

VEGETARIAN DIETS

Vegetarian diets have become increasingly popular in the United States because people are concerned about hypertension; cholesterol; obesity; cardiovascular disease; cancer of the stomach, intestine, and colon; and the influence of the animal rights movement. The American Dietetic Association and the American Academy of Pediatrics endorse vegetarian diets for adults and children (Schürmann, Kersting, & Alexy, 2017). Well-planned vegetarian diets are adequate for all stages of the life cycle; promote normal growth; and have been shown to have lower intakes of cholesterol, saturated fat, and total fat and higher intakes of fruits, fiber, and vegetables than nonvegetarian diets. However, vegetarian diets may vary considerably, and assessment of dietary adequacy is essential to ensure that children are receiving adequate nutrients (Schürmann et al., 2017)

The major types of vegetarianism are:

Lacto-ovo vegetarians, who exclude meat from their diet but consume dairy products and rarely fish

Lactovegetarians, who exclude meat and eggs but drink milk

Pure vegetarians (vegans), who eliminate all foods of animal origin, including milk and eggs

Macrobiotics, who are even more restrictive than pure vegetarians, allowing only a few types of fruits, vegetables, and legumes

BOX 11.2 Factors That Affect Iron Absorption

Increase

Acidity (low pH): Administer iron between meals (gastric hydrochloric acid).
Ascorbic acid (vitamin C): Administer iron with juice, fruit, or multivitamin preparation.
Vitamin A
Tissue (cellular) need
Meat, fish, poultry
Cooking in cast iron pots

Decrease

Alkalinity (high pH): Avoid any antacid preparation.
Phosphates: Milk is unfavorable vehicle for iron administration.
Phytates—found in cereals
Oxalates—found in many fruits and vegetables (plums, currants, green beans, spinach, sweet potatoes, tomatoes)
Tannins—found in tea, coffee
Tissue (cellular) saturation
Malabsorptive disorders
Disturbances that cause diarrhea or steatorrhea
Infection

Semi-vegetarians, who consume a lacto-ovo vegetarian diet with some fish and poultry: This is an increasingly popular form of vegetarianism and poses little or no nutritional risk to infants unless dietary fat and cholesterol intake is severely restricted.

Many individuals who are concerned about healthy diets subscribe to vegetarian diets that may not be typified by the above categories. Therefore during nutritional assessment, it is necessary to clearly list exactly what the diet includes and excludes.[g]

The major deficiencies that may occur in the stricter vegan diets are inadequate protein for growth; inadequate calories for energy and growth; poor digestibility of many of the bulky natural, unprocessed foods, especially for infants; and deficiencies of vitamin B_6, niacin, riboflavin, vitamin D, iron, calcium, and zinc. Vitamin D is essential if exposure to sunlight is inadequate (≈5 to 15 min/day on the hands, arms, and face of light-skinned persons; slightly more in darker pigmented individuals) or in persons who are dark skinned or who live in northern latitudes or cloudy or smoky areas. Many of these deficiencies can be avoided in children who are not consuming 100% of the RDA of vitamins and minerals with a multivitamin and mineral supplement.

Evaluate for **iron-deficiency anemia** and **rickets** in children who are on strict vegetarian and macrobiotic diets; these problems may occur as a result of consuming plant foods such as unrefined cereals, which impair the absorption of iron, calcium, and zinc. The American Academy of Pediatrics, Committee on Nutrition (2014) recommends iron supplementation of 1 mg/kg/day in infants exclusively breastfed after 4 to 6 months old by vegetarian mothers and no dietary fat restrictions in vegetarian children younger than 2 years old. Other factors that affect iron absorption are listed in Box 11.2.

Achieving a nutritionally adequate vegetarian diet is not difficult (except with the strictest diets), but it requires careful planning and knowledge of nutrient sources (American Academy of Pediatrics, Committee on Nutrition, 2014). For children, the lacto-ovo vegetarian diet is nutritionally adequate; however, the vegan diet requires supplementation with vitamins D and B_{12} for children 2 to 12 years old.

To ensure sufficient protein in the diet, foods with incomplete proteins (those that do not have all of the essential amino acids) must be eaten at the same meal with other foods that supply the missing amino acids. The three basic combinations of foods consumed by vegetarians that generally provide the appropriate amounts of essential amino acids are:

1. Grains (cereal, rice, pasta) and legumes (beans, peas, lentils, peanuts)
2. Grains and milk products (milk, cheese, yogurt)
3. Seeds (sesame, sunflower) and legumes

Additional dietary considerations for young children are found in Chapter 12.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

There are four **complementary and alternative medicine (CAM)** domains according to the National Center for Complementary and Integrative Health; this discussion centers on only one of those—biologically based practices, which include herbs, vitamins, and foods. The National Center for Complementary and Integrative Health (2018) classifies **probiotics** as a type of natural product and CAM. Many CAM products are sold over the counter as dietary supplements, but the use of some dietary supplements such as calcium for bone health or a multivitamin supplement are not considered to be CAM (National Center for Complementary and Integrative Health, 2018). The National Center for Complementary and Integrative Health (2018) reports that natural products are the most commonly used CAM products in children and that most often these products are used for chronic conditions (such as neck and back pain) and for head and chest colds. Other surveys confirm that CAM is often used for children's chronic remedies for which traditional therapy is not effective (National Center for Complementary and Integrative Health, 2018).

The misuse of CAM has the potential for placing some children at risk for health problems. Although 55% of children have used CAM at least once, only 4.4% of CAM use was reported to emergency department physicians, primarily because the parent or child did not think it was important to inform the physician and/or the physician did not ask about CAM use (Taylor, Dhir, Craig, et al., 2015). A survey in a Women, Infants, and Children clinic found that child herbal use was common, especially among Hispanic children attending the clinic. Some herbs used by the children (ma huang, foxglove, anise tea, and mistletoe) have questionable safety (Kemper and Gardiner, 2016). A survey of four pediatric emergency departments found that child herbal use was common, especially among children 6 years of age and older (Taylor, Dhir, Craig, et al., 2015). Some of the herbs used by the children in the survey included chamomile, cranberry, parsley, ginger, celery, amino acids, and green tea, and herbal therapies with known toxicity included garlic, licorice, belladonna, and ginkgo biloba.

There is concern that terms often used to market supplements (such as megavitamins) may mislead parents about the actual benefits (or harm) of such therapies. The intention here is not to discredit the use of CAM such as vitamin supplements but rather to ensure safety and efficacy in children who may experience inadvertent harm. The use of various herbal therapies, or intake of herbs, is also becoming more popular; many of these have been a part of medicine since early days and are beneficial in some cases. Growing evidence from clinical samples suggests that CAM therapies are desired by families and

[g]Additional information on vegetarian diets may be found at the Vegetarian Resource Group; 410-366-8343; http://www.vrg.org. Another helpful resource is the KidsHealth website: http://kidshealth.org/parent/nutrition_center/dietary_needs/vegetarianism.html

may benefit some children with pain conditions (Groenewald, Beals-Erickson, Ralston-Wilson, et al., 2017)

Herbs known to have adverse effects in children include ephedra, comfrey, and pennyroyal; some herbs may not be harmful taken alone but may counteract or potentiate prescription medications when taken together. Parents should be fully informed of the use of herbs to ensure that there is more benefit than potential harm in the ingredients being used. Health care workers also need to be knowledgeable of the benefits or potential harm in herbs to appropriately counsel parents and address their concerns. Little research has been performed in children on many over-the-counter herbal medicines, yet some herbs are known to cause harm in children (Kemper & Gardiner, 2016). Parents should be cautioned not to exceed the upper limits of vitamin intake according to the new DRIs.[h]

SLEEP AND ACTIVITY

Total sleep decreases only slightly during the second year and averages about 11 to 12 hours a day. Most children take one nap a day but may relinquish this habit by the end of the second or third year.

Toddlers are more prone to having bedtime resistance (refusal to go to bed) and frequent night waking. Fears can be provoked by a child's daily stressors, such as pressure to toilet train, moves, sibling birth, experiences of loss, or separation from parents. A recent study found that a consistent nightly bedtime routine is associated with better sleep patterns, such as shorter sleep onset latency, decreased waking, longer total sleep, and decreased daytime behavior problems (Mindell, Li, Sadeh, et al., 2015). In addition, providing transitional objects, such as a favorite stuffed animal or blanket, can ease the child's insecurity at bedtime (see Fig. 11.2). Children may need a light snack before bedtime; a heavy meal immediately before bedtime may interfere with sleep. Other suggestions to help small children sleep better include keeping the television out of the child's room, making the hour before bedtime a quiet time of reading stories, and avoiding stimulating activities, such as computer games and roughhousing (Owens, 2016). Toddlers no longer sleeping in a crib may come out of their rooms after being put to bed. Limit prolonged bedtime rituals by defining a length of time and set of activities (one more story, one more drink). Toddlers who are too immature to respond to the measures identified may need their doorways gated.

A toddler's activity level is high, and there is rarely a problem with too little physical exercise, provided inappropriate restrictions are not instituted. Recently, however, there has been concern that decreased time spent in actual physical play and more time involved with computers and television watching have increased the tendency toward being overweight. This is especially true in large urban centers during the winter months where there may not be adequate "safe" play and physical exercise space. With increasing numbers of young children being cared for outside the home, attention to the kinds of activity provided is important. For example, children with high activity levels may benefit from an environment that encourages vigorous play whether outside or in a large indoor play area.

DENTAL HEALTH

Regular Dental Examinations

The American Academy of Pediatric Dentistry (2016) recommends that every child have an oral health examination by a practitioner by 6 months old; if the child is in a high-risk category for caries, it is recommended that an initial visit to a dentist or pedodontist (pediatric dentist) occur by 6 months old or within 6 months of the eruption of the first tooth. Every child should have an established dental home by 12 months old (American Academy of Pediatric Dentistry, 2016). Initial visits to the dentist should be nontraumatizing. Because toddlers react negatively to new and potentially frightening experiences, the initial visit can center around meeting the dentist, seeing the equipment, and sitting in the chair. If the child is cooperative, the dentist may just look at the teeth but reserve a more thorough examination for another visit. Modeling, in which the child observes procedures performed on the parent or a cooperative sibling, can also be effective but may not work on all toddlers.

Plaque Removal

Oral hygiene measures should be implemented in toddlers to remove plaque, soft bacterial deposits that adhere to the teeth and cause dental caries (decay or cavities) and periodontal (gum) disease. Poor oral hygiene and poor dietary habits are associated with the development of caries in children.

The most effective methods for plaque removal are brushing and flossing. Several brushing techniques exist, although there is no universal agreement on the best method. One that is suitable for cleaning the primary teeth is the scrub method. The tips of the bristles are placed firmly at a 45-degree angle against the teeth and gums and moved back and forth in a vibratory motion. The ends of the bristles should be wiggling but not moving forcefully back and forth, which can damage the gums and enamel. All surfaces of the teeth are cleaned in this manner except the lingual (inner) surfaces of the anterior teeth. To clean these surfaces, the toothbrush is placed vertical to the teeth and moved up and down. Only a few teeth are brushed at one time, using six to eight strokes for each section. A systematic approach is used so that all surfaces are thoroughly cleaned (Fig. 11.6).

Fig. 11.7 The most effective cleaning of teeth is done by parents.

For young children, the most effective cleaning is done by parents (Fig. 11.7). Several positions can be used that facilitate access to the mouth and help stabilize the head for comfort:

- Stand with the child's back toward the adult. (When performed in front of a bathroom mirror, both the child and the adult can see what is being done in the mirror.)
- Sit on a couch or bed with the child's head resting in the adult's lap.
- Sit on the floor or a stool with the child's head resting between the adult's thighs.

Use one hand to cup the chin and one to brush the teeth. For easier access to back teeth, hold the mouth partially open. After brushing with a fluoridated paste or gel, avoid rinsing the mouth to maximize the beneficial effects of the fluoride.

NURSING TIP

- To encourage children to open their mouths, ask them to "tweet like a bird" or say "cheese" to brush the front teeth and to "roar like a lion" to brush the back teeth.
- Sing, tell stories, or talk to children during teeth cleaning to prevent boredom.

For effective cleaning, a small toothbrush with soft, rounded, multitufted nylon bristles that are short and uniform in length is recommended. Nylon bristles dry more rapidly after use and retain their shape better than natural bristles. Toothbrushes are replaced as soon as the bristles are frayed or bent. With young children, brushing may be more easily accomplished using only water because many children dislike the foam from toothpaste, and the foam interferes with visibility. Use a "smear" or "rice-size" amount of toothpaste for children younger than 3 years old (apply across the narrow width of the toothbrush, rather than along its length, to decrease the chance of applying an excessive amount); a "pea-size" amount of toothpaste should be used in children 3 to 6 years old (American Academy of Pediatric Dentistry, 2018).

After the teeth have been cleaned, they are flossed to remove plaque and debris from between the teeth and below the gum margin, where brushing is ineffective. Because young children do not have the dexterity to manipulate dental floss, parents must perform the procedure.

Ideally, the teeth should be cleaned after each meal and especially before bedtime, and the child should be given nothing to eat or drink after the night brushing except water. At times when brushing is impractical, the "swish-and-swallow" method of cleaning the mouth is taught; with a mouthful of water the child rinses the mouth and swallows, repeating the procedure three or four times.[i]

Fluoride

Fluoride supplementation should be considered for any child. Fluoride, a mineral, is found in water, foods, or drinks in which fluoridated water was used as part of the processing system. Because the water fluoridation process and manufacturing of fluoride toothpaste are almost impossible to standardize in the United States, the dosage of fluoride supplements should be determined in consultation with a medical professional (American Academy of Pediatric Dentistry, 2018). Increased fluoride ingestion leads to enamel protein retention, hypomineralization of the enamel and dentin, and disturbance of crystal formation. The effects caused by this change range from barely discernible white fiberlike lines or spots to gray-brown stains or pitted areas. Parents should be cautioned against regular use of fluoridated water or beverages such as bottled water containing fluoride if the community water supply already has an adequate amount of fluoride. Topical fluoride treatments (e.g., fluoride varnish) performed in the dental home is also effective in decreasing caries (American Academy of Pediatric Dentistry, 2018).

Dietary Factors

Diet is critical to developing good teeth because the carious process depends primarily on fermentable sugars, especially sucrose, and other carbohydrates. Refined table sugar, honey, molasses, corn syrup, and dried fruits (such as raisins) are highly cariogenic. Complex carbohydrates, such as breads, potatoes, and pasta, also contribute to caries because they lower the plaque pH. Beverages that are commonly consumed by children and adolescents and snacks are also highly cariogenic and may contribute to the incidence of overweight and obesity (American Academy of Pediatric Dentistry, 2018).

Ideally, highly cariogenic foods, especially those containing complex sugars, should be eliminated. However, because this is impractical, some suggestions can be helpful. First, *the frequency with which sugar is consumed is more important than the total amount eaten.* Therefore when sweets are eaten, they are less damaging if consumed immediately after a meal rather than as a snack between meals. When sweets are served as the dessert, the teeth can be cleaned afterward, decreasing the amount of time the sugar is in the mouth.

Second, the form of sugar (sucrose) is important. The more cariogenic foods are those that are sticky or hard because they remain in the mouth longer. Consequently, sucking on lollipops is more cariogenic than eating a chocolate bar. Sometimes the source of the sugar is "hidden," as in numerous prescription and nonprescription drugs and in many popular cereals, including the "all-natural" variety. Reading food labels is essential in eliminating sources of sucrose.

Some snacks do not contribute to tooth decay. Aged cheeses, such as cheddar, may alter the pH and delay bacterial growth. Sugarless gum chewed after eating may protect against cavities by stimulating saliva that neutralizes acid.

A special form of tooth decay in children between 18 months and 3 years old is **early childhood caries (ECC)** (historically called *nursing*

[i]More detailed information can be obtained from the American Academy of Pediatric Dentistry, http://www.aapd.org.

Fig. 11.8 Early childhood caries (ECC). (Courtesy of Bruce Carter, DDS, Texas Children's Hospital, Houston, TX.)

caries or *baby bottle tooth decay*) (Fig. 11.8). This often occurs when a child is routinely given a bottle of milk or juice at naptime or bedtime or uses the bottle as a pacifier while awake. Frequent nocturnal breastfeeding for prolonged periods also leads to extensive destruction of the teeth. The practice of coating pacifiers in honey can also contribute to caries and may be a potential source of botulism. As the sweet liquid pools in the mouth, the teeth are bathed for several hours in this cariogenic environment. Prolonged bottle-feeding, fruit juice consumption, lack of periodic dental examination, and nocturnal feeding contribute to significant ECC (Ozen, Van Strijp, Ozer, et al., 2016). The maxillary (upper) incisors and molars are affected most because the mandibular (lower) incisors are protected by the lower lip, tongue, and saliva. Severely decayed teeth may require the application of stainless steel bands to preserve the spacing until the permanent teeth erupt.

ECC is now considered to be an infectious disease of childhood. There is evidence that *Streptococcus mutans* is a highly cariogenic bacteria (American Academy of Pediatric Dentistry, 2016). One of the early origins of *S. mutans* is the mother's saliva; infants of mothers with high counts of the bacteria have a greater incidence of ECC. Therefore it is important to discuss oral hygiene with pregnant women because of its impact on their children's tooth development.

Prevention involves eliminating the bedtime bottle completely, feeding the last bottle before bedtime, substituting a bottle of water for milk or juice, not using the bottle as a pacifier, and never coating pacifiers in sweet substances. Juice in bottles, especially commercially available ready-to-use bottles, is discouraged; these beverages are especially damaging because the sugar is more readily converted to acid. Juice should always be offered in a cup to avoid prolonging the bottle-feeding habit. Toddlers should be encouraged to drink from a cup at the first birthday and weaned from a bottle by 14 months old. Nurses are in an excellent position to counsel parents on the dangers of this habit and other aspects of dental care.[j]

SAFETY PROMOTION AND INJURY PREVENTION

Unintentional childhood injury was the leading cause of death among children 1 to 4 years old in 2013, accounting for 32% of all deaths in this age-group (Centers for Disease Control and Prevention, 2016). Leading causes of accidental death include suffocation for children less than 1 year of age and drowning for children 1 to 4 years of age (Centers for Disease Control and Prevention, 2016). Falls are the leading cause of nonfatal injuries among children. These deaths and injuries are preventable, and they highlight the need for public health action and education. There is evidence that one-on-one and face-to-face education in the home, safety interventions, and safety equipment are effective in reducing the number of unintentional childhood injuries that can have catastrophic results (Folger, Bowers, Dexheimer, et al., 2017).

A major factor in the critical increase of injuries during early childhood is the unrestricted freedom achieved through locomotion combined with a lack of awareness of danger within the environment. Toddlers delight in the repetitive use of gross motor skills, and with increasing age, these skills are refined. This age-group is also very curious about how things work, and exploration of previously unknown or unseen objects and places is common. Toddlers also have not fully developed an understanding of cause-and-effect principles and often are unable to gauge danger; poorly developed depth perception may also contribute to falls and tumbles, as does the general body structure of toddlers. Specific categories of injuries and appropriate prevention are best understood by associating them with the major growth and developmental achievements of this age (Table 11.2). The discussions of injuries in Chapter 13 are also relevant to safety concerns at this age.

Motor Vehicle Safety

Motor vehicle injuries cause more accidental deaths in children ages 5 to 19 years than any other type of injury and are responsible for a significant number of all accidental deaths among children ages 1 to 4 years (Centers for Disease Control and Prevention, 2016). Many of the deaths are caused by injuries within the car when restraints have not been used or age-related guidelines have not been properly followed. Unrestrained children riding in the vehicle's front seat are at the highest risk for injury. Approved restraints properly installed and applied can reduce most fatalities and injuries.

Car Restraints

Nurses are responsible for educating parents regarding the importance of car restraints and their proper use. Five types of restraints are available: (1) infant-only devices, (2) convertible models for both infants and toddlers, (3) booster seats, (4) safety belts, and (5) devices for children with special needs (see Chapter 17). Chapter 9 discusses the infant-type restraints; convertible restraints and boosters are included here. Convertible restraints are suitable for infants and toddlers in the rearward-facing position (Fig. 11.9). The American Academy of Pediatrics (2015) and National Highway Traffic Safety Administration now recommend that children up to 2 years old ride in rear-facing car safety seats for as long as possible or until they have outgrown the manufacturer's weight and height recommendation, then transition the child to a forward-facing safety seat with a harness in the back seat of the vehicle (Rivara & Grossman, 2016). Many rear-facing car safety seats can accommodate children weighing up to a maximum of 35 pounds (according to manufacturer specifications). Studies indicate that toddlers are safer riding in convertible seats in the rear-facing position (American Academy of Pediatrics, 2018). Another study confirmed that children 0 to 3 years of age riding properly restrained in the rear seat had significantly less risk of death than passengers in the front seats (Durbin, Jermakian, Kallan, et al., 2015).

TABLE 11.2 Injury Prevention During Early Childhood

Developmental Abilities Related to Risk of Injury	Injury Prevention
Motor Vehicles	
Walks, runs, and climbs Able to open doors and gates Can ride tricycle Can throw ball and other objects	Use federally approved car restraint per manufacturer's recommendations for weight and height. Supervise child while playing outside. Do not allow child to play on curb or behind a parked car. Do not permit child to play in pile of leaves, snow, or large cardboard container in trafficked area. Supervise tricycle riding; have child wear helmet. Limit playing in driveways with parked cars or provide physical barriers limiting access. Lock fences and doors if not directly supervising children. Teach child to obey pedestrian safety rules: • Obey traffic regulations; cross only at crosswalks and only when traffic signal indicates it is safe. • Stand back a step from the curb until it is time to cross. • Look left, right, and left again, and check for turning cars before crossing street. • Use sidewalks; when there is no sidewalk, walk on the left, facing traffic. • Wear light colors at night and attach fluorescent material to clothing.
Drowning	
Able to explore if left unsupervised Has great curiosity Helpless in water; unaware of its danger; depth of water has no significance	Supervise closely when near any source of water, including buckets. Never, under any circumstance, leave unsupervised in bathtub. Keep bathroom doors closed and lid down on toilet. Have fence around swimming pool and lock gate.[a]
Burns	
Able to reach heights by climbing, stretching, and standing on toes Pulls objects Explores any holes or opening Can open drawers and closets Unaware of potential sources of heat or fire Plays with mechanical objects	Turn pot handles toward back of stove. Place electric appliances, such as coffee maker and popcorn machine, toward back of counter. Place guardrails in front of radiators, fireplaces, and other heating elements. Store matches and cigarette lighters in locked or inaccessible area; discard carefully. Place burning candles, incense, hot foods, and cigarettes out of reach. Do not let tablecloth hang within child's reach. Do not let electric cord from iron or other appliance hang within child's reach. Cover electrical outlets with protective plastic caps. Keep electrical wires hidden or out of reach. Do not allow child to play with electrical appliance, wires, or lighters. Stress danger of open flames; teach what "hot" means. Always check bathwater temperature; adjust water heater temperature to 49°C (120°F) or lower; do not allow children to play with faucets. Apply a sunscreen when child is exposed to sunlight (all year round).
Accidental Poisoning	
Explores by putting objects in mouth Can open drawers, closets, and most containers Climbs Cannot read labels Does not know safe dose or amount	Place all potentially toxic agents, including cosmetics, personal care items, cleaning products, pesticides, and medications, out of reach or in a locked cabinet. Caution against eating nonedible items, such as plants. Replace medications or poisons immediately in locked cabinet; replace child-guard caps promptly. Administer medications as a drug, not as a candy. Do not store large surplus of toxic agents. Promptly discard empty poison containers; never reuse to store a food item or other poison. Teach child not to play in trash containers. Never remove labels from containers of toxic substances. Know number of nearest poison control center: **800-222-1222.**
Falls	
Able to open doors and some windows Goes up and down stairs Depth perception unrefined	Use window guards; do not rely on screens to stop falls. Place gates at top and bottom of stairs. Keep doors locked or use childproof doorknob covers at entry to stairs, high porch, or other elevated area, including laundry chute. Ensure safe and effective barriers on porches, balconies, decks. Remove unsecured or scatter rugs.

TABLE 11.2 Injury Prevention During Early Childhood—cont'd

Developmental Abilities Related to Risk of Injury	Injury Prevention
	Apply nonskid decals in bathtub or shower. Keep crib rails fully raised and mattress at lowest level. Place carpeting under crib and in bathroom. Keep large toys and bumper pads out of crib or play yard (child can use these as "stairs" to climb out) and then move to youth bed when child is able to climb out of crib. Avoid using mobile walker, especially near stairs. Dress in safe clothing (soles that do not "catch" on floor, tied shoelaces, pant legs that do not touch floor). Keep child restrained in vehicle; never leave unattended in vehicle or shopping cart. Never leave child unattended in high chair. Supervise at playgrounds; select play areas with soft ground cover and safe equipment.
Choking and Suffocation	
Puts things in mouth May swallow hard or inedible pieces of food	Avoid large, round chunks of meat, such as whole hot dogs (slice lengthwise into short pieces). Avoid fruit with pits, fish with bones, hard candy, chewing gum, nuts, popcorn, grapes, and marshmallows. Choose large, sturdy toys without sharp edges or small removable parts. Discard old refrigerators, ovens, and so on, and remove the door. Install smoke and carbon monoxide alarms; change batteries every 6 months. Develop a fire escape plan for the entire family and have drills. Keep automatic garage door transmitter in an inaccessible place. Select safe toy boxes or chests without heavy, hinged lids. Keep venetian blind cords out of child's reach. Remove drawstrings from clothing; shorten essential drawstrings to 15.24 cm (6 inches) or less. Avoid contact with round, hollow, semirigid plastic items such as half of a plastic ball.
Bodily Injury	
Still clumsy in many skills Easily distracted from tasks Unaware of potential danger from strangers or other people	Avoid giving sharp or pointed objects (e.g., knives, scissors, toothpicks), especially when walking or running. Do not allow lollipops or similar objects in mouth when walking or running. Teach safety precautions (e.g., to carry knife or scissors with pointed end away from face). Store all dangerous tools, garden equipment, and firearms in locked cabinet. Be alert to danger of unsupervised animals and household pets. Use safety glass on large glassed areas, such as sliding glass doors. Teach child name, address, and phone number and to ask for help from appropriate people (cashier, security guard, police officer) if lost; have identification on child (sewn in clothes, inside shoe). Teach stranger safety: • Avoid personalized clothing in public places. • Never go with a stranger. • Tell parents if anyone makes child feel uncomfortable in any way. • Always listen to child's concerns regarding others' behavior. • Teach child to say "no" when confronted with uncomfortable situations.

[a]Detailed guidelines for swimming pool safety may be found at http://www.poolsafely.gov.

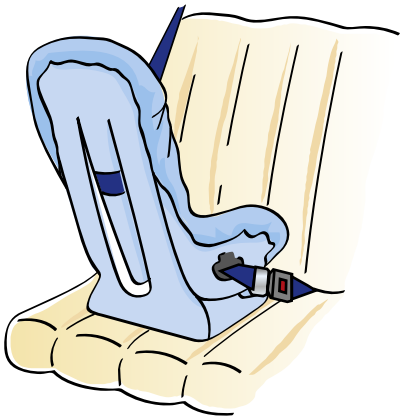

Fig. 11.9 Rear-facing convertible car seat.

Convertible restraints use different types of harness systems: a **five-point harness** that consists of a strap over each shoulder, one on each side of the pelvis, and one between the legs (all five come together at a common buckle), as well as a **padded overhead shield** that uses shoulder straps attached to a shield that is held in place by a crotch strap. With both infant and toddler restraints, it is important not to add extra blankets, head cushions, or padding between the child and the restraint straps that did not come as original equipment because these "add-ons" create spaces of air between the child and the restraint and decrease support for the back, head, and neck. Cars with free-sliding latch plates on the lap or shoulder belt require the use of a metal locking clip to keep the belt in a tight-holding position. The locking clip is threaded onto the belt above the latch plate (Fig. 11.10A). If parents have newer cars with automatic lap and shoulder belts, they need to have additional lap belts installed to properly secure the restraint.

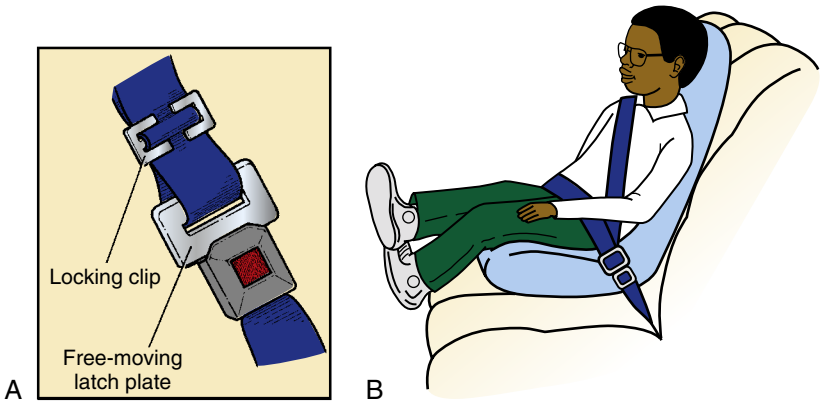

Fig. 11.10 A, Locking clip used with free-sliding lap or shoulder belt to keep the belt in a tight-holding position. B, Automobile booster seat. Note placement of the shoulder strap (away from the neck and face.)

Booster seats are not restraint systems like the convertible devices, because they depend on the vehicle belts to hold the child and booster seat in place. Three booster models have been approved by the National Highway Traffic Safety Administration: the high-back belt-positioning seat (see Fig. 11.10B), which provides head and neck support for the child riding in a vehicle seat without a head rest; the no-back belt-positioning seat, which should be used only if the vehicle seat has a head rest; and a combination seat, which converts from a forward-facing toddler seat to a booster seat. This last model is equipped with a harness for use by toddlers; the harness may be removed and a shoulder-lap belt used when the child outgrows the harness. The belt-positioning booster seats are used for children who are less than 145 cm (4 feet, 9 inches) tall and who weigh 15.9 to 36.3 kg (35 to 80 pounds), depending on the type of booster seat. In general, school-age children should ride in a belt-positioning booster seat until approximately 7 to 8 years old. Note, however, that because children's sizes vary considerably, manufacturer's recommendations should be followed regarding height and weight limitations. A booster seat should be used until the child is able to sit against the back of the seat with feet hanging down and legs bent at the knees. The belt-positioning booster model raises a child higher in the seat, moving the shoulder part of the belt off the neck and the lap portion of the belt off the abdomen onto the pelvis. Children who outgrow the convertible restraint may still be able to ride safely in a booster seat until the midpoint of the head is higher than the vehicle seat back.

Children should use specially designed car restraints until they are 145 cm (4 feet, 9 inches) in height and are between 8 and 12 years old (American Academy of Pediatrics, 2015). **Shoulder-lap safety belts** should be worn low on the hips, snug, and not on the abdominal area. Children should be taught to sit up straight to allow for proper fit. The shoulder belt is used only if it does not cross the child's neck or face.

Shoulder-only automatic belts are designed to protect adults. Children should use the manual shoulder belts in the rear seat. Air bags do not take the place of child safety seats or seat belts and can be lethal to young children. The safest area of the car for children is the back seat. Children who must ride in the passenger side of the front seat with an air bag should be positioned as far back as possible or have the air bag disabled.

For any restraint to be effective, it must be used consistently and properly. Examples of misuse include misrouting the vehicle seat belt through the restraint; failing to use the vehicle seat belt to secure the restraint; failing to use a tether strap; failing to use the restraint's harness system; and incorrectly positioning the child, especially by facing infants forward instead of rearward. To address these issues, nurses must stress correct use of car restraints and rules that ensure compliance (see Family-Centered Care box). Children riding in car safety seats are generally much better behaved than children left unrestrained, which can be a major benefit to parents and should be emphasized as an additional advantage of restraints.

The LATCH (lower anchors and tethers for children) universal child safety seat system was implemented starting in 2002 as a requirement for all new automobiles and child safety seats. This system provides uniform anchorage consisting of two lower anchorages and one upper anchorage in the rear seat of the vehicle (Fig. 11.11). When used appropriately, the top anchor (tether) strap prevents the child from pitching forward in a crash. If the tether strap is not used, up to 90% of the restraint's protection is lost. Instructions for proper installation of the tether strap and permanent bracket are included with the car restraint. New child safety seats will have a hook, buckle, strap, or other connector that attaches to the anchorage. Seat belts will no longer be used to anchor child safety seats to newer vehicles. After Fall 2002, all new cars were required to have the entire LATCH system.

FAMILY-CENTERED CARE

Using Car Safety Restraints

- Read manufacturer's directions and follow them exactly.
- Provide favorite toy, stuffed animal, or snack for child while in car seat.
- Anchor car safety seat securely to car's anchoring system and apply harness snugly to child.[a]
- Do not start the car until everyone is properly restrained.
- Always use the restraint, even for short trips.
- If child begins to climb out or undo the harness, firmly say, "No." It may be necessary to stop the car to reinforce the expected behavior. Use rewards, such as stars or stickers, to encourage cooperation.
- Encourage child to help attach buckles, straps, and shields but always double-check fastenings.
- Decrease boredom on long trips. Keep soft toys in the car for quiet play, talk to child, and point out objects and teach child about them. Stop periodically. If child wishes to sleep, make certain he or she stays in the restraint.
- Insist that others who transport children also follow these safety rules.

[a] A free car seat restraint inspection may be obtained from a SafeKids inspector. Check for local inspection SafeKids clinics or access website for information: http://www.safekids.org.

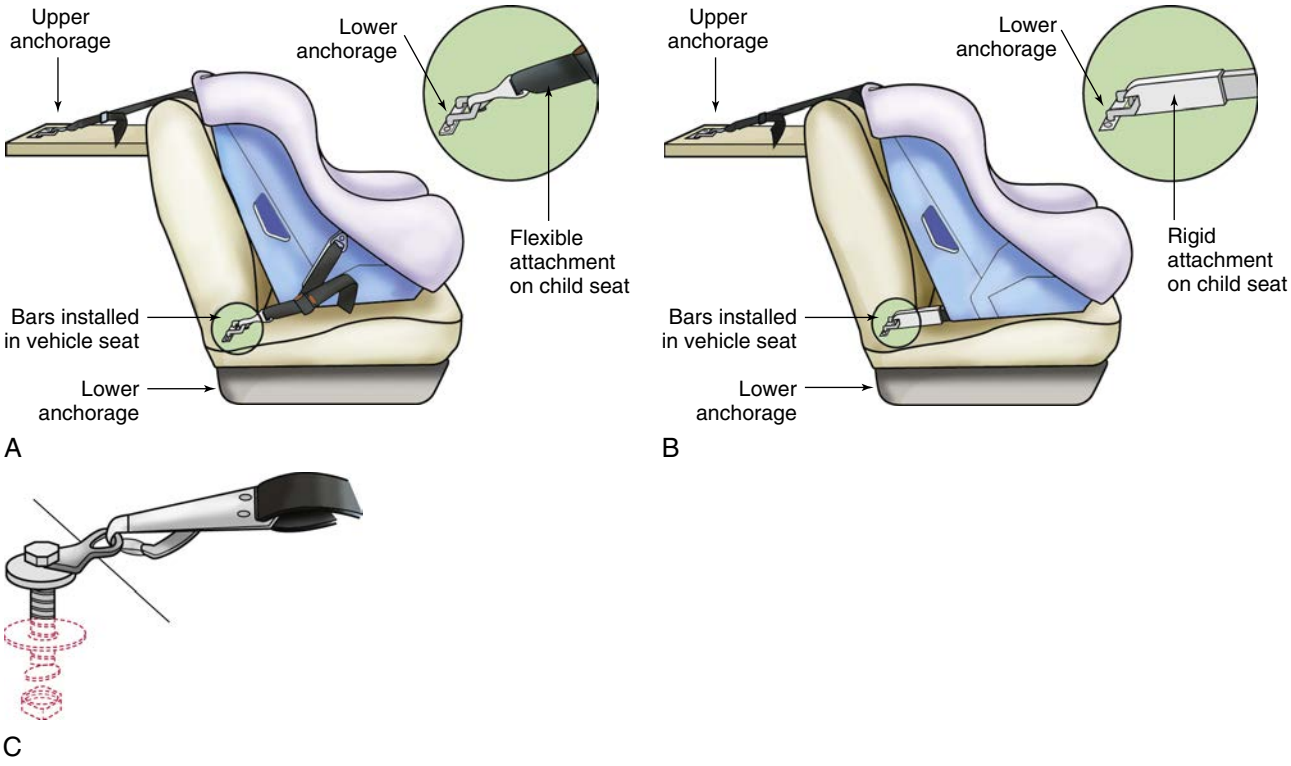

Fig. 11.11 LATCH (lower anchors and tethers for children) universal child safety seat system. **A,** Flexible two-point attachment with top tether. **B,** Rigid two-point attachment with top tether. **C,** Top tether. (Courtesy US Department of Transportation, National Highway Traffic Safety Administration.)

Children with disabilities may require a restraint system that secures them appropriately in the event of a crash. Examples of such devices include car bed restraints for infants who cannot tolerate a semireclining position and specially adapted molded-plastic chairs for children who have spica casts. The EZ-On vest is a special safety harness for larger children with poor trunk control. A HIPPO (Spica Cast) car seat is available for transporting children with spica casts; these are sold only in the United States. Additional safety restraints and a list of distributors are available at the SafetyBeltSafe U.S.A. website.[k] See also Chapter 8 for a discussion of preterm infants being discharged home and car seat evaluation.

Children should not ride in the open back of a truck. The danger of falls can be compounded by another vehicle striking the child or by the truck rolling over. In addition, leaving children unsupervised in a parked vehicle provides an opportunity for a child to release the brake or put the car in gear.

Motor Vehicle–Related Injuries

Toddlers are often involved in pedestrian traffic injuries. Because of their gross motor skills of walking, running, and climbing, and their fine motor skills of opening doors and fence gates, they are likely to be in hazardous areas when unsupervised. Unaware of danger and unable to approximate the speed of cars, they are hit by moving vehicles. Running after a ball, riding a tricycle, and playing behind a parked car are common activities that may result in a vehicular tragedy.

Toddlers playing in driveways or farmyards are at risk of backover injury from vehicles in reverse gear. A precaution when children are playing in driveways is to attach a pole to tricycles with a bright flag that is high enough to see through an automobile's back window. Another safeguard is the use of a device that beeps when the vehicle is driven in reverse to alert children to the moving car, van, tractor, or truck. Many vehicles now include a rearview motion camera so that the driver can see the driveway clearly while backing out. Physical barriers (fences or barricades) limiting children from playing near vehicles help prevent these injuries.

A type of injury that has become more commonplace occurs when children crawl into an open trunk and pull it closed. Asphyxia may occur in such cases; therefore car trunks should not be left open when children are unsupervised. Some cars are equipped with a safety switch that can be activated from inside the trunk to open a closed trunk door.

Another automobile-related hazard for toddlers is overheating (hyperthermia) and subsequent death when left in a vehicle in hot weather (>27°C [80°F]). Small children dissipate heat poorly, and an increase in body temperature can cause death in a few hours. Since 1998, a total of 661 children have died from hyperthermia when left alone in parked cars; in 2014 the number of child deaths was 41, and it is estimated that an average of 37 children die each year from overheating in cars (Null, 2015). It is estimated that with the ambient temperature at 22° to 35.5°C (72° to 96°F), the vehicle interior temperature rises by 10.5° to 11°C (19° to 20°F) each 10 minutes, even with a window cracked (Duzinski, Barczyk, Wheeler, et al., 2014). Approximately 50% of adults who left a child in a car either forgot or were unaware that the child was still in the car (Duzinski et al., 2014). Parents are cautioned against leaving infants alone in a vehicle for *any reason.*

Preventing vehicular injuries involves protecting and educating children about the danger of moving and parked vehicles. Although preschool children are too young to be trusted to always obey, parents should emphasize looking for moving vehicles before crossing the street, recognizing the stop and go colors of traffic lights, and following traffic officers' signals. Physical barriers limiting children from playing near vehicles help prevent these injuries. Most important, what is

[k] http://www.carseat.org.

preached must be practiced. Children learn through imitation, and consistency reinforces learning.

Drowning

The highest rate of drowning occurs in children ages 1 to 4 years; one-third of these children died from drowning (Centers for Disease Control and Prevention, 2016). Drowning deaths in infants occur most commonly in the bathtub and large buckets. With well-developed skills of locomotion, toddlers can reach potentially dangerous areas, such as bathtubs, toilets, buckets, swimming pools, hot tubs, and ponds or lakes. Toddlers' intense drive for exploration and investigation combined with an unawareness of the danger of water and their helplessness in water makes drowning a viable threat. It is also one category of injury that results in death within minutes, diminishing the chance for rescue and survival. Close adult supervision of children when near any source of water is essential; many drownings in this age-group occur when a supervising adult becomes distracted. Teaching swimming and water safety can be helpful, but this cannot be regarded as sufficient protection. Pool fencing, although critical, does not always deter fast-moving children.

Burns

Toddlers' ability to climb, stretch, and reach objects above their heads makes any hot surface a potential source of danger. Children pulling pots with hot liquids, especially oil and grease, on top of themselves is a major source of burns. As a precaution, turn pot handles toward the back of the stove, and electric pots and their cords should be placed out of reach.

Other sources of heat, such as radiators, fireplaces, accessible furnaces, kerosene heaters, and wood-burning stoves, should have guards placed in front of them. Portable electric heaters must be placed in a high area, well out of reach of climbing young children. Hair curling irons and hot curlers may also be easily reached and can burn the hands of curious toddlers.

Hot objects such as candles, incense, cigarettes, pots of tea or coffee, and irons must be placed away from children. Flame burns are one of the most fatal types of burns and commonly occur when children play with matches and accidentally set themselves (and the home) on fire. To prevent flame burns, matches and lighters must be stored safely away from children, and parents need to teach children the dangers of playing with such objects. In addition, all homes should have smoke detectors installed to alert the occupants of a fire. A safety plan for immediate escape is also essential.

Electrical burns represent an immediate danger to children. Young toddlers may explore outlets with conductive articles and wires by mouthing them. Because water is an excellent conductor, the chance for a severe circumoral electrical burn is great. Electrical outlets should have protective guards plugged into them when not in use (Fig. 11.12) or be made inaccessible by having furniture placed in front of them when feasible. Children should not be allowed to play with electrical cords, appliances, or batteries.

Scald burns are the most common type of thermal injury in children. A scalding burn is often caused by high-temperature tap water, which children come in contact with as a result of turning on the hot-water faucet, falling into a bathtub of hot water, pulling hot pots onto themselves, or suffering deliberate abuse. Limiting household water temperatures to less than 49°C (120°F) is highly recommended. At this temperature, it takes 10 minutes of exposure to the water to cause a full-thickness burn. Conversely, water temperatures of 54°C (130°F), the usual setting of most water heaters, expose household members to the risk of full-thickness burns within 30 seconds. Nurses can help prevent such burns by advising parents of this common household danger and recommending that they adjust their water heaters to a safe temperature (see Chapter 31, Burns).

Fig. 11.12 Special plastic caps in electrical sockets prevent young fingers from exploring dangerous areas. (©2011 Photos.com, a division of Getty Images. All rights reserved.)

Sunburns are a year-round concern in certain regions. Children spend a large amount of time outdoors, and their increased mobility makes it difficult to prevent sun exposure. Sunburn can be prevented by applying a sunscreen with a sun protection factor (SPF) of 15 or greater, dressing in protective clothing (wide-brimmed hat, protective cotton clothing with a tight weave), and avoiding sun exposure between 10 AM and 2 PM.

Accidental Poisoning

Toddlers are at the highest risk for accidental poisoning because of the innate curiosity and ability to open "childproof" containers. Mouthing activity continues to be prevalent after 1 year old, and exploring objects by tasting them is part of children's curious investigation. Toddlers' curiosity and inability to understand logical consequences further place them at risk for ingesting harmful substances. Many household products, medications, and plants can be poisonous if swallowed, if they come in contact with the skin or eyes, or if they are inhaled. Although in many instances poisoning does not result in death, it may cause significant morbidity, such as esophageal stricture from lye ingestion. Toddlers can climb most heights, open most drawers or closets, and unscrew most lids. By trial and error, younger children also manage to undo tops of bottles, plastic containers, aerosol cans, and jars, including those with child-resistant lids. Newer forms of drugs, such as transdermal patches and cough-suppressant lozenges, have created additional dangers because they are not packaged with safety caps and the lozenges look like candy.

The major reason for poisoning is improper storage (Fig. 11.13). The guidelines suggested in Chapter 13 apply to children in this age-group as well. However, unlike infants, who are confined to certain heights and unable to unlatch childproof locks, young children manage to find access to many high-level, tight-security places. For this age-group, only a locked cabinet is safe.

Recent attention has focused on the use of over-the-counter medications used for cough and colds as a common cause of accidental poisonous ingestion in toddlers. Ingestion of acetaminophen is also a common cause of morbidity because it is found in many combination over-the-counter products; caregivers may unknowingly administer a dose of acetaminophen in addition to an over-the-counter drug containing the product without knowing the danger.

Fig. 11.13 Children are most likely to ingest substances that are on their level, such as household cleaning agents stored under sinks, rat poison, or plants.

Emergency and preventive measures for accidental poisoning are discussed in Chapter 13. Parents should have ready access to the telephone number for the poison control center (National Poison Center, 800-222-1222) and be prepared to act on the advice of the center.

Falls

Falls are still a hazard to children in this age-group, although by the later part of early childhood, gross and fine motor skills are well developed, decreasing the incidence of falls down stairs and from chairs. However, playground injuries are common. Children need to learn safety at play areas, such as no horseplay on high slides or jungle gyms, sitting on swings, and staying away from moving swings. Passive prevention includes placement of grass, sand, or wood chips under play equipment. Swing seats should be made of plastic, canvas, or rubber and have smooth or rounded edges. Slides should have inclines of no more than 30 degrees and have evenly spaced rungs for climbing.

The climbing and running of the typical toddler are complicated by the child's total disregard and lack of appreciation for danger, immature coordination, and a high center of gravity. Gates must be placed at both ends of stairs. Accessible windows must have window guards, not screens, to prevent falls to the ground below. Falling from furniture is a major cause of injury, with more children in this age-group sustaining head injuries than older children. Doors leading to stairwells or porches must be locked. A convenient type of lock is a sliding bar or hook that can be attached to the door and frame at a level higher than the child can reach. The manufacture and sale of drop-side cribs has been banned by the Consumer Product Safety Commission (2010).

Children can fall from high chairs, shopping carts, carriages, car seats, and strollers if not properly restrained or if balance changes from the placing of heavy objects. Therefore proper restraint and adequate supervision are essential. Children, especially older infants who are mobile, should not be placed in an infant seat on top of a shopping cart because the infant seat may fall off the cart; the safest place for an infant seat is inside the cart's bed.

Aspiration and Suffocation

Suffocation death rates are the leading cause of accidental death among infants less than 1 year of age (Centers for Disease Control and Prevention, 2016). Suffocation deaths usually occur in this age-group by choking on food items; other causes include choking on undersize infant pacifiers, small balls, and latex balloons (Rivara & Grossman, 2016). As noted earlier, the Consumer Pubic Safety Commission issued a ban on the manufacture of drop-side cribs in 2010 because of deaths attributed to infants becoming trapped between the crib mattress and side rail and suffocating.

Usually by 1 year old, children chew well, but they may have difficulty with large pieces of food, such as meat and whole hot dogs, and with hard foods, such as nuts. Young children cannot discard pits from fruit or bones from fish. Gel snacks that are sealed in plastic wrappers can be difficult to manage, and the plastic wrapper can be aspirated. Therefore parents must implement the same precautions as discussed for infants regarding food selection (see Chapter 9).

Play objects for toddlers must still be chosen with an awareness of danger from small parts. Large, sturdy toys without sharp edges or removable parts are safest. Balloons, coins, paper clips, pins, bells, button batteries, pull-tabs on cans, thumbtacks, nails, screws, jewelry (especially pierced earrings), and all types of pins are common household objects that can cause significant harm if swallowed or aspirated. Because of the danger of aspiration, parents should be taught emergency procedures for choking.

Suffocation from causes seen during infancy is less frequent, but old refrigerators, car trunks, ovens, and other large appliances are an ever-present threat. Toddlers can climb inside these appliances and, if they close the door behind them, be trapped inside. Removing all doors before discarding or storing old appliances prevents such tragic deaths. Toddlers may also suffocate when toy boxes with heavy, hinged lids accidentally close on their heads or necks. Advise parents of this danger and encourage them to buy storage chests with lightweight, removable covers.

Bodily Harm

Toddlers are still clumsy in many of their skills and can seriously harm themselves when walking while holding a sharp or pointed object or having food or objects (such as spoons) in their mouths. Preventing such occurrences is the best approach with toddlers. The child should be taught that when walking with a pointed object such as a knife or scissors, the pointed end is held away from the face. Dangerous garden or workshop equipment and all firearms should be stored in locked cabinets. Power lawn mowers and weed eaters are especially dangerous because they can throw rocks and other solid items (projectiles); young children should not be allowed in an area where such tools are in use, nor should they be taken for a ride on a mower or allowed to operate the device.

Toddlers are often unable to understand that all pets are not as safe as their own; because of the toddlers' height, they are often at the eye level of some dogs and may be bitten on the face. It is imperative to teach pet safety to toddlers and keep animals at a safe distance.

Safety education should include respect for firearms and their appropriate use, including nonpowder guns, such as air guns, rifles (BB and pellet), and paintball guns, which can cause serious penetrating injuries. Firearm safety devices (such as trigger locks, gun safes, and personalized locks) should be used to prevent unintentional firing of guns and subsequent injuries or fatalities.

An additional safeguard for young children is the use of safety glass in doors, windows, and tabletops, and the application of decals on glass doors and windows to reduce the likelihood of running through glass. Also, children should not be allowed to run, jump, wrestle, or play ball near glass structures.

ANTICIPATORY GUIDANCE—CARE OF FAMILIES

Understanding toddlers is fundamental to successful childrearing. Nurses, particularly those in ambulatory or child health centers, are in a favorable position to assist parents in facilitating the tasks and meeting the needs of children in this age-group. Prevention yields better results than treatment. Anticipatory guidance is paramount if one wishes to prevent future problems (see Family-Centered Care box).

FAMILY-CENTERED CARE

Guidance During the Toddler Years

12 to 18 Months Old

Prepare parents for expected behavioral changes of toddlers, especially negativism and ritualism.

Assess present feeding habits and encourage gradual weaning from bottle and increased intake of solid foods.

Stress expected feeding changes of physiologic anorexia, food fads and strong taste preferences, need for scheduled routine at mealtimes, inability to sit through an entire meal, and lack of table manners.

Assess sleep patterns at night, particularly habit of a bedtime bottle, which is a major cause of early childhood caries (ECC), and procrastination behaviors that delay hour of sleep.

Prepare parents for potential dangers of the home and motor vehicle environment, particularly motor vehicle injuries, drowning, accidental poisoning, and falling injuries; give appropriate suggestions for childproofing the home.

Discuss need for firm but gentle discipline and ways to deal with negativism and temper tantrums; stress positive benefits of appropriate discipline.

Emphasize importance for both child and parents of brief, periodic separations.

Discuss toys that use developing gross and fine motor, language, cognitive, and social skills.

Emphasize need for dental supervision, types of basic dental hygiene at home, and food habits that predispose to caries; stress importance of supplemental fluoride.

18 to 24 Months Old

Stress importance of peer companionship in play.

Explore need for preparation for additional sibling; stress importance of preparing child for new experiences.

Discuss present discipline methods, their effectiveness, and parents' feelings about child's negativism; stress that negativism is an important aspect of developing self-assertion and independence and is not a sign of spoiling.

Discuss signs of readiness for toilet training; emphasize importance of waiting for physical and psychologic readiness.

Discuss development of fears, such as darkness or loud noises, and of habits, such as security blanket or thumb sucking; stress normalcy of these transient behaviors.

Prepare parents for signs of regression in time of stress.

Assess child's ability to separate easily from parents for brief periods under familiar circumstances.

Allow parents to express their feelings of weariness, frustration, and exasperation; be aware that it is often difficult to love toddlers at times when they are not asleep!

Point out some of the expected changes of the next year, such as longer attention span, somewhat less negativism, and increased concern for pleasing others.

24 to 36 Months Old

Discuss importance of imitation and domestic mimicry and need to include child in activities.

Discuss approaches toward toilet training, particularly realistic expectations and attitude toward accidents.

Stress uniqueness of toddlers' thought processes, especially through their use of language, poor understanding of time, causal relationships in terms of proximity of events, and inability to see events from another's perspective.

Stress that discipline still must be structured and concrete and that relying solely on verbal reasoning and explanation leads to injuries, confusion, and misunderstanding.

Discuss investigation of preschool or daycare center toward completion of second year.

Advice is sometimes not the sole answer. Actual assistance, such as being available for home visiting or telephone consulting, should be part of the nurse's flexible repertoire of interventions. Whether parents are experiencing the dilemmas of rearing a first or a subsequent child, they benefit from sharing their feelings, frustrations, and satisfactions. They need adult companionship, freedom from childrearing responsibilities, and periodic separations from their children. Part of a nurse's responsibility is to provide opportunities for parents to express their feelings and to meet their physical, mental, and spiritual needs.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. The nurse is examining a 4-year-old child and is discussing the child's development with the mother. What findings would require the nurse to intervene? **Select the findings that demonstrate this period of preoperational thought in a 4-year-old child. Select all that apply.**
   - **A.** Child may refuse to eat a food because something previously did not taste good
   - **B.** Child will not sleep in his room because the bed was moved
   - **C.** Child wants to be with friends to affirm their self-image
   - **D.** Child may scold the stairs because they made him fall down
   - **E.** Child may think he is bad because they had bad thoughts
   - **F.** Child has a rich fantasy life

2. Parents of an 18-month-old boy is worried that he is not yet potty trained. The mother states all of her friend's children were potty trained at this age. **In discussing potty training readiness with the parents, select the findings below that indicate the toddler is ready to begin toilet training. Select all that apply.**
   - **A.** Recognizes urge to let go and hold on and is able to communicate this sensation
   - **B.** Has a wet diaper in the morning after sleeping through the night
   - **C.** Demonstrates mastery of dressing and undressing self
   - **D.** Asks parent to have wet or soiled diaper changed
   - **E.** Says 10 or more words

3. When discussing eating practices with a mother of a 3-year-old child, which of the following actions for feeding toddlers would be included in the teaching plan so that adequate amounts of nutrients for growth and development are consumed? **Use an X for the health teaching below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
Avoid placing large food portions on the toddler's plate.			
Allow the child to graze on snacks during the day.			
Insist that the child sit at the table until all persons have completed their meals.			
Allow the child to make certain food choices (within reasonable limits)			
Provide meals at the same time of day as much as possible so that the toddler has a sense of consistency.			
Offer the child oranges or applies each day.			
Make the child eat all of the food provided and use disciplinary actions if the plate is not cleaned.			

4. A common cause of accidental death in children 1 to 19 years old involves motor vehicle crashes. A nurse is preparing to discharge a young infant and is reviewing the use of a care restraint seat with the parents. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**

Placing a young child in a _____1_____ weight-appropriate car restraint seat reduces the risk of death from a motor vehicle accident. This type of care restraint seat should be used _____2_____ to assure child passenger safety.

Options for 1	Options for 2
rear-facing	until the child is 2 years of age
front seat	for as long as possible
forward-facing	until the child can sit in the front seat
booster that is a	until the child weighs 50 pounds

Health Promotion of the Preschooler and Family

Rebecca A. Monroe

http://evolve.elsevier.com/wong/essentials

CONCEPTS

- Development
- Behavior
- Temperament

PROMOTING OPTIMAL GROWTH AND DEVELOPMENT

BIOLOGIC DEVELOPMENT

The rate of physical growth slows and stabilizes during the preschool years. The average weight is 14.5 kg (32 pounds) at 3 years old, 16.7 kg (36.8 pounds) at 4 years old, and 18.7 kg (41.5 pounds) at 5 years old. The average weight gain per year remains approximately 2 to 3 kg (4.5 to 6.5 pounds).

Growth in height also remains steady, with a yearly increase of 6.5 to 9 cm (2.5 to 3.5 inches), and generally occurs by elongation of the legs rather than of the trunk. The average height is 95 cm (37.5 inches) at 3 years old, 103 cm (40.5 inches) at 4 years old, and 110 cm (43.5 inches) at 5 years old.

Physical proportions no longer resemble those of the squat, pot-bellied toddler. Preschoolers are slender but sturdy, graceful, agile, and posturally erect. There is little difference in physical characteristics according to gender except as dictated by such factors as dress and hairstyle.

Most organ systems can adjust to moderate stress and change. During this period, most children are toilet trained. For the most part, motor development consists of increases in strength and refinement of previously learned skills, such as walking, running, and jumping. However, muscle development and bone growth are still far from mature. Excessive activity and overexertion can injure delicate tissues. Good posture, appropriate exercise, and adequate nutrition and rest are essential for optimal development of the musculoskeletal system.

Gross and Fine Motor Skills

Walking, running, climbing, and jumping are well established by 36 months old. Refinement in eye–hand and muscle coordination is evident in several areas. At 3 years old, preschoolers can ride a tricycle, walk on tiptoe, balance on one foot for a few seconds, and do broad jumps. By 4 years old, children can skip and hop proficiently on one foot (Fig. 12.1) and catch a ball reliably. By 5 years old, children can skip on alternate feet and jump rope and begin to skate and swim.

Fine motor development is evident in the child's increasingly skillful manipulation, such as in drawing and dressing. These skills provide readiness for learning and independence for entry into school.

PSYCHOSOCIAL DEVELOPMENT

Developing a Sense of Initiative (Erikson)

After preschoolers have mastered the tasks of the toddler period, they are ready to face the developmental endeavors of the preschool period. Erikson maintained that the chief psychosocial task of this period is acquiring a sense of initiative. Children are in a stage of energetic learning. They play, work, and live to the fullest and feel a real sense of accomplishment and satisfaction in their activities. Conflict arises when children overstep the limits of their ability and inquiry and experience a sense of guilt for not having behaved appropriately. Feelings of guilt, anxiety, and fear may also result from thoughts that differ from expected behavior.

A particularly stressful thought is wishing one's parent dead. As a sense of rivalry or competition develops between the child and same-sex parent, the child may think of ways to get rid of the interfering parent. In most situations, this rivalry is resolved when the child strongly identifies with the same-sex parent and peers during the school years. However, if that parent dies before the identification process is completed, the preschooler may be overwhelmed with feelings of guilt for having wished and therefore "caused" the death. Clarifying for children that wishes cannot and do not make events occur is essential in helping them overcome their guilt and anxiety.

Development of the **superego**, or **conscience**, begins toward the end of the toddler years and is a major task for preschoolers (see Cultural Considerations box). Learning right from wrong and good from bad is the beginning of morality (see the Moral Development section later in the chapter).

COGNITIVE DEVELOPMENT

One of the tasks related to the preschool period is readiness for school and scholastic learning. Many of the thought processes of this period are crucial for achieving such readiness, and it is intentional that

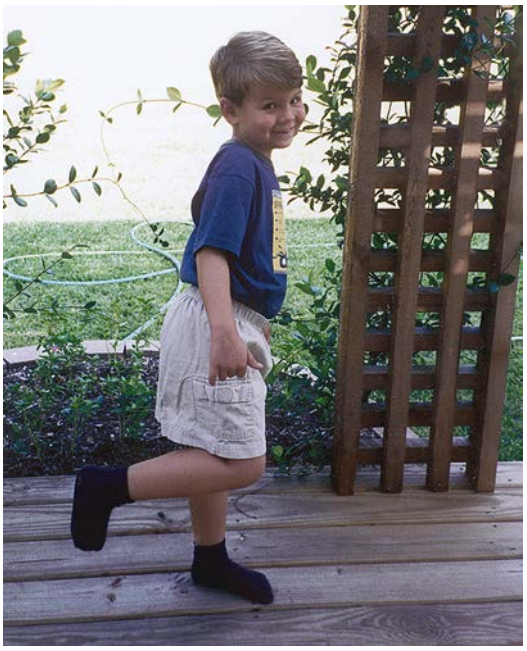

Fig. 12.1 A 4-year-old child has enough balance to stand or hop on one foot.

CULTURAL CONSIDERATIONS

Learning Sociocultural Mores

Developing a conscience implies learning the sociocultural mores of the family's heritage. Depending on the type of attitudes conveyed, children will learn not only appropriate behaviors but also tolerant, biased, or prejudicial values concerning their ethnic, religious, and social background and those of other groups. Much of this influence may remain dormant until they associate with children or adults of a different heritage. Then, depending on the group, they may be accepted or ostracized for their attitudes.

children begin school between 5 and 6 years old rather than at an earlier age.

Preoperational Phase (Piaget)

Piaget's cognitive theory does not include a period specifically for children who are 3 to 5 years old. The preoperational phase covers the age span from 2 to 7 years old and is divided into two stages: the preconceptual phase, ages 2 to 4 years, and the phase of intuitive thought, ages 4 to 7 years. One of the main transitions during these two phases is the shift from totally egocentric thought to social awareness and the ability to consider other viewpoints. However, egocentricity is still evident. (For a review of the characteristics of preoperational thought, see Chapter 11.)

Language continues to develop during the preschool period. Speech remains primarily a vehicle of egocentric communication. Preschoolers assume that everyone thinks as they do and that a brief explanation of their thinking makes the entire thought understood by others. Because of this self-referenced, egocentric verbal communication, it is often necessary to explore and understand young children's thinking through other, nonverbal approaches. For children in this age-group, the most enlightening and effective method is **play**, which becomes children's way of understanding, adjusting to, and working out life's experiences.

Preschoolers increasingly use language without comprehending the meaning of words, particularly concepts of left and right, causality, and time. Children may use the concepts correctly but only in the circumstances in which they have learned them. For example, they may know how to put on shoes by remembering that the buckle is always on the outside of the foot. However, if different shoes have no buckles, they cannot reason which shoe fits which foot. In other words, they do not understand the concept of *left* and *right*.

Superficially, **causality** resembles logical thought. Preschoolers explain a concept as they heard it described by others, but their understanding is limited. An example is the concept of time. Because time is still incompletely understood, the child interprets it according to his or her own frame of reference, such as "*a long time* means until Christmas." Consequently, time is best explained in relationship to an event, such as "Your mother will visit you after you finish your lunch." Avoiding words such as *yesterday, tomorrow, next week,* or *Tuesday* to express when an event is expected to occur and instead associating time with expected daily events help children learn about temporal relationships while increasing their trust in others' predictions.

Preschoolers' thinking is often described as **magical thinking**. Because of their egocentrism and transductive reasoning, they believe that thoughts are all-powerful. Such thinking places them in the vulnerable position of feeling guilty and responsible for bad thoughts, which may coincide with the occurrence of a wished event. Their inability to logically reason the cause and effect of illness or an injury makes it especially difficult for them to understand such events.

NURSING ALERT

Counseling children whose parents are going through a separation or divorce should involve a discussion with the child about his or her role. Because of magical thinking, the child may believe that he or she wished the other parent away. The child should be reassured that this is not the case.

Preschoolers believe in the power of words and accept their meaning literally. An example of this type of thinking is calling children "bad" because they did something wrong. In the preschooler's mind, calling him or her "bad" means that he or she is a bad person; thus it is better to say that the child's actions were bad by saying, for example, "That was a bad thing to do."

MORAL DEVELOPMENT

Preconventional or Premoral Level (Kohlberg)

Young children's development of moral judgment is at the most basic level. They have little, if any, concern about why something is wrong. They behave because of the freedom or restriction that is placed on actions. In the punishment and obedience orientation, children (about 2 to 4 years old) judge whether an action is good or bad depending on whether it results in a reward or a punishment. If children are punished for it, the action is bad. If they are not punished, the action is good, regardless of the meaning of the act. For example, if parents allow hitting, the child will perceive that hitting is good because it is not associated with punishment.

From approximately 4 to 7 years old, children are in the stage of **naive instrumental orientation** in which actions are directed toward satisfying their needs and, less frequently, the needs of others. They have a concrete sense of justice and fairness during this period of development.

SPIRITUAL DEVELOPMENT

Children generally learn about faith and religion from significant others in their environment, usually from parents and their religious beliefs and practices. However, young children's understanding of spirituality

is influenced by their cognitive level. Preschoolers have a concrete concept of a god with physical characteristics, often similar to an imaginary friend. They understand simple Bible stories, memorize short prayers, and imitate the religious practices of their parents without fully understanding the significance of these rituals. Preschoolers benefit from concrete representations of religious practices, such as picture Bible books and small statues, such as those of the Nativity scene.

Development of the conscience is strongly linked to spiritual development. At this age, children are learning right from wrong and behaving correctly to avoid punishment. Wrongdoing provokes feelings of guilt, and preschoolers often misinterpret illness as a punishment for real or imagined transgressions. It is important that children view God as one who bestows unconditional love, rather than as a judge of good or bad behavior. Spirituality and participation in religious traditions often help children cope during illness and hospitalization (Drutchas & Anandarajah, 2014).

DEVELOPMENT OF BODY IMAGE

The preschool years play a significant role in the development of body image. With increasing comprehension of language, preschoolers recognize that individuals have desirable and undesirable appearances. They recognize differences in skin color and racial identity and are vulnerable to learning prejudices and biases. They are aware of the meaning of words such as *pretty* or *ugly,* and they reflect the opinions of others regarding their own appearance. By 5 years old, children compare their size with that of their peers and can become conscious of being large or short, especially if others refer to them as "so big" or "so little" for their age. Research indicates that children as young as preschool age experience body dissatisfaction (Tatangelo, McCabe, Mellor, et al., 2016). Because these are formative years for both boys and girls, parents should instill positive principles on body image, give their children encouraging feedback regarding their appearance, and emphasize the importance of accepting individuals no matter their differences in appearance.

Despite the advances in body image development, preschoolers have poorly defined body boundaries and little knowledge of their internal anatomy. Intrusive experiences are frightening, especially those that disrupt the integrity of the skin, such as injections and surgery. They fear that if their skin is "broken," all of their blood and "insides" can leak out. Therefore bandages are critical to "keep everything from coming out."

DEVELOPMENT OF SEXUALITY

Sexual development during these years is an important phase in a person's overall sexual identity and beliefs. Preschoolers are forming strong attachments to the opposite-sex parent while identifying with the same-sex parent. Sex typing, or the process by which an individual develops the behavior, personality, attitudes, and beliefs appropriate for his or her culture and sex, occurs through several mechanisms during this period. Probably the most powerful mechanisms are childrearing practices and imitations. Gender identification is a result of complex prenatal and postnatal psychologic factors, as well as biologic, social, and genetic factors. Most children are aware of their gender and the expected sets of related behaviors by 1½ to 2½ years of age.

As sexual identity develops beyond gender recognition, modesty may become a concern. Sex-role imitation and dressing up like Mommy or Daddy are important activities. Attitudes and the responses of others to role-playing can condition children to views of themselves and others. For example, comments such as "Boys shouldn't play with dolls" can influence a boy's self-concept of masculinity.

Fig. 12.2 Preschool children enjoy friends and often use nonverbal messages to communicate.

Sexual exploration may be more pronounced now than ever before, particularly in terms of exploring and manipulating the genitalia. Questions about sexual reproduction may come to the forefront in preschoolers' search for understanding (see the Sex Education sections later in this chapter and in Chapter 14).

SOCIAL DEVELOPMENT

During the preschool period, the separation-individuation process is completed. Preschoolers have overcome much of the anxiety associated with strangers and the fear of separation of earlier years. They relate to unfamiliar people easily and tolerate brief separations from their parents with little or no protest. However, they still need parental security, reassurance, guidance, and approval, especially when entering preschool or elementary school. Prolonged separation, such as that imposed by illness and hospitalization, is difficult, but preschoolers respond to anticipatory preparation and concrete explanation. They can cope with changes in daily routine much better than toddlers, although they may develop more imaginary fears. Preschoolers gain security and comfort from familiar objects, such as toys, dolls, or photographs of family members. They are able to work through many of their unresolved fears, fantasies, and anxieties through play, especially if guided with appropriate play objects (e.g., dolls, puppets) that represent family members, health care professionals, and other children.

Language

During the preschool years, language becomes more sophisticated and complex and becomes a major mode of communication and social interaction (Fig. 12.2). Through language, preschool children learn to express feelings of frustration or anger without acting them out. Both cognitive ability and environment—particularly consistent role models—influence vocabulary, speech, and comprehension. Vocabulary increases dramatically, from 300 words at 2 years old to more than 2100 words at the end of 5 years. Sentence structure, grammatical usage, and intelligibility also advance to a more adult level. Language development during these early years predicts school readiness and sets the stage for later success in school (Hammer, Morgan, Farkas, et al., 2017).

Children between 3 and 4 years old form sentences of about three or four words and include only the most essential words to convey a meaning. Such speech is often termed **telegraphic** for its brevity. Three-year-old children ask many questions and use plurals, correct

Fig. 12.3 Most preschoolers can dress themselves but need help with more difficult items of clothing.

pronouns, and the past tense of verbs. They name familiar objects, such as animals, parts of the body, relatives, and friends. They can give and follow simple commands. They talk incessantly regardless of whether anyone is listening or answering them. They enjoy musical or talking toys or dolls and imitate new words proficiently.

From 4 to 5 years old, preschoolers use longer sentences of four or five words and use more words to convey a message, such as prepositions, adjectives, and a variety of verbs. They follow simple directional commands, such as "Put the ball on the chair," but can carry out only one request at a time. They answer questions such as "What do you do when you are hungry?" by describing the appropriate action. The pattern of asking questions is at its peak, and children usually repeat a question until they receive an answer.

Personal-Social Behavior

The pervasive ritualism and negativism of toddlerhood gradually diminish during the preschool years. Although self-assertion is still a major theme, preschoolers demonstrate their sense of autonomy differently. They are able to verbalize their request for independence and perform independently because of their much-refined physical and cognitive development. By 4 or 5 years old, they need little if any assistance with dressing, eating, or toileting (Fig. 12.3). They can also be trusted to obey warnings of danger; however, 3- or 4-year-old children may exceed their boundaries at times.

Preschoolers are also much more sociable and willing to please. They have internalized many of the standards and values of the family and culture. However, by the end of early childhood, they begin to question parental values and compare them with those of their peer group and other authority figures. As a result, they may be less willing to abide by the family's code of conduct. Preschoolers become increasingly aware of their position and role within the family. Although this is a more secure age for experiencing the addition of another sibling,

Fig. 12.4 Preschoolers enjoy play activities that promote motor skills, such as jumping and running. Water play is an exciting activity for preschoolers.

relinquishing the position of only or youngest child is still difficult and requires appropriate preparation (see Chapter 11, Sibling Rivalry).

Play

Various types of play are typical of this period, but preschoolers especially enjoy associative play—group play in similar or identical activities but without rigid organization or rules. Play should provide for physical, social, and mental development.

Play activities for physical growth and refinement of motor skills include jumping, running, and climbing. Tricycles, wagons, gym and sports equipment, sandboxes, wading pools, and activities at water parks can help develop muscles and coordination (Fig. 12.4). Activities such as swimming and skating teach safety as well as muscle development and coordination. Children involved in the work of play do not require expensive toys and gadgets to keep them entertained but often enjoy playing with common household items such as a broom handle or even items adults consider junk (boxes, sticks, rocks, and dirt). The imaginative mind of the preschooler enjoys playing for play's sake.

Manipulative, constructive, creative, and educational toys provide for quiet activities, fine motor development, and self-expression. Easy construction sets, blocks of various sizes and shapes, a counting frame, alphabet or number flash cards, paints, crayons, simple carpentry tools, musical toys, illustrated books, simple sewing or handicraft sets, large puzzles, and clay are suitable toys. Electronic games and computer programs can be valuable in helping children learn basic skills, such as letters and simple words.

Probably the most characteristic and pervasive preschool activity is **imitative**, **imaginative**, and **dramatic play**. Dress-up clothes, dolls, housekeeping toys, dollhouses, play store toys, telephones, farm animals and equipment, village sets, trains, trucks, cars, planes, hand puppets, and medical kits provide hours of self-expression (Fig. 12.5). Probably at no other time is the reproduction of adult behavior so faithful and absorbing as in 4- and 5-year-old children. Toward the end of the preschool period, children are less satisfied with make-believe or pretend objects and enjoy doing the actual activity, such as cooking and carpentry.

Television and other media also have their place in children's play, although each should be only one part of children's total repertoire of social and recreational activities. Time spent watching television

Fig. 12.5 Imaginative and imitative play is typical of preschoolers.

or engaging in digital play may limit time spent in other meaningful activities, such as reading, physical activity, and socialization (American Academy of Pediatrics Council on Communications and Media, 2016). Considering the significant increase in media accessibility through various portable electronic devices and smart phones, parents need to be aware of the potential positive and negative effects of media exposure. Parents and other caregivers should supervise the selection of programs and applications, co-view and discuss programs with their children, play games with their children, limit media exposure to 1 hour per day for children 2 to 5 years of age, and set a good example of media use (American Academy of Pediatrics Council on Communications and Media, 2016). When parents view media with their children and discuss program content, the activity can become interactive and educational.

Play is so much a part of young children's lives that reality and fantasy become blurred. Make-believe is reality during play and only becomes fantasy when the toys are put away or the dress-up clothes are removed. It is no wonder that imaginary playmates are so much a part of this age period. The appearance of imaginary companions usually occurs between 2½ and 3 years old, and for the most part, such playmates are relinquished when the child enters school.

Imaginary companions serve many purposes. They become friends in times of loneliness, they accomplish what the child is still attempting, and they experience what the child wants to forget or remember. It is not unusual for the "friend" to have myriad vices and to be blamed for wrongdoing. Sometimes the child hopes to escape punishment by saying, "My friend George broke the glass." At other times, the child may fantasize that the companion misbehaved and play the role of the parent. This becomes a way of assuming control and authority in a safe situation.

Parents often worry about the imaginary playmates, not realizing how normal and useful they are. Parents need to be reassured that the child's fantasy is a sign of health that helps differentiate make-believe and reality. Parents can acknowledge the presence of the imaginary companion by calling him or her by name and even agreeing to simple requests such as setting an extra place at the table, but they should not allow the child to use the playmate to avoid punishment or responsibility. For example, if the child blames the companion for messing up a room, parents need to state clearly that the child is the only one they see; therefore the child is responsible for cleaning up.

Children also benefit from play that occurs between them and a parent. **Mutual play** fosters development from birth through the school years and provides enriched opportunities for learning. Through mutual play, parents can provide tactile and kinesthetic experiences, maximize verbal and language abilities, and offer praise and encouragement for exploration of the world. In addition, mutual play encourages positive interactions between the parent and child, strengthening their relationship.

Table 12.1 summarizes the major developmental achievements for children 3, 4, and 5 years old.

COPING WITH CONCERNS RELATED TO NORMAL GROWTH AND DEVELOPMENT

Preschool and Kindergarten Experience

Some children are home-schooled, but many children attend some type of early childhood program, usually preschool or a daycare center. Group care has become commonplace with the large number of parents currently employed outside the home (see Chapter 9, Alternate Child Care Arrangements). The effects of early education and stimulation on children have increasingly gained recognition. (For a discussion of the effects of daycare on young children, see Chapter 2, Working Mothers). Because social development widens to include age-mates and other significant adults, preschool provides an excellent vehicle for expanding children's experiences with others. It is also excellent preparation for entrance into elementary school.

In preschool or daycare centers, children are exposed to opportunities for learning group cooperation; adjusting to sociocultural differences; and coping with frustration, dissatisfaction, and anger. If activities are tailored to provide mastery and achievement, children increasingly have feelings of success, self-confidence, and personal competence. Whether structured learning is imposed is less important than the social climate, type of guidance, and attitude toward the children that is fostered by the teacher or leader. With a teacher who is aware of preschoolers' developmental abilities and needs, children will learn from the activity that is provided. Most programs incorporate a daily schedule of quiet play, active outdoor activity, group activities such as games and projects, creative or free play, and snack and rest periods. Preschool is particularly beneficial for children who lack a peer-group experience, such as only children, and for children from impoverished homes.

One of the issues that parents face is their children's readiness for preschool or kindergarten. School readiness is influenced by many factors, including a child's social and emotional maturity, self-regulation, physical development, health status, ability to maintain attention, desire to learn, family environment, and parental support. These elements are as important as a child's academic readiness. Using a developmental screening tool that addresses cognitive (especially language), social, and physical milestones can identify children who may benefit from diagnostic testing and early intervention programs before starting school. Parents play an integral role in their children's school readiness. They can promote school readiness by engaging in the 5 Rs recommended by the American Academy of Pediatrics Early Brain and Child Development (2018) program: **R**ead with their children daily; **R**hyme, play, and cuddle with their children daily; maintain family **R**outines for meals, playtime, and sleeping; **R**eward their children with praise for successes; and establish strong, nurturing **R**elationships with their children.

Nurses and other health care workers can guide parents in selecting enriched social and educational early intervention programs, schools, and child care centers. Careful selection of early childhood education is intrinsic to future learning and development. Licensed and regulated

TABLE 12.1 Growth and Development During the Preschool Years

Physical	Gross Motor	Fine Motor	Language	Socialization	Cognition	Family Relationships
3 Years Old						
Usual weight gain of 1.8-2.7 kg (4-6 pounds) Average weight of 14.5 kg (32 pounds) Usual gain in height of 7.5 cm (3 inches) per year Average height of 95 cm (3 feet, 1½ inches) May have achieved nighttime control of bowel and bladder	Rides tricycle Jumps off bottom step Stands on one foot for few seconds Goes up stairs using alternate feet; may still come down using both feet on step Broad jumps May try to dance, but balance may not be adequate	Builds tower of 9-10 cubes Builds bridge with three cubes Adeptly places small pellets in narrow-necked bottle In drawing, copies circle, imitates cross, names what has been drawn; cannot draw stick figure but may make circle with facial features	Has vocabulary of about 900 words Uses primarily "telegraphic" speech Uses complete sentences of three or four words Talks incessantly regardless of whether anyone is paying attention Repeats sentence of six syllables Asks many questions	Dresses self almost completely if helped with back buttons and told which shoe is right or left Pulls on shoes Has increased attention span Feeds self completely Can prepare simple meals, such as cold cereal and milk Can help set table; can dry dishes without breaking any May have fears, especially of dark and going to bed Knows own gender and gender of others Play is parallel and associative; begins to learn simple games but often follows own rules; begins to share	Is in preconceptual phase Is egocentric in thought and behavior Has beginning understanding of time; uses many time-oriented expressions, talks about past and future as much as about present, pretends to tell time Has improved concept of space, as demonstrated by understanding of prepositions and ability to follow directional command Has beginning ability to view concepts from another perspective	Attempts to please parents and conform to their expectations Is less jealous of younger sibling; may be opportune time for birth of additional sibling Is aware of family relationships and sex-role functions Boys tend to identify more with father or other male figure Has increased ability to separate easily and comfortably from parents for short periods
4 Years Old						
Pulse and respiration rates decrease slightly Growth rate is similar to that of previous year Average weight of 16.5 kg (36.5 pounds) Average height of 103 cm (3 feet, 4½ inches) Length at birth is doubled Maximum potential for development of amblyopia	Skips and hops on one foot Catches ball reliably Throws ball overhead Walks downstairs using alternate footing	Uses scissors successfully to cut out picture following outline Can lace shoes but may not be able to tie bow In drawing, copies square, traces cross and diamond, adds three parts to stick figure	Has vocabulary of 1500 words or more Uses sentences of four or five words Questioning is at peak Tells exaggerated stories Knows simple songs May be mildly profane if associates with older children Obeys prepositional phrases, such as "under," "on top of," "beside," "in back of," or "in front of" Names one or more colors Comprehends analogies, such as "If ice is cold, fire is ___"	Very independent Tends to be selfish and impatient Aggressive physically as well as verbally Takes pride in accomplishments Has mood swings Shows off dramatically, enjoys entertaining others Tells family tales to others with no restraint Still has many fears Play is associative Imaginary playmates common Uses dramatic, imaginative, and imitative devices Sexual exploration and curiosity demonstrated through play, such as being "doctor" or "nurse"	Is in phase of intuitive thought Causality is still related to proximity of events Understands time better, especially in terms of sequence of daily events Unable to conserve matter Judges everything according to one dimension, such as height, width, or order Immediate perceptual clues dominate judgment Is beginning to develop less egocentrism and more social awareness May count correctly but has poor mathematic concept of numbers Obeys because parents have set limits, not because of understanding of right or wrong	Rebels if parents expect too much, such as impeccable table manners Takes aggression and frustration out on parents or siblings Do's and don'ts become important May have rivalry with older or younger siblings; may resent older sibling's privileges and younger sibling's invasion of privacy and possessions May "run away" from home Identifies strongly with parent of opposite sex Is able to run simple errands outside the home

TABLE 12.1 Growth and Development During the Preschool Years—cont'd

Physical	Gross Motor	Fine Motor	Language	Socialization	Cognition	Family Relationships
5 Years Old						
Pulse and respiration rates decrease slightly Average weight of 18.5 kg (41 pounds) Average height of 110 cm (3 feet, 7½ inches) Eruption of permanent dentition may begin Handedness is established (about 90% are right-handed)	Skips and hops on alternate feet Throws and catches ball well Jumps rope Skates with good balance Walks backward with heel to toe Jumps from height of 12 inches and lands on toes Balances on alternate feet with eyes closed	Ties shoelaces Uses scissors, simple tools, or pencil well In drawing, copies diamond and triangle; adds seven to nine parts to stick figure; prints a few letters, numbers, or words, such as first name	Has vocabulary of about 2100 words Uses sentences of six to eight words, with all parts of speech Names coins (e.g., nickel, dime) Names four or more colors Describes drawing or pictures with much comment and enumeration Knows names of days of week, months, and other time-associated words Knows composition of articles, such as "A shoe is made of ____" Can follow three commands in succession	Less rebellious and quarrelsome than at 4 years old More settled and eager to get down to business Not as open and accessible in thoughts and behavior as in earlier years Independent but trustworthy, not fool-hardy; more responsible Has fewer fears; relies on outer authority to control world Eager to do things right and to please; tries to "live by the rules" Has better manners Cares for self totally, occasionally needing supervision in dress or hygiene Not ready for concentrated close work or small print because of slight farsightedness and still unrefined eye–hand coordination Play is associative; tries to follow rules but may cheat to avoid losing	Begins to question what parents think by comparing them with age-mates and other adults May notice prejudice and bias in outside world Is more able to view other's perspective but tolerates differences rather than understanding them May begin to show understanding of conservation of numbers through counting objects regardless of arrangement Uses time-oriented words with increased understanding Cautious about factual information regarding world	Gets along well with parents May seek out parent more often than at 4 years old for reassurance and security, especially when entering school Begins to question parents' thinking and principles Strongly identifies with parent of same sex, especially boys with their fathers Enjoys activities such as sports, cooking, and shopping with parent of same sex

programs are mandated to abide by established standards, which represent minimum requirements and safeguards. Regulation is important to protect children from harm and to promote the conditions essential for a child's healthy development and learning. The National Association for the Education of Young Children serves as the model for optimal care of small children.[a]

Areas for parents to evaluate include the facility's daily program, teacher qualifications, staff-to-student ratio, discipline policy, environmental safety precautions, provision of meals, sanitary conditions, adequate indoor and outdoor space per child, and fee schedule. References from other parents help in evaluating a facility, but personal observation of the facility is recommended. Encourage parents to meet the director and some of the employees at a few facilities to make an informed choice.

Evaluation of the facility's health practices is extremely important. Preschoolers in child care centers have more illnesses than those not in child care centers, especially gastrointestinal tract and respiratory tract infections (Sacri, De Serres, Quach, et al., 2014). Nurses play an important role in infection control. Not only can they advise parents on the evaluation of a facility's sanitary practices, but they can also take an active part in educating staff in measures to minimize transmission of infection (Fig. 12.6).

Children need preparation for the preschool or kindergarten experience. For young children, it represents a change from their usual home environment and prolonged separation from their parents. Before children begin school, parents should present the idea as exciting and pleasurable. Talking to children about activities (such as painting, building with blocks, or enjoying swings and other outdoor equipment) allows children to fantasize about

[a]Information about accreditation criteria and procedures of the National Association for the Education of Young Children Accreditation of Programs for Young Children is available from the National Association for the Education of Young Children, 1313 L St. NW, Suite 500, Washington, DC 20005; 800-424-2460 or 202-232-8777; fax: 202-328-1846; http://www.naeyc.org. These criteria are excellent guidelines for evaluating preschools and daycare centers.

Fig. 12.6 Thorough hand washing is the single most effective method of preventing infection.

the forthcoming event in a positive manner. When the first day of school arrives, parents should behave confidently. Such behavior requires parents to have resolved their own feelings about the experience.

Parents should introduce their child to the teacher and the facility. In some instances, it is helpful for parents to remain with the child for at least part of the first day until the child is comfortable and at ease. Other specific actions that can help reduce separation anxiety include providing the school with detailed information about the child's home environment, such as familiar routines, favorite activities, food preferences, names of siblings or pets, and personal habits. Such information helps the child feel comfortable in the strange surroundings. When schools automatically request this information, the parent has a valuable clue to evaluating the quality of the program because the request represents the staff's awareness of each child's needs. Transitional objects, such as a favorite toy, may also help the child bridge the gap from home to school.

Sex Education

Preschoolers have assimilated a tremendous amount of information during their short lifetimes. Although their thinking may not be mature, they search constantly for explanations and reasons that are logical and reasonable to them. The word "why" seems to supplant the word "no," which was common in toddlerhood. It is only natural that as they learn about "me," they will also want to know "Why me?" and "How me?" Questions such as "Where do babies come from?" are as casual as "What makes it rain?" or "Who is that?" It is the way in which questions about procreation are answered that conditions children, even the youngest, to separate these questions from others about their world.

Two rules govern answering sensitive questions about topics such as sex. The first is to *find out what children know and think.* After investigating the theories children have produced as a reasonable explanation, parents can give correct information but can also help children understand why their explanation is inaccurate. Another reason for ascertaining what the child thinks before offering any information is that the "unasked for" answer may be given. For example, 4-year-old Emma asked her father, "Where did I come from?" Both parents quickly took this inquiry as a clue for offering sex education. After the explanation, Emma exclaimed, "I don't know about all that! All I know is Katie came from New York, and I want to know where I came from."

The second rule for giving information is to *be honest.* It is true that much of the correct information will be forgotten or misunderstood by the preschooler, but the correct information can be restated until the child absorbs and comprehends the facts. Even though the correct anatomic words may be hard to pronounce or even more difficult to remember, they become foundational content for explaining other concepts later on.

Honesty does not imply imparting to children every fact of life or allowing excessive permissiveness in sexual curiosity. When children ask one question, they are looking for one answer. When they are ready, they will ask about the other "unfinished" parts of the story. Sooner or later they will wonder how the "sperm meets the egg" and "how the baby gets out," but during this period it is best to wait until they ask.

Regardless of whether children are given sex education, they will engage in games of sexual curiosity and exploration. At about 3 years old, children are aware of the anatomic differences between the sexes and are curious about how the other works. This is not really "sexual" curiosity because many children are still unaware of the reproductive function of the genitalia. Their curiosity is for the eliminative function of the anatomy. Little boys wonder how girls can urinate without a penis, so they watch girls go to the bathroom. Because they cannot see anything but the stream of urine coming out, they want to observe further. "Doctor play" is often a game invented for such investigation. Little girls are no less curious about boys' anatomy. It is intriguing to closely inspect this "thing" that girls do not have.

One question that parents often have is how to handle such sexual curiosity. A positive approach is to neither condone nor condemn the sexual curiosity but to express that if children have questions, they should ask their parents. Then parents can answer their questions and encourage them to engage in some other activity. In this way, children can be helped to understand that there are ways that their sexual curiosity can be satisfied other than through playing investigative games. This in no way condemns the act but stresses alternate methods to seek solutions and answers. Allowing children unrestricted permissiveness only intensifies their anxiety and concern because exploring and searching usually yield little evidence to satisfy their curiosity.

Many excellent books on sex education are available for preschool children at public libraries. The Sexuality Information and Education Council of the United States[b] and the American Academy of Pediatrics[c] have bibliographies of suggested reading material. Parents should read the books themselves *before* giving or reading them to their children.

Another concern for some parents is **masturbation**, or self-stimulation of the genitalia. This occurs at any age for a variety of reasons and, if not excessive, is normal and healthy. It is most common at 4 years old and during adolescence. For preschoolers, it is a part of sexual curiosity and exploration. If parents are concerned about their child masturbating, it is essential for nurses to investigate the circumstances associated with the activity. Masturbation can be an expression of anxiety, boredom, or stress. In the case of excessive masturbation, it may be associated with physical or sexual abuse, exposure to sexual content, or sexual exposure (Wilkinson & John, 2018). Management of normal childhood masturbation includes parent education and reassurance, redirection of the child to other activities, and discussion with the child regarding appropriate boundaries (Wilkinson & John, 2018). In

[b]Sexuality Information and Education Council of the United States (SIECUS), 1012 14th St. NW, Suite 1108, Washington, DC 20005; 202-265-2405; http://www.siecus.org.

[c]American Academy of Pediatrics, 345 Park Blvd., Itasca, IL 60143; 800-433-9016; http://www.aap.org.

addition, parents should emphasize that masturbation is a private act, thus teaching children socially acceptable behavior.

Fears

A great number and variety of real and imagined fears are present during the preschool years, including fear of the dark, being left alone (especially at bedtime), animals (particularly large dogs), ghosts, sexual matters (castration), and objects or persons associated with pain. The exact cause of children's fears is unknown. Parents often become perplexed about handling the fears because no amount of logical persuasion, coercion, or ridicule will send away the ghosts, bogeymen, monsters, and devils. Inappropriate television viewing by preschoolers may increase fears and anxieties because of the inability to separate reality-based experiences from fantasy portrayed on television.

The concept of **animism**, ascribing lifelike qualities to inanimate objects, helps explain why children fear objects. For example, a child may refuse to use the toilet after watching a television commercial in which the toilet bowl is portrayed as turning into a monster and swallowing a child.

Preschoolers also experience fear of annihilation. Because of poorly defined body boundaries and improved cognitive abilities, young children develop concerns related to loss of body parts. They fear losing body parts with certain medical procedures (such as an intravenous insertion or cast application on a limb) and may see these procedures as real threats to their existence.

The best way to help children overcome their fears is by actively involving them in finding practical methods to deal with the frightening experience. This may be as simple as keeping a night-light on in the child's bedroom for assurance that no monsters lurk in the dark. Exposing children to the feared object in a safe situation also provides a type of conditioning, or **desensitization**. For instance, children who are afraid of dogs should never be forced to approach or touch one, but they may be gradually introduced to the experience by watching other children play with the animal. This type of modeling, with others demonstrating fearlessness, can be effective if the child is allowed to progress at his or her own rate.

Usually by 5 or 6 years old, children relinquish many of their fears. Explaining the developmental sequence of fears and their gradual disappearance may help parents feel more secure in handling preschoolers' fears. Sometimes fears do not subside with simple measures or developmental maturation. When children experience severe fears that disrupt family life, professional help is necessary.

Stress

Although for parents the preschool years generally are less troublesome than toddlerhood, this period of life presents children with many unique stresses. Some, such as fears, are innate and stem from preschoolers' unique understanding of the world. Others are imposed, such as beginning school. Although minimal amounts of stress are beneficial during the early years to help children develop effective coping skills, excessive stress is harmful. Young children are especially vulnerable because of their limited capacity to cope. Expression of frustration, fear, or anxiety is hampered by inadequate expressive language.

To help parents deal with stress in their children's lives, they must be aware of signs of stress and be helped to identify the source. Any number of stressors may be present, such as the birth of a sibling, marital discord, separation and divorce, relocation, or illness.

The best approach to dealing with stress is prevention—monitoring the amount of stress in children's lives so that levels do not exceed their coping ability. In many instances, structuring children's schedules to allow rest and preparing them for change, such as entering school, are sufficient measures.

Aggression

The term **aggression** refers to behavior that attempts to hurt a person or destroy property. Aggression differs from anger, which is a temporary emotional state, but anger may be expressed through aggression. Hyperaggressive behavior in preschoolers is characterized by unprovoked physical attacks on other children and adults, destruction of others' property, frequent intense temper tantrums, extreme impulsivity, disrespect, and noncompliance. Aggression is influenced by a complex set of biologic, sociocultural, and familial variables. Factors that tend to increase aggressive behavior are gender, frustration, modeling, and reinforcement.

Aggressive behavior is exhibited by both boys and girls; however, research indicates that types of aggression differ between genders. Physical aggression peaks in both genders during the second year of life (Dayton & Malone, 2017), but boys exhibit more physical aggression than girls during preschool years (Kung, Li, Golding, et al., 2018). Relational aggression is exhibited at similar rates in boys and girls (Casper & Card, 2017). However, relational aggression has been shown to be the more typical form of aggression in girls, when assessing the proportion of relational aggression to total aggression exhibited (Björkqvist, 2018).

Frustration, or the continual thwarting of self-satisfaction by disapproval, humiliation, punishment, or insults, can lead children to act out against others as a means of release. Especially if they fear their parents, these children will displace their anger on others, particularly peers and other authority figures. This type of aggression often applies to children who are well behaved at home but have a discipline problem at school or are bullies among their playmates.

Modeling, or imitating the behavior of significant others, is a powerful influencing force in preschoolers. Children who see their parents being physically aggressive, through discipline or abuse, are observing behavior they come to know as acceptable and therefore may exhibit this behavior with others (Fleckman, Drury, Taylor, et al., 2016). Another aspect of modeling is the "double standard" for acceptable conduct. For example, in some families, aggression is synonymous with masculinity, and boys are encouraged to defend themselves. Media exposure is also a significant source for modeling at this impressionable age. Studies have found a positive correlation between violent media exposure and aggressive behavior; therefore parents should be encouraged to supervise programming and protect young minds from virtual violence (Hill, 2016). The American Academy of Pediatrics Council on Communications and Media (2016) offers recommendations for healthy media exposure.

Reinforcement can also shape aggressive behavior. Sometimes the reward for aggression is negative (e.g., punishment) yet reinforcing, because it brings attention. For example, children who are ignored by a parent until they hit a sibling or the parent learn that this act garners attention.

When children exhibit extreme behaviors, such as aggression, parents may be concerned about the need for professional help. Generally, the difference between normal and problematic behavior is not the behavior itself but its **quantity** (number of occurrences), **severity** (interference with social or cognitive functioning), **distribution** (different manifestations), **onset** (when behavior started), and **duration** (at least 4 weeks).[d]

[d]Information on child development and behavior can be obtained through the American Academy of Pediatrics, Section on Developmental and Behavioral Pediatrics, http://www.aap.org/en-us/about-the-aap/Sections/Section-on-Developmental-and-Behavioral-Pediatrics/Pages/SODBP.aspx.

Speech Problems

The most critical period for speech development occurs between 2 and 4 years of age. During this period, children are using their rapidly growing vocabulary faster than they can produce the words. Failure to master sensorimotor integrations results in stuttering or stammering as children try to say the word they are already thinking about. This dysfluency in speech pattern is common during language development in children 2 to 5 years old (Nelson, 2013). Stuttering affects boys more frequently than girls, has been shown to have a genetic link, and usually resolves during childhood (Perez & Stoeckle, 2016). The National Institute on Deafness and Other Communication Disorders (2016) encourages parents and caregivers of children who stutter to speak slowly and in a relaxed manner, refrain from interrupting the child's speech, resist completing the child's sentences, and take time to listen attentively.

The best therapy for speech problems is prevention and early detection. Common causes of speech problems include hearing deficits, developmental delay, and physical conditions that impede normal speech production. Referral for further evaluation and treatment may be necessary to prevent a problem from interfering with learning. Anticipatory preparation of parents for expected developmental norms may allay caregiver concerns.

Children pressured into producing sounds ahead of their developmental level may develop **dyslalia** (articulation problems) or revert to using infantile speech. Prevention involves educating parents on the usual achievement of speech production during childhood. The **Denver Articulation Screening Exam** is an excellent tool for assessing articulation skills of a child and for explaining to parents the expected progression of sounds.

PROMOTING OPTIMAL HEALTH DURING THE PRESCHOOL YEARS

Well-child visits during the preschool years are essential to provide guidance for health promotion and disease prevention. Table 12.2 defines the National Quality Forum's pediatric quality indicator for well-child visits.

Nutrition

Healthy nutrition during childhood should include consuming a variety of nutrient-dense foods, ensuring sufficient energy to promote growth and development, and balancing energy intake with energy expenditure to maintain a healthy weight (American Academy of Pediatrics Committee on Nutrition, 2014). Nutritional needs vary depending on age, gender, activity level, and state of health. For moderately active preschoolers, the estimated daily caloric requirement ranges from 1200 to 1400 calories (US Department of Health and Human Services & US Department of Agriculture, 2015). Fluid requirements depend on activity level, climatic conditions, and state of health. Protein requirements increase during childhood, and the recommended intake for preschoolers is 13 to 19 g/day (US Department of Health and Human Services & US Department of Agriculture, 2015).

The American Academy of Pediatrics Committee on Nutrition (2014) recommends that the total fat intake, averaged over several days, be reduced to 30% of total caloric intake for children 2 years old and older. This recommendation is important in the prevention of childhood obesity and the development of other morbidities. Research has shown that the development of obesity, cardiovascular disease, diabetes, and cancer can be influenced by early eating patterns (Macaulay, Donovan, Leask, et al., 2014).

TABLE 12.2 Pediatric Quality Indicator: Well-Child Visits

Well-Child Visits in the Third, Fourth, Fifth, and Sixth Years of Life[a]	
Measure	The percentage of children 3-6 years of age who received one or more well-child visits during the measurement year.
Numerator	At least one well-child visit during the measurement year.
Denominator	Number of children ages 3-6 years as of December 31 of the measurement year who had well-child visits This measure supports regular well-care visits and provides opportunities for nurses to share information with the child's parents or guardian on health and safety issues, nutrition and physical activity, and how to handle illness and emergencies.

[a]Endorsed by the National Quality Forum NQF #1516 and 2019 Core Set of Children's Health Care Quality Measures for Medicaid and CHIP, https://www.medicaid.gov/federal-policy-guidance/downloads/cib112018.pdf.

While limiting fat consumption, it is also important to ensure that diets contain adequate nutrients. This can be done simultaneously, as in the following example regarding calcium. The Recommended Dietary Allowance for calcium for children 1 to 3 years old is 700 mg/day, and the recommendation for children 4 to 8 years old is 1000 mg/day (US Department of Health and Human Services & US Department of Agriculture, 2015). Milk and dairy products are excellent sources of calcium. Low-fat and nonfat milk may be substituted for higher fat choices, so that the quantity of milk may remain the same while limiting fat intake overall.

Excessive consumption of fruit juices and sugar-sweetened beverages has been associated with dental caries, obesity, and adverse cardiometabolic effects (Rader, Mullen, Sterkel, et al., 2014). The American Academy of Pediatrics (2017) recommends limiting the intake of 100% fruit juice to 4 oz/day for children 1 to 3 years of age and 4 to 6 oz/day for children 4 to 6 years of age. Parents should be educated regarding nonnutritious fruit drinks, which usually contain less than 10% fruit juice yet are often advertised as healthy and nutritious. While counseling parents regarding moderation in fruit juice consumption, providers should offer suggestions for more appropriate sources of nutrients, such as ascorbic acid, folate, and potassium. In young children, intake of carbonated beverages that are acidic or that contain high amounts of sugar is also known to contribute to dental caries; large amounts of nonnutritive calories in such beverages may also displace or preclude intake of nutrients necessary for growth.

In 2011 the US Department of Agriculture released a new food guide system called MyPlate (US Department of Agriculture, 2018). This system is comprehensive and provides information for developing a healthy lifestyle at an early age. Parents can develop customizable food plans created specifically for children 2 to 5 years old and access information on growth during the preschool years, healthy eating habits, physical activity, and food safety at http://www.ChooseMyPlate.gov. Parents can use this information to assist their children in making healthy lifestyle choices and to help prevent adverse health

NURSING ALERT

Obesity in young children has increased significantly over the past 3 decades, so efforts to provide a healthy diet and to encourage physical activity should begin early to help children achieve optimal health (Khalsa, Kharofa, Ollberding, et al., 2017). The 5-2-1-0 framework provides a foundation for patient education regarding healthy lifestyle choices. This framework refers to five or more servings of fruits and vegetables per day, 2 hours or less of screen time per day, a minimum of 1 hour of physical activity per day, and 0 servings of sugar-sweetened beverages (Khalsa, Kharofa, Ollberding, et al., 2017).

conditions secondary to poor nutrition. The importance of role modeling by parents cannot be overemphasized in regard to food intake and dietary habits; if parents will not eat a particular food or if their dietary habits are poor, their children are likely to develop the same habits.

Some preschoolers still have food habits that are typical of toddlers, such as food fads and strong taste preferences. When children reach 4 years of age, they seem to enter another period of finicky eating, which is generally characteristic of the more rebellious behavior of children in this age-group. As with toddlers, small portions of each item being served should be offered. The practice of having children remain at the table until the plate is clean should be avoided, because this may contribute to overeating and the development of poor eating habits that contribute to poor health later in life. By 5 years old, children are more agreeable to trying new foods, especially if they are encouraged by an adult who allows them to help with food preparation or experiment with a new taste or different dish (Fig. 12.7). Mealtimes can become battlegrounds if parents expect perfect table manners.[e] Usually 5-year-old children are ready for the social side of eating, but 3- or 4-year-old children still have difficulty sitting quietly through long family meals.

The amount and variety of foods consumed by young children vary greatly from day to day. Consequently, parents sometimes worry about the quantity and quality of food that preschoolers consume. In general, the quality is much more important than the quantity, a fact that should be stressed during nutritional counseling.

One way to reduce parental concern is advising parents to keep a weekly record of everything the child eats. In particular, the parents can measure the amount of food, such as setting aside a half cup of vegetables and serving the child from this premeasured amount, to provide a more accurate estimate of food intake at each meal. When parents look at the food record at the end of the week, they are usually amazed by how much the child has consumed. In general, preschoolers consume only slightly more than toddlers, or about half an adult's portion.

SLEEP AND ACTIVITY

Sleep patterns vary widely, but the average preschooler sleeps about 12 hours a night and infrequently takes daytime naps. Waking during the night is common throughout early childhood. An appropriate and consistent bedtime, nap schedule (as needed), and bedtime routine can help prevent and treat common sleep problems and night wakings experienced by young children (Honaker & Meltzer, 2014).

Fig. 12.7 Preschool-age children enjoy helping adults and are more likely to try new foods if they can assist in the preparation.

Motor activity levels continue to be high and allow preschoolers to explore their environment, begin learning physical games and sports, and interact with others. Sedentary activities, such as television and video or computer games, are increasingly appealing and can become unhealthy substitutes for active play.

Preschoolers' increased gross motor abilities and coordination allow them to engage in many physical activities, if only at a novice level. At this age, children benefit from a variety of both structured and unstructured play activities. Whether young children should begin formalized training in an activity at this early age is controversial. Training programs must consider the child's physical and psychologic immaturity, and readiness to participate in organized sports should be determined individually. The decision to participate should be based on the child's, not the parents', motivation and enjoyment. Another key aspect of organized play for preschoolers is that the activity is developmentally appropriate and occurs in a nonthreatening, fun, and safe environment.

DENTAL HEALTH

By the beginning of the preschool period, the eruption of the deciduous (primary) teeth is complete. Dental care is essential to preserve these temporary teeth and to teach good dental habits (see Chapter 11). Although preschoolers' fine motor control is improved, they still require assistance and supervision with brushing, and flossing should be performed by parents. Professional care and prophylaxis, especially fluoride supplements (if needed), should be continued. The frequency of professional dental care should be based on a child's individual needs and risk assessment, including family oral health habits, dental development, presence or absence of dental disease, special health care needs, and dietary habits (American Academy of Pediatric Dentistry, 2016). For children cared for away from home, parents should be encouraged to monitor the dental care provided by others, including minimizing cariogenic food and beverages in the diet. Trauma to teeth during this period is common, and prompt evaluation by a dentist is warranted if oral trauma occurs. Preservation of the space previously occupied by an avulsed tooth is necessary for proper eruption of the secondary tooth.

[e]Excellent resources for parents related to mealtimes with toddlers and preschoolers include Jana, L. A., & Shu, J. (2012). *Food fights: Winning the nutritional challenges of parenthood armed with insight, humor, and a bottle of ketchup* (2nd ed.). Elk Grove Village, IL: American Academy of Pediatrics; and Satter, E. (1987). *How to get your kid to eat: but not too much.* Boulder, CO: Bull Publishing Co.

INJURY PREVENTION

Because of improved gross and fine motor skills, coordination, and balance, preschoolers are less prone to falls than toddlers. They tend to be less reckless; listen more to parental rules; and are aware of potential dangers, such as hot objects, sharp instruments, and dangerous heights. Putting objects in the mouth as part of exploration has all but ceased, although accidental poisoning is still a danger. Pedestrian motor vehicle injuries increase because of activities such as playing in parking lots, driveways, or streets; riding tricycles, bicycles, and other play vehicles; running after balls; or forgetting safety regulations when crossing streets.

In general, the guidelines suggested for injury prevention in Chapter 11, Table 11.2 apply to children in this age-group as well. However, emphasis is now on education concerning safety and potential hazards in addition to appropriate protection. This period is an excellent time for enforcing the use of safety items, such as bicycle helmets to prevent head trauma; children are less likely to warm to the idea later in life because of peer pressure. Because preschoolers are great imitators, it is essential that parents set a good example by "practicing what they preach." Children quickly observe discrepancies in what they are told to do and what they see others do. Establishing good habits at this time, such as wearing protective equipment, can create long-term safety behaviors.

ANTICIPATORY GUIDANCE—CARE OF FAMILIES

The preschool years present fewer childrearing difficulties than do the earlier years, and this stage of development is facilitated by appropriate anticipatory guidance in the areas already discussed (see Family-Centered Care box). There is a shift in childrearing practices from protection to education. Whereas injury prevention previously focused on safeguarding the immediate environment with less emphasis on reasoning, now the protective guardrails or electrical outlet caps may be replaced by verbal explanations of why danger exists and how to avoid it.

During this period, an emotional transition between parent and child occurs. Although children are still attached to their parents and accept all of their values and beliefs, they are nearing the period of life when they will question previous teachings and prefer the companionship of peers. Entry into school marks a separation from home for parents as well as for children. Parents may need help in adjusting to this change, particularly if one parent has focused his or her daily activities primarily on home responsibilities. All family members must adjust to changes, which is part of the process of growth and development.

FAMILY-CENTERED CARE

Guidance During Preschool Years

3 Years Old

Prepare parents for child's increasing interest in widening relationships.
Encourage enrollment in preschool.
Emphasize importance of setting limits.
Prepare parents to expect exaggerated tension-reduction behaviors, such as need for a "security blanket."
Encourage parents to offer child choices.
Prepare parents to expect marked changes at 3½ years old when child becomes insecure and exhibits emotional extremes.
Prepare parents for normal dysfluency in speech and advise them to avoid focusing on the pattern.
Prepare parents to expect extra demands on their attention as a reflection of child's emotional insecurity and fear of loss of love.
Warn parents that the equilibrium of a 3-year-old child will change to the aggressive, out-of-bounds behavior of a 4-year-old child.
Inform parents to anticipate a more stable appetite with more food selections.
Stress need for protection and education of child to prevent injury (see Chapter 11, Safety Promotion and Injury Prevention).

4 Years Old

Prepare parents for more aggressive behavior, including motor activity and offensive language.
Prepare parents to expect resistance to parental authority.
Explore parental feelings regarding child's behavior.
Suggest some type of respite for primary caregivers, such as placing child in preschool for part of the day.
Prepare parents for child's increasing sexual curiosity.
Emphasize the importance of realistic limit setting on behavior and appropriate disciplinary techniques.
Prepare parents for the highly imaginative 4-year-old child who indulges in "tall tales" (to be differentiated from lies) and develops imaginary playmates.
Prepare parents to expect nightmares or an increase in them.
Provide reassurance that a period of calmness begins at 5 years of age.

5 Years Old

Inform parents to expect a tranquil period at 5 years of age.
Help parents prepare the child for entrance into school environment.
Make certain that immunizations are up to date before child enters school.
Suggest that unemployed parental caregivers consider own activities when children begin school.
Suggest swimming lessons for the child.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. During a routine visit for a girl who is 3 years of age, the nurse notices the child is withdrawn and does not interact even when asked direct questions. The nurse performs a history and assessment and notes the following. **Select all the child's history and assessment findings that would require the nurse to further investigate. Select all that apply.**
   - **A.** Able to say about 100 words.
   - **B.** Unable to form sentences.
   - **C.** Knows familiar objects.
   - **D.** Can follow simple commands.
   - **E.** The mother states the child is unable to express feelings

2. When a 4-year-old is in the hospital for pneumonia, the parent tells the nurse, "I think there is something wrong with him because he is so skinny." The mother asks the nurse to explain what a healthy preschooler of this age should look like. The nurse provides health teaching on specific growth parameters for a preschooler to the parent. **Use an X for the health teaching statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
Most preschoolers weigh between 10 and 12 kilograms.			
The legs of a preschooler, rather than the trunk, increase in length, which may make him look thinner.			
Preschoolers usually keep that pot-bellied appearance until about 6 years old.			
Most preschoolers gain 1/2 to 1 pound per year.			
Most preschoolers do not like to get their weight and height checked.			

3. At the clinic appointment, a 5-year-old's mother wants to discuss several concerns about her daughter with the nurse. The daughter weighs 41 pounds; the mother thinks she is too thin. The mother also states the child questions everything she says and often talks back to her at home. She is worried that the child is becoming a "bad child" and will not follow the conservative views of their family. The child seems withdrawn and quiet, but when the nurse asks a direct question, she readily answers it. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**
   Based on the mother's concern and the child's assessment, the nurse teaches the mother that children this age begin to _____1_____ what parents think and notice _____2_____ in the outside world. They begin to view other's _____3_____ as well as their own.

Options for 1	Options for 2	Options for 3
understand	prejudice	perspective
wonder	change	likeness
question	colors	family
fear	hardship	status
realize	temperature	parents

4. A five- year old boy is being seen by the nurse for a well-child exam. The mother states the child is gaining weight and is concerned. The nurse's assessment findings include the following. **Select all the child's history and assessment findings that would require the nurse to further investigate. Select all that apply.**
   - **A.** A nutrition intake assessment reveals an average daily intake of 1700 calories.
   - **B.** The child sometimes eats less at one meal and then compensates at another meal or with a snack.
   - **C.** The child drinks fruit juice at every meal and often has a juice box between meals.
   - **D.** The nutrition intake assessment reveals 40% of his calories are from fat consumption.
   - **E.** The child does not want to try new foods at home.

Health Problems of Toddlers and Preschoolers

Elizabeth A. Duffy

http://evolve.elsevier.com/wong/essentials

CONCEPTS

- Sleep
- Ingestion of Injurious Agents
- Abuse

SLEEP PROBLEMS

The preschool years are a prime time for sleep disturbances. Children may have trouble going to sleep, wake during the night, have difficulty resuming sleep after waking during the night, have nightmares or sleep terrors, or prolong the inevitable bedtime through elaborate rituals. Such sleep disturbances are typically related to increasing autonomy, negative sleep associations, nighttime fears, inconsistent bedtime routines, and lack of limit setting (Mindell & Williamson, 2018).

Media use can also contribute to sleep disturbances. Research has revealed a direct correlation between sleep problems in preschool children and evening media use, as well as daytime exposure to violent media content (Bathory & Tomopoulus, 2017). Specific sleep problems associated with media use include delayed sleep onset, nightmares, night wakings, daytime tiredness, and difficulty waking in the morning (Bathory & Tomopoulus, 2017). In addition to limiting the duration of television viewing and other media exposure, parents should ensure that all types of media are age appropriate and are not too frightening or overstimulating.

Consequences of inadequate sleep include daytime tiredness, behavior changes, hyperactivity, difficulty concentrating, impaired learning ability, poor control of emotions and impulses, and strain on family relationships (Bathory & Tomopoulus, 2017). Nurses should incorporate assessment of sleep patterns and education about the development of healthy sleep behaviors into every well-child visit. Recommendations for handling a sleep disturbance are offered only after a thorough assessment. Cultural traditions may dictate sleep practices contrary to certain well-accepted professional recommendations. Thus parents may not perceive particular sleep habits as problematic (see Cultural Considerations box).

Interventions differ greatly; for example, **nightmares** and **sleep terrors** require different approaches (Table 13.1). For children who delay going to bed, a recommended approach involves counseling consistent bedtime ritual and emphasizing the normalcy of this type of behavior in young children. Parents should ignore attention-seeking behavior, and the child should not be taken into the parents' bed or allowed to stay up past a reasonable hour. Other measures that may be helpful include keeping a light on in the room, providing transitional objects such as a favorite toy, or leaving a drink of water by the bed.

CULTURAL CONSIDERATIONS

Co-Sleeping

Many experts recommend that infants and children be trained to always sleep in their own crib or bed. However, co-sleeping, or the "family bed" (in which parents allow the children to sleep with them), is an accepted cultural practice among many African American and Asian families (Ward & Doering, 2014; Ward, Robb, & Kanu, 2016). Others who have adopted co-sleeping include parents who believe that co-sleeping promotes parent-child bonding, parents who think that co-sleeping diminishes their child's nighttime fears or other sleep disturbances, and mothers who are breastfeeding. Co-sleeping may be a practical solution to limited numbers of bedrooms or beds in lower-socioeconomic families. Controversy exists regarding the medical, developmental, and social advantages and disadvantages of co-sleeping. Studies have indicated that co-sleeping is associated with sleep problems, such as frequent night wakings, poor sleep quality, and decreased length of sleep (Covington, Armstrong, & Black, 2018). Parents who are considering co-sleeping should fully investigate the potential risks and benefits. Health care providers should be proactive in discussing sleeping arrangements with families at each visit to ensure children's safety and healthy sleep habits.

Helping children slow down before bedtime also reduces resistance to going to bed. One approach is to establish soothing, limited rituals that signal readiness for bed, such as a bath or story. Parents can reinforce the pattern by stating, "After this story, it is bedtime," and consistently carrying through the routine. If anticipated extra stimulation (e.g., having visitors arrive at the children's bedtime) disrupts this routine, it is advisable to settle children in bed beforehand.

INGESTION OF INJURIOUS AGENTS

Since the passage of the Poison Prevention Packaging Act of 1970, which requires that certain potentially hazardous drugs and household products be sold in child-resistant containers, the incidence of poisonings in children has decreased dramatically. However, despite these advances, poisoning remains a significant health concern, with most cases occurring between 1 and 5 years of age (Lee, Connolly, & Calello, 2017). Although pharmaceuticals (such as analgesics, cough and cold

TABLE 13.1 Comparison of Nightmares to Sleep Terrors

Characteristics	Nightmares	Sleep Terrors
Description	A scary dream; takes place during rapid eye movement (REM) sleep and is followed by full waking	A partial arousal from very deep sleep (state IV, non-REM sleep)
Time of distress	After dream is over, not during nightmare itself, child wakes and cries or calls	During terror itself, child screams and thrashes; afterward is calm
Time of occurrence	In second half of night, when dreams are most intense	Usually 1-4 h after falling asleep, when non-REM sleep is deepest
Child's behavior	Crying in younger children, fright in all; behaviors persistent even though child is awake	Initially may sit up, thrash, or run in bizarre manner, with eyes bulging, heart racing, and profuse perspiring; may cry, scream, talk, or moan; shows apparent fright, anger, or obvious confusion, which disappears when child is fully awake
Responsiveness to others	Is aware of and reassured by another's presence	Is not very aware of another's presence, is not comforted, and may push person away and scream and thrash more if held or restrained
Return to sleep	May be considerably delayed because of persistent fear	Usually rapid; often difficult to keep child awake
Description of dream interventions	Yes (if old enough) Accept dream as real fear Sit with child; offer comfort, assurance, and sense of protection Avoid forcing child back to his or her own bed Consider professional counseling for recurrent nightmares unresponsive to above approaches	No memory of dream or of yelling or thrashing Observe child for a few minutes, without interfering, until child becomes calm or wakes fully Intervene only if necessary to protect child from injury Guide child back to bed if needed Stress to parents that sleep terrors are a normal, common phenomenon in preschoolers that requires relatively little intervention

Modified from Haupt, M., Sheldon, S. H., & Loghmanee, D. (2013). Just a scary dream? A brief review of sleep terrors, nightmares, and rapid eye movement sleep behavior disorder. *Pediatric Annals, 42*(10), 211–216.

preparations, topical preparations, antibiotics, vitamins, gastrointestinal preparations, hormones, and antihistamines) are frequently the agents of poisonings, a variety of other substances can also poison children. The most frequently ingested poisons include the following (Lee et al., 2017)[a]

- Cosmetics and personal care products (deodorants, makeup, perfume, cologne, mouthwash)
- Medications (acetaminophen, acetylsalicylic acid, ibuprofen, opioid analgesics, benzodiazapines, amphetamines)
- Household cleaning products (bleaches, laundry pods, disinfectants)
- Foreign bodies, toys, and miscellaneous substances (desiccants, thermometers, bubble-blowing solutions)

Many poisonings reflect the ready accessibility of the products in the home, which is where more than 90% of poisonings occur (Lee et al., 2017). In a recent review of the American Association of Poison Control Centers, more than 60% of exposures to plants occurred in children 5 years old and younger (Bronstein, Spyker, Cantilena, et al., 2012; Petersen, 2011). Box 13.1 lists common poisonous and nonpoisonous plants.

The developmental characteristics of young children predispose them to poisoning by ingestion. Infants and toddlers explore their environment through oral experimentation. Because their sense of taste is not discriminating at this age, they ingest many unpalatable substances. In addition, toddlers and preschoolers are developing autonomy and initiative, which increases their curiosity and noncompliant behavior. Imitation is also a powerful motivator, especially when combined with a lack of awareness of danger.

This section is primarily concerned with the immediate emergency treatment of ingestion of injurious agents. Box 13.2 summarizes

[a]The most common substances in each category are in parentheses. Substances ingested are not necessarily the most toxic but often are readily available.

BOX 13.1 Poisonous and Nonpoisonous Plants

Poisonous Plants (Toxic Parts)

Apple (leaves, seeds)
Apricot (leaves, stem, seed pits)
Azalea (all parts)
Buttercup (all parts)
Castor oil plant (bean or seeds—extremely toxic)
Cherry (wild or cultivated) (twigs, seeds, foliage)
Daffodil (bulbs)
Dumb cane (dieffenbachia) (all parts)
Elephant ear (all parts)
Foxglove (leaves, seeds, flowers)
Holly (berries)
Hyacinth (bulbs)
Ivy (leaves)
Mistletoe[a] (berries, leaves)
Oak tree (acorn, foliage)
Philodendron (all parts)
Plum (pit)
Poinsettia[b] (leaves)
Poison ivy, poison oak (leaves, stems, sap, fruit, smoke from burning plants)
Pokeweed, pokeberry (roots, berries, leaves [when eaten raw])
Pothos (all parts)
Rhubarb (leaves)
Tulip (bulbs)
Wisteria (seeds, pods)
Yew (all parts)

Nonpoisonous Plants

African violet
Aluminum plant
Asparagus fern
Begonia
Boston fern
Christmas cactus
Coleus
Gardenia
Grape ivy
Jade plant
Piggyback plant
Poinsettia[b]
Prayer plant
Rose
Rubber tree
Snake plant
Spider plant
Swedish ivy
Wax plant
Weeping fig
Zebra plant

[a]Eating one or two berries or leaves is probably nontoxic.
[b]Mildly toxic if ingested in massive quantities.

BOX 13.2 Selected Poisonings in Children

Corrosives (Strong Acids or Alkalis)

Drain, toilet, and oven cleaners
Electric dishwasher detergent (liquid because of higher pH, is more hazardous than granular)
Mildew remover
Batteries
Clinitest tablets
Denture cleaners
Bleach

Clinical Manifestations

Severe burning pain in the mouth, throat, and stomach
White, swollen mucous membranes; edema of the lips, tongue, and pharynx (respiratory obstruction)
Coughing, hemoptysis
Drooling and inability to clear secretions
Signs of shock
Anxiety and agitation

Comments

Household bleach is a frequently ingested corrosive but rarely causes serious damage.
Liquid corrosives are easily ingested and cause more damage than granular or solid preparations. Liquids may also be aspirated, causing upper airway injury.
Solid products tend to stick to and burn tissues, causing localized damage.

Treatment

Inducing emesis is contraindicated (vomiting redamages the mucosa).
Contact the PCC immediately. If the PCC or medical advice and treatment not immediately available, it may be appropriate to dilute corrosive with water or milk (usually ≤120 ml [4 oz]).
Do not neutralize. Neutralization can cause an exothermic reaction (which produces heat and causes increased symptoms or produces a thermal burn in addition to a chemical burn).
Maintain patent airway as needed.
Administer analgesics.
Give oral fluids when tolerated.
Esophageal stricture may require repeated dilations or surgery.

Hydrocarbons

Gasoline
Kerosene
Lamp oil
Mineral seal oil (found in furniture polish)
Lighter fluid
Turpentine
Paint thinner and remover (some types)

Clinical Manifestations

Gagging, choking, and coughing
Burning throat and stomach
Nausea
Vomiting
Alterations in sensorium, such as lethargy
Weakness
Respiratory symptoms of pulmonary involvement
- Tachypnea
- Cyanosis
- Retractions
- Grunting

Comments

Immediate danger is aspiration (even small amounts can cause bronchitis and chemical pneumonia).
Gasoline, kerosene, lighter fluid, mineral seal oil, and turpentine cause severe pneumonia.

Treatment

Inducing emesis is generally contraindicated.
Gastric decontamination and emptying are questionable even when the hydrocarbon contains a heavy metal or pesticide; if gastric lavage must be performed, a cuffed endotracheal tube should be in place before lavage because of a high risk of aspiration.
Symptomatic treatment of chemical pneumonia includes high humidity, oxygen, hydration, and acetaminophen.

Acetaminophen

Clinical Manifestations

Occurs in four stages post ingestion:
1. 0 to 24 hours
   - Nausea
   - Vomiting
   - Sweating
   - Pallor
2. 24 to 72 hours
   - Patient improves
   - May have right upper quadrant abdominal pain
3. 72 to 96 hours
   - Pain in right upper quadrant
   - Jaundice
   - Vomiting
   - Confusion
   - Stupor
   - Coagulation abnormalities
   - Sometimes renal failure, pancreatitis
4. More than 5 days
   - Resolution of hepatoxicity or progress to multiple organ failure
   - May be fatal

Comments

This is the most common accidental drug poisoning in children.
Toxicity occurs from acute ingestion. Toxic dose is 150 mg/kg or greater in children.

Treatment

Antidote *N*-acetylcysteine (Mucomyst) is equally effective given intravenously or orally. When given orally may first be diluted in fruit juice or soda because of the antidote's offensive odor. An antiemetic may be given if vomiting occurs.
Given as 1 loading dose followed by 17 additional doses in different dosages. IV administration is given as a continuous infusion.

Aspirin (Acetylsalicylic Acid)

Clinical Manifestations

Acute poisoning (early symptoms):
- Nausea
- Hyperventilation
- Vomiting
- Tinnitus

Acute poisoning (later symptoms):
- Hyperactivity
- Fever

Continued

BOX 13.2 Selected Poisonings in Children—cont'd

- Confusion
- Seizures
- Renal failure
- Respiratory failure

Chronic poisoning:

- Same as listed above but subtle onset and nonspecific symptoms (often mistaken for viral illness)
- Bleeding tendencies

Comments

May be caused by acute ingestion (severe toxicity occurs with 300 to 500 mg/kg).
May be caused by chronic ingestion (i.e., >100 mg/kg/day for ≥2 days); can be more serious than acute ingestion.
Time to peak serum salicylate level can vary with enteric aspirin or the presence of concretions (bezoars).

Treatment

Hospitalization is necessary for severe toxicity.
Activated charcoal is given as soon as possible (unless contraindicated by altered mental status). If bowel sounds are present, may be repeated every 4 hours until charcoal appears in the stool.
Lavage will not remove concretions of ASA.
Sodium bicarbonate transfusions are used to correct metabolic acidosis, and urinary alkalinization may be effective in enhancing elimination; hypokalemia may interfere with achieving urinary alkalinization.
Be aware of the risk for fluid overload and pulmonary edema.
Use external cooling for hyperpyrexia.
Administer anticonvulsants if seizures present.
Provide oxygen and ventilation for respiratory depression.
Administer vitamin K for bleeding.
In severe cases, hemodialysis (not peritoneal dialysis) is used.

Iron

Mineral supplement or vitamin containing iron

Clinical Manifestations

Occurs in five stages (may have significant variation in symptoms and their progression):

1. Within 6 hours (if child does not develop gastrointestinal symptoms in 6 hours, toxicity is unlikely)
   - Vomiting
   - Hematemesis
   - Diarrhea
   - Hematochezia (bloody stools)
   - Abdominal pain
   - Severe toxicity may have tachypnea, tachycardia, hypotension, coma
2. Latency period—up to 24 hours of apparent improvement
3. 12 to 24 hours
   - Metabolic acidosis
   - Fever
   - Hyperglycemia
   - Bleeding
   - Seizures
   - Shock
   - Death (may occur)
4. 2 to 5 days
   - Jaundice
   - Liver failure
   - Hypoglycemia
   - Coma
5. 2 to 5 weeks
   - Pyloric stenosis or duodenal obstruction may occur secondary to scarring.

Comments

Factors related to frequency of iron poisoning include:

- Widespread availability
- Packaging of large quantities in individual containers
- Lack of parental awareness of iron toxicity
- Resemblance of iron tablets to candy (e.g., M&Ms)

Toxic dose is based on the amount of elemental iron ingested. Common preparations include ferrous sulfate (20% elemental iron), ferrous gluconate (12%), and ferrous fumarate (33%). Ingestions of 20 to 60 mg/kg are considered mildly to moderately toxic, and >60 mg/kg is severely toxic and may be fatal.

Treatment

Hospitalization is required when more than mild gastroenteritis is present.
Use whole bowel irrigation if radiopaque tablets are visible on abdominal x-ray; may need to be given via nasogastric tube.
Emesis empties the stomach more effectively than lavage.
Activated charcoal does not absorb iron.
Chelation therapy with deferoxamine should be used in severe intoxication (may turn urine red to orange).
If IV deferoxamine is given too rapidly, hypotension, facial flushing, rash, urticaria, tachycardia, and shock may occur; stop the infusion, maintain the IV line with normal saline, and notify the practitioner immediately.

Plants

Poisonous plants listed in Box 13.1

Clinical Manifestations

Depends on type of plant ingested.
May cause local irritation of oropharynx and entire gastrointestinal tract.
May cause respiratory, renal, and central nervous system symptoms.
Topical contact with plants can cause dermatitis.

Comments

Plants are some of the most frequently ingested substances.
They rarely cause serious problems, although some plant ingestions can be fatal.
Plants can also cause choking and allergic reactions.

Treatment

Wash from skin or eyes.
Provide supportive care as needed.

ASA, Acetylsalicylic acid; *IV,* intravenous; *PCC,* poison control center.

specific management of corrosive, hydrocarbon, acetaminophen, salicylate, iron, and plant poisoning. Because of the importance of lead poisoning among young children, ingestion of lead is discussed separately. Appropriate suggestions for poison prevention are discussed later in the chapter.

PRINCIPLES OF EMERGENCY TREATMENT

A poisoning may or may not require emergency intervention, but in every instance medical evaluation is necessary to initiate appropriate action. Advise parents to call the **poison control center (PCC)** *before* initiating any intervention. Parents should post the

local PCC telephone number (usually listed in the front of the telephone directory) near each phone in the house[b] (see Emergency Treatment box).

EMERGENCY TREATMENT

Poisoning

1. Assess the victim:
   - Initiate cardiorespiratory support if needed (circulation, airway, breathing).
   - Assess mental status; reevaluate routinely.
   - Take vital signs; reevaluate routinely.
   - Evaluate for possibility of concomitant trauma or illness; treat prior to initiation of gastric decontamination.
2. Terminate exposure:
   - Empty mouth of pills, plant parts, or other material.
   - Flush any body surface (including the eyes) exposed to a toxin with large amounts of moderately warm water or saline.
   - Remove contaminated clothes, including socks and shoes, and jewelry. Ensure protection of rescuers and health care workers from exposure.
   - Bring victim of an inhalation poisoning into fresh air.
3. Identify the poison:
   - Question the victim and witnesses.
   - Observe the circumstances surrounding the poisoning (e.g., location, activity before ingestion).
   - Look for environmental clues (empty container, nearby spill, odor on breath) and save all evidence of poison (container, vomitus, urine).
   - Be alert to signs and symptoms of potential poisoning in the absence of other evidence, including symptoms of ocular or dermal exposure.
   - Call the poison control center (PCC) or other competent emergency facility for immediate advice regarding treatment.
4. Prevent poison absorption:
   - Place the child in a side-lying, sitting, or kneeling position with the head below the chest to prevent aspiration.

Based on the initial telephone assessment, the PCC counsels the parents to begin treatment at home or to take the child to an emergency facility. When a call is taken, the name and telephone number of the caller are recorded to reestablish contact if the connection is interrupted. Because most poisonings are managed in the home, expert advice is essential in minimizing adverse effects. When the exact quantity or type of ingested toxin is not known, admission to a health care facility with pediatric emergency treatment services for laboratory evaluation and surveillance during the time after ingestion is critical.

Assessment

The first and most important principle in dealing with a poisoning is to treat the child first, not the poison. This requires an immediate concern for life support. Vital signs are taken, mental status is assessed, and respiratory or circulatory support is instituted as needed. The child's condition is routinely reevaluated. Because shock is a complication of several types of household poisons, particularly corrosives, measures to reduce the effects of shock are important, beginning with the CABs (circulation, airway, and breathing support measures) of resuscitation. Establishing and maintaining vascular access for rapid intravascular volume expansion is vital in the treatment of pediatric shock.

The emergency department nurse's responsibility is to be prepared for immediate intervention with all of the necessary equipment. Because time and speed are critical factors in recovery from serious poisonings, anticipating potential problems and complications may mean the difference between life and death.

Gastric Decontamination

Although pediatric poison ingestions are common, they rarely result in significant morbidity or mortality (Mowry, Spyker, Brooks, et al., 2016). Consider using gastrointestinal decontamination (GID) only after careful evaluation of the potential toxicity of the poison and the risks versus benefits. GID (such as ipecac, activated charcoal, and gastric lavage) is not routinely recommended for most childhood poisonings. Because of continuing controversy regarding the use of these methods, treat each toxic ingestion individually (Mowry et al., 2016). Specific antidotes may be administered for certain poisonings.

Syrup of ipecac, an emetic that exerts its action through irritation of the gastric mucosa and by stimulation of the vomiting center, is no longer recommended for routine treatment of poison ingestion (Albertson, Owen, Sutter, et al., 2011; Theurer & Bhavsar, 2013).

NURSING ALERT

Syrup of ipecac is not recommended for routine poison treatment intervention in the home (Albertson et al., 2011; Theurer & Bhavsar, 2013).

A common method of GID is the use of **activated charcoal**, an odorless, tasteless, fine black powder that absorbs many compounds, creating a stable complex (Frithsen & Simpson, 2010). The use of activated charcoal has become less common and was used in only 1.1% of pediatric toxic exposures in 2015 (Mowry et al., 2016). Activated charcoal may be considered in the following situations:

- Child may have ingested large amounts of carbamazepine, dapsone, phenobarbital, quinine, or theophylline.
- Time to activated charcoal administration is within 1 hour after the poison ingestion.
- Child has an intact or protected airway.

Activated charcoal is mixed with water or a saline cathartic to form a slurry. Slurries are neither gritty nor distasteful but resemble black mud. To increase the child's acceptance of activated charcoal, the nurse should mix it with small amounts of chocolate milk, fruit syrup, or cola drinks and serve it through a straw in an opaque container with a cover (e.g., a disposable coffee cup and lid) or an ordinary cup covered with aluminum foil or placed inside a small paper bag. Super-activated charcoal has three to four times the surface area and can absorb greater quantities of poison (Olson, 2010). For small children, a nasogastric tube may be required to administer activated charcoal. Potential complications from the use of activated charcoal include vomiting and potential aspiration, constipation, and intestinal obstruction (in multiple doses) (Albertson et al., 2011).

If the child is admitted to an emergency facility, **gastric lavage** may be performed to empty the stomach of the toxic agent; however, this procedure can be associated with serious complications (gastrointestinal perforation, hypoxia, aspiration). There is no conclusive evidence that gastric lavage decreases morbidity, and it is no longer recommended to be performed routinely, if at all (Albertson et al., 2011; Benson, Hoppu, Troutman, et al., 2013). In addition, gastric lavage may be of little benefit if used later than 1 hour after ingestion (Albertson et al., 2011; McGregor, Parkar, & Rao, 2009). Conditions that may be appropriate for the use of gastric lavage include presentation within 1 hour of ingestion of a toxin, ingestion in a patient who has decreased gastrointestinal motility, the ingestion of a toxic amount of sustained-release medication, and a large or life-threatening amount

[b]Also available by calling 800-222-1222 or online at American Association of Poison Control Centers, http://www.aapcc.org.

of poison (Albertson et al., 2011). When gastric lavage is used, the patient requires a protected airway, possible sedation, and the largest diameter tube that can be inserted to facilitate passage of gastric contents. Gastric lavage should only be performed by medical personnel with proper training and expertise (Benson et al., 2013).

In a minority of poisonings, specific **antidotes** are available to counteract the poison. They are highly effective and should be available in all emergency facilities. The supply of antidotes should be checked routinely and replaced as used or according to expiration dates. Antidotes available to treat toxin ingestion include *N*-acetylcysteine for acetaminophen poisoning, oxygen for carbon monoxide inhalation, naloxone for opioid overdose, flumazenil (Romazicon) for benzodiazepine (diazepam [Valium], midazolam [Versed]) overdose, digoxin immune fab (Digibind) for digoxin toxicity, amyl nitrate for cyanide, and antivenin for certain poisonous bites.

Prevention of Recurrence

The ultimate objective is to prevent poisonings from occurring or recurring. Home safety education improves poison prevention practices (Lee et al., 2017). Research supports the effectiveness of parent education on preventing unintentional injuries (Patel, Magnusen, & Sandell, 2017). One effective counseling method is first to discuss the difficulties of constantly watching and safeguarding young children (see Family-Centered Care box). In this way, the challenging task of raising children can lead to a discussion of injury prevention as part of the parental role. This approach also incorporates contributory causes for the incident, such as inadequate support systems; marital discord; discipline techniques (especially use of physical punishment); and any disruption in the family or family activities, such as vacations, moves, visitors, illnesses, or births. A visit to the home, especially after repeat poisonings, is recommended as part of the follow-up care to assess hazards, including family factors, and to evaluate appropriate injury-proofing measures. One method of identifying risk areas is to ask specific questions or to have the parent complete a questionnaire designed to isolate factors that predispose children to poisoning. Another approach is to encourage parents to bend down to the child's eye level and survey the home environment for potential hazards. Have the parents try to open cabinets and reach shelves to access poisons.

FAMILY-CENTERED CARE

Poisoning

A poisoning is more than a physical emergency for the child; it also usually represents an emotional crisis for the parents, particularly in terms of guilt, self-reproach, and insecurity in the parenting role. The emergency department is no place to admonish the family for negligence, lack of appropriate supervision, or failure to injury-proof the home. Rather, it is a time to calm and support the child and parents while unaccusingly exploring the circumstances of the injury. If the nurse prematurely attempts to discuss ways of preventing such an incident from recurring, the parents' anxiety will block out any suggestions or offered guidance. It is preferable for the nurse to delay the discussion until the child's condition is stabilized or, if the child is discharged immediately after emergency treatment, to make a public health referral or send a packet of information.

Passive measures (those that do not require active participation) have been the most successful in preventing poisoning and include using child-resistant closures and limiting the number of tablets in one container. However, these measures alone are not sufficient to prevent poisoning, because most toxic agents in the home do not have safety closures. **Active measures** (those that require participation) are essential. The Nursing Care Guidelines box lists the guidelines for preventing the occurrence or recurrence of a poisoning.

NURSING CARE GUIDELINES

Poison Prevention

- Assess possible contributing factors in occurrence of injury, such as discipline, parent-child relationship, developmental ability, environmental factors, and behavior problems.
- Institute anticipatory guidance for possible future injuries based on child's age and developmental level.
- Initiate referral to appropriate agency to evaluate home environment and need for injury-proofing measures.
- Provide assistance with environmental manipulation, such as lead removal, when necessary.
- Educate parents regarding safe storage of toxic substances.
- Advise parents to take drugs out of sight of children.
- Teach children the hazards of ingesting nonfood items.
- Advise parents against using plants for teas or medicine.
- Discuss problems of discipline and children's noncompliance and offer strategies for effective discipline.
- Instruct parents regarding correct administration of drugs for therapeutic purposes and to discontinue drug if there is evidence of mild toxicity.
- Advise parents to contact the poison control center (PCC; 800-222-1222) or practitioner immediately when a poisoning occurs.
- Tell them to post the number of the regional PCC with an emergency phone list by the telephone.
- Include by the telephone the home address with nearest cross street in case an ambulance is needed. (In an emergency, family members may not remember the house address, and babysitters may not be aware of the information.)

HEAVY METAL POISONING

Heavy metal poisoning can occur from the ingestion of a variety of substances, the most common being lead. Other sources that are important in terms of children are iron and mercury. **Mercury toxicity**, a rare form of heavy metal poisoning, has occurred in children from a variety of sources, such as predator fish (king mackerel, shark, swordfish, tilefish), broken thermometers or thermostats, broken fluorescent light bulbs, disk batteries, topical medications, gas regulators, cathartics, and interior latex house paint (Carman, Tutkun, Yilmaz, et al., 2013). Elemental mercury (also called *metallic mercury* or *quicksilver*) is nontoxic if ingested and if the gastrointestinal tract is healthy (e.g., has no fistulas). However, mercury is volatile at room temperature and enters the bloodstream after it is inhaled. Chronic exposure produces symptoms ranging from nonspecific (e.g., anorexia, weight loss, memory loss, insomnia, gingivitis, diarrhea) to severe (e.g., tremors, extreme behavior changes, delirium). The classic form of mercury poisoning is called **acrodynia** (or "painful extremities").

NURSING ALERT

Mercury thermometers are no longer recommended because if they are broken, the inhaled vapors can cause toxicity. To prevent inhalation, clean up spilled mercury quickly, using disposable towels and rubber gloves and washing the hands well afterward.

Heavy metals have an affinity for certain essential tissue chemicals, which must remain free for adequate cell functioning. When metals are bound to these substances, cellular enzyme systems are inactivated. Treatment involves **chelation**, use of a chemical compound that combines with the metal for rapid and safe excretion.

BOX 13.3 Sources of Lead[a]

Lead-based paint in deteriorating condition
Lead solder
Lead crystal
Battery casings
Lead fishing sinkers
Lead curtain weights
Lead bullets
Some of these may contain lead:

- Ceramic ware
- Water
- Pottery
- Pewter
- Dyes
- Industrial factories
- Vinyl miniblinds
- Playground equipment
- Collectible toys
- Some imported toys or children's metal jewelry
- Artists' paints
- Pool cue chalk

Occupations and hobbies involving lead:

- Battery and aircraft manufacturing
- Lead smelting
- Brass foundry work
- Radiator repair
- Construction work
- Furniture refinishing
- Bridge repair work
- Painting contracting
- Mining
- Ceramics work
- Stained-glass making
- Jewelry making

[a]The US Consumer Product Safety Commission issues alerts and recalls for products that contain lead and may unexpectedly pose a hazard to young children. Additional information is available from Alliance for Healthy Homes, https://nchh.org/who-we-are/afhh/.

LEAD POISONING

Poisoning from lead has been a problem throughout history and throughout the world. In the United States, the problem became apparent in the early 1900s when white lead was added to paints and when tetraethyl lead was added to gasoline as an antiknock compound. Lead content in paint was decreased in 1950, and in 1978 the use of lead in household paint was banned. The use of lead in paint and leaded gasoline has been banned in the United States. After this change in policy, the average blood lead level (BLL) in the United States for people 1 to 74 years old dropped from 12.8 mcg/dl in 1980 to 1.3 mcg/dl in 2010 (Centers for Disease Control and Prevention, 2012, 2017). However, children continue to be exposed to lead; an estimated 0.8% of children in the United States 1 to 5 years old had BLLs of more than 10 mcg/dl in 2010, and more than 5% had BLLs of 5 mcg/dl or higher (Centers for Disease Control and Prevention, 2017). There are no safe blood levels in children.

Causes of Lead Poisoning

Although there are numerous sources of lead (Box 13.3), in most instances of acute childhood lead poisoning, the source is nonintact lead-based paint in an older home or lead-contaminated bare soil in the yard. Microparticles of lead gain entrance into a child's body through ingestion or inhalation and, in the case of an exposed pregnant woman, by placental transfer. When measured, a mother's lead level is nearly the same as that of her unborn child. Although the level of lead may not be harmful to adult women, it can be harmful to fetuses.

Whereas inhalation exposure usually occurs during renovation and remodeling activities in the home, ingestion happens during normal day-to-day play and mouthing activities. Sometimes a child will swallow loose chips of lead-based paint because it has a sweet taste. Water and food may also be contaminated with lead. A child does not need to eat loose paint chips to be exposed to the toxin; normal hand-to-mouth behavior, coupled with the presence of lead dust in the environment that has settled over decades, is the usual method of poisoning (Bellinger, Chen, & Lanphear, 2017).

Because of family, cultural, or ethnic traditions, a source of lead may be a routine part of life for a child. Nurses must educate themselves about the practices of their patients and identify when such products may be a source of lead. The use of pottery or dishes containing lead may be an issue, as may the use of folk remedies for stomach aches or the use of some cosmetics (see Cultural Considerations box). Children of immigrants and internationally adopted children may have been exposed to sources of lead before arrival in the United States and should also be carefully evaluated for lead exposure (Raymond, Kennedy, & Brown, 2013). Other risk factors for having an elevated BLL include living in poverty, being younger than 6 years old, dwelling in urban areas, and living in older rental homes where lead decontamination may not be a priority. Nurses are often in a position to observe or elicit information about these practices and educate families about their potential harm.

CULTURAL CONSIDERATIONS

Sources of Lead

In some cultures, the use of traditional ethnic remedies that contain lead may increase children's risk of lead poisoning. These remedies include:

Azarcon (Mexico): For digestive problems; a bright orange powder; usual dose is 0.25 to 1 tsp, often mixed with oil, milk, or sugar or sometimes given as a tea; sometimes a pinch is added to a baby bottle or tortilla dough for preventive purposes

Greta (Mexico): A yellow-orange powder used in the same way as azarcon

Paylooah (Southeast Asia): Used for rash or fever; an orange-red powder given as 0.5 tsp straight or in a tea

Surma (India and Pakistan): Black powder used as a cosmetic and as teething powder

Unknown ayurvedic (Tibet): Small, gray-brown balls used to improve slow development; two balls are given orally three times a day

Tamarind jellied, fruit candy (Mexico): Fruit candy packaged in paper wrappers that contain high lead levels

Lozeena (Iraq): A bright orange powder used to color meat and rice

Litargirio (Dominican Republic): Yellow or peach-colored powder used as a folk remedy and as an antiperspirant or deodorant

Ba-Baw-San (China): Herbal medicine used to treat colic pain

Data from Centers for Disease Control and Prevention. (1993). Lead poisoning associated with use of traditional ethnic remedies—California, 1991–1992. *Morbidity and Mortality Weekly Report, 42*(27), 521–524; Centers for Disease Control and Prevention (1998). Lead poisoning associated with imported candy and powdered food coloring—California and Michigan. *Morbidity and Mortality Weekly Report,* 47(48), 1041–1043; Centers for Disease Control and Prevention. (2002). Childhood lead poisoning associated with tamarind candy and folk remedies—California, 1992–2000. *Morbidity and Mortality Weekly Report,* 51(31), 684–686; Centers for Disease Control and Prevention. (2005). Lead poisoning associated with use of litargirio—Rhode Island. *Morbidity and Mortality Weekly Report,* 54(09), 227–229.

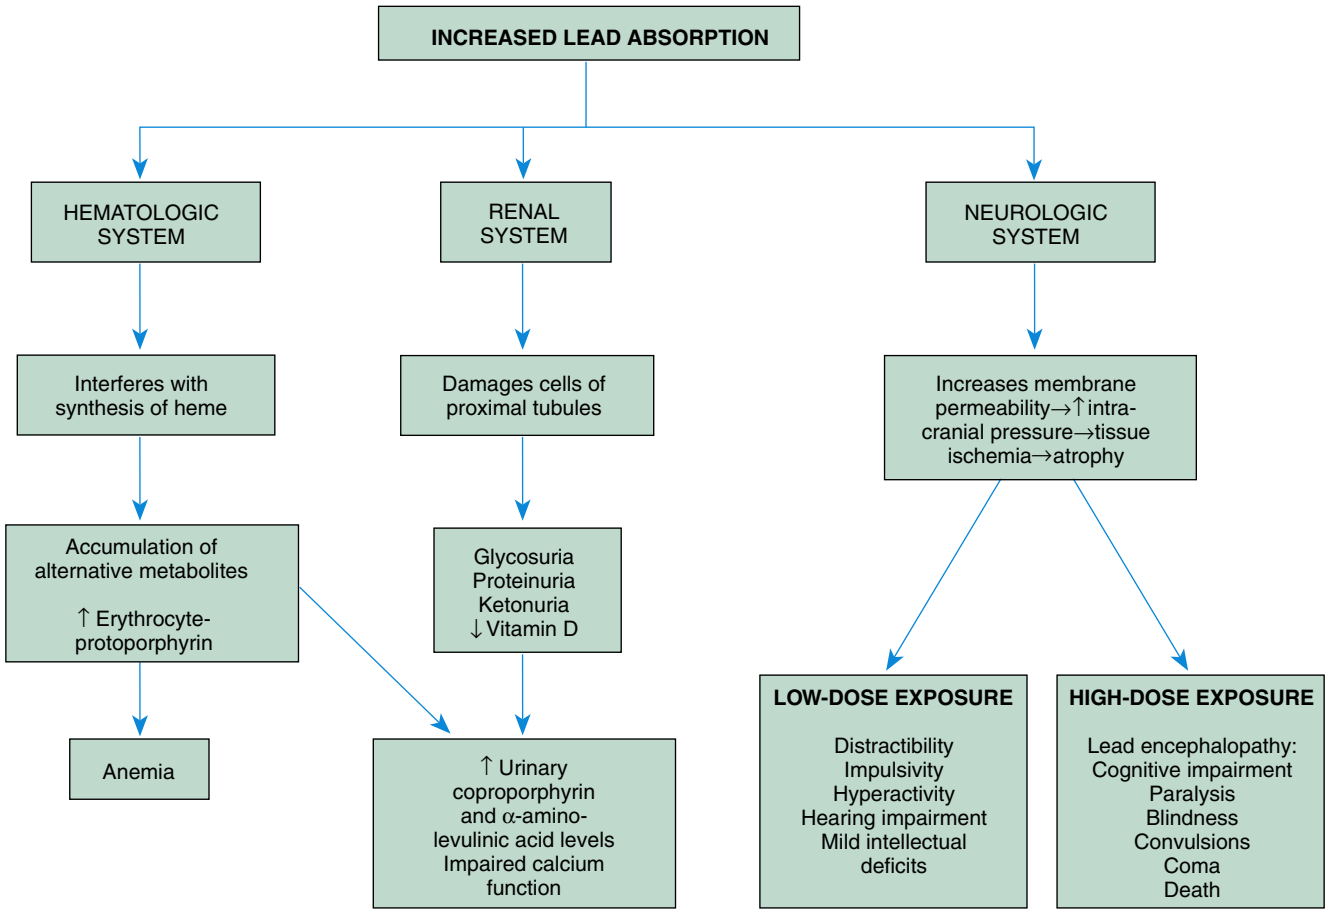

Fig. 13.1 Main effects of lead on body systems.

Pathophysiology and Clinical Manifestation

Lead can affect any part of the body, including the renal, hematologic, and neurologic systems (Fig. 13.1). Of most concern for young children is the developing brain and nervous system, which are more vulnerable than those of older children and adults. Lead in the body moves via an equilibration process between the blood, the soft tissues and organs, and the bones and teeth. Lead ultimately settles in the bones and teeth, where it remains inert and in storage. This makes up the largest portion of the body burden, approximately 75% to 90%. At the cellular level, it competes with molecules of calcium, interfering with the regulating action of calcium. In the brain, lead disrupts the biochemical processes and may have a direct effect on the release of neurotransmitters, may cause alterations in the blood-brain barrier, and may interfere with the regulation of synaptic activity (Cunningham, 2012; Jones, 2009).

There is a relationship between anemia and lead poisoning. Children who are iron deficient absorb lead more readily than those with sufficient iron stores. Lead can interfere with the binding of iron onto the heme molecule. This sometimes creates a picture of anemia even though the child is not iron deficient. Lead toxicity to the erythrocytes leads to the release of the enzyme erythrocyte protoporphyrin (EP). Because EP is not sensitive to BLLs of less than about 16 to 25 mcg/dl, it is no longer used as a screening test. The BLL test is currently used for screening and diagnosis. However, elevation of the EP level (>35 mcg/dl of whole blood) is a good indicator of toxicity from lead and reflects the length of exposure and body burden of lead in an individual child.

Although adults have been shown to experience adverse renal effects from occupational lead exposure, few studies document renal effects in children except at extremely high lead levels. One can hypothesize that lead can affect the renal integrity of children as well as adults. The renal system of a child is still considered a potential target for the harmful effects of lead.

The lead levels identified in children have declined since the initiation of screening for children at risk for lead poisoning. With earlier intervention, the most prevalent effects have changed. Since the late 1960s, children have rarely died of lead poisoning, and seizures or cognitive impairment have become less likely. However, even mild and moderate lead poisoning can cause a number of cognitive and behavioral problems in young children, including aggression, hyperactivity, impulsivity, delinquency, disinterest, and withdrawal. Long-term neurocognitive signs of lead poisoning include developmental delays, lowered intelligence quotient (IQ), reading skill deficits, visual-spatial problems, visual-motor problems, learning disabilities, and lower academic success. Chronic lead toxicity may also affect physical growth and reproductive efficiency (Burns & Gerstenberger, 2014).

Diagnostic Evaluation

Children with lead poisoning rarely have symptoms even at levels requiring chelation therapy. A diagnosis of lead poisoning is based only on the lead testing of a venous blood specimen from a venipuncture. The collection process is important. Blood must be collected carefully

to avoid contamination by lead on the skin. The acceptable BLL has dropped from 40 mcg/dl in 1970 to 5 mcg/dl today (Centers for Disease Control and Prevention Advisory Committee on Childhood Lead Poisoning Prevention, 2012).

Anticipatory Guidance

The most effective prevention of lead exposure is ensuring that environmental exposures are reduced before children are exposed. The following information should be made available to families beginning during prenatal and postnatal care (Centers for Disease Control and Prevention Advisory Committee on Childhood Lead Poisoning Prevention, 2012):

- Hazards of lead-based paint in older housing
- Ways to control lead hazards safely
- How to choose safe toys
- Hazards accompanying repainting and renovation of homes built before 1978
- Other exposure sources, such as traditional remedies, that might be relevant for a family

There has been recent concern regarding toys and other imported items children play with that were found to contain lead. Parents should carefully evaluate the source of the toy (manufacturer) or item the child may play with and not assume it is safe because it is sold in a US market. The US Consumer Product Safety Commission (http://www.cpsc.gov) is an excellent resource for parents and caregivers concerned about the safety of a given toy or product that may be harmful.

Screening for Lead Poisoning

When primary prevention fails, secondary prevention screening efforts for elevated BLLs can identify children much earlier than in the past. This need is established using BLL surveillance and other risk factor data collected over time to establish the status and risk of children throughout each state. Universal screening should be done at 1 and 2 years old. Any child between 3 and 6 years old who has not been previously screened should also be tested. All children with risk factors should be screened more often.

Targeted screening is acceptable when an area has been determined by existing data to have less risk. Children should be screened when they live in a high-risk geographic area or are members of a group determined to be at risk (e.g., Medicaid recipients) or if their family cannot answer "no" to the following personal risk questions:

- Does your child live in or regularly visit a house that was built before 1950?
- Does your child live in or regularly visit a house that was built before 1978 with recent or ongoing renovations or remodeling within the past 6 months?
- Does your child have a sibling or playmate who has or had lead poisoning?

Therapeutic Management

The degree of concern, urgency, and need for medical intervention change as the lead level increases. Education is one of the most important elements of the treatment process. Areas that the nurse needs to discuss with the family of every child who has an elevated BLL (≥5 mcg/dl) include the following (Centers for Disease Control and Prevention Advisory Committee on Childhood Lead Poisoning Prevention, 2012):

- The child's BLL and what it means
- Potential adverse health effects of an elevated BLL
- Sources of lead exposure and suggestions on how to reduce exposure, such as the importance of wet cleaning to remove lead dust on floors, windowsills, and other surfaces
- Importance of good nutrition in reducing the absorption and effects of lead; for persons with poor nutritional patterns, adequate intake of calcium and iron and importance of regular meals
- Need for follow-up testing to monitor the child's BLL
- Results of an environmental investigation if applicable
- Hazards of improper removal of lead paint (dry sanding, scraping, or open-flame burning)

Treatment actions vary depending on the child's BLL. Based on a diagnosis from a venous BLL test, the Centers for Disease Control and Prevention (2002) recommends the following actions:

Blood Lead Level (mcg/dl)	Action
<5	Provide family with lead education. Reassess or rescreen in 1 year. If exposure status changes, do this sooner.
5-14	Provide family with lead education, regular developmental and behavioral surveillance, and social service referral if necessary. Provide follow-up testing within 1 month, then every 3 to 4 months.
15-19	Provide family with lead education, regular developmental and behavioral surveillance, and social service referral if necessary. Provide follow-up testing within 1 month, then every 3 to 4 months. Initiate professional environmental cleanup. Follow guidelines for BLL of 20-44 mcg/dl if BLL remains ≥15 mcg/dl on two samples obtained at least 3 months apart.
20-44	Provide family with lead education, regular developmental and behavioral surveillance, and social service referral if necessary. Refer to clinical center specializing in lead poisoning. Provide both clinical and environmental management. Consider treating with appropriate chelation therapy.
45-69	Provide lead education. Refer to clinical center specializing in lead poisoning; provide coordination of care. Provide diagnostic testing within 24-48 h. Perform clinical evaluation and management within 48 h. Provide appropriate chelation therapy. Ensure aggressive environmental intervention. Follow-up testing at least once per month.
≥70	*Immediately* provide diagnostic testing and initiate chelation therapy. Begin other activities (listed above).

Chelation Therapy

Chelation is the term used for removing lead from circulating blood and, theoretically, some lead from organs and tissues. It is unclear whether chelation affects lead stores in bones. Although not an antidote

in the truest sense, it does serve a similar purpose in that the toxic substance or poison is removed from the body. However, chelation does not counteract any effects of the lead.

Historically, three chelating agents have been used consistently: calcium disodium edetate ($CaNa_2EDTA$, or calcium EDTA), British anti-Lewisite (BAL; dimercaprol, dimercaptopropanol), and Meso-2,3-dimercaptosuccinic acid (DMSA, Chemet, Succimer). BAL (dimercaprol, dimercaptopropanol) is used in conjunction with EDTA with high lead levels or the presence of lead encephalopathy. All of the agents have potential toxic side effects and contraindications. Renal, hepatic, and hematologic parameters should be monitored.

Because of the equilibration process between blood, soft tissues, and other sites in the body, there is often a rebound of the BLL after chelation. After the body burden of lead is reduced enough to stabilize the BLL, rebound will cease. Multiple chelation treatments may be necessary. Adequate hydration is essential during therapy because the chelates are excreted via the kidneys.

Severe lead toxicity (lead level ≥70 mcg/dl) requires immediate inpatient treatment, whether symptoms are present or not. BAL is contraindicated in children with peanut allergies or hepatic insufficiency, nor should it be given in conjunction with iron. Also, use with caution in children with renal impairment or hypertension; monitor for hemolysis with presence of glucose-6-phosphate dehydrogenase deficiency. It must be given only at a deep intramuscular site, in repeated doses over several days. Calcium EDTA should be given intravenously or intramuscularly (in a different site from BAL). The intravenous route should not be used in children with cerebral edema.

For lead levels of 45 to 69 mcg/dl and an absence of symptoms, DMSA can be used. The capsule is opened and sprinkled on a small amount of food or may be swallowed whole. DMSA can be used in conjunction with iron. Adverse effects include nausea, vomiting, diarrhea, loss of appetite, rash, elevated liver function tests, and neutropenia. Because the chelates are excreted via the kidneys, adequate hydration is essential.

A less used oral chelating agent, D-penicillamine, is sometimes used to treat lead poisoning, but the medication is not approved by the US Food and Drug Administration for use in the United States (Dapul & Laraque, 2014).

Prognosis

Although most of the pathophysiologic effects of lead are reversible, the most serious consequences of both high and low lead exposure are the effects on the central nervous system. In children with lead encephalopathy, permanent brain damage can result in cognitive impairment, behavior changes, possible paralysis, and seizures. However, low-dose exposure may also cause permanent neurologic deficits. Increased distractibility, short attention span, impulsivity, reading disabilities, and school failure have been associated with lead exposure (Centers for Disease Control and Prevention Advisory Committee on Childhood Lead Poisoning Prevention, 2012).

Nursing Care Management

The primary nursing goal in lead poisoning is to prevent the child's initial or further exposure to lead. For children with low-level exposure, this requires identifying the sources of lead in the environment. Careful history taking is the most useful and most valuable tool and should concentrate on the personal risk questions. Suggestions for reducing lead in the child's environment are listed in the Community Focus box.

COMMUNITY FOCUS

Reducing Blood Lead Levels

- Make certain children do not have access to peeling paint or chewable surfaces painted with lead-based paint, especially windowsills and wells.
- If a house was built before 1978 and has hard-surface floors, wet mop them at least once per week. Wipe other hard surfaces (e.g., windowsills, baseboards). If there are loose paint chips in an area, such as a window well, use a wet disposable cloth to pick up and discard them. Do not vacuum hard-surfaced floors or windowsills or wells because this spreads dust. Use vacuum cleaners with agitators to remove dust from rugs rather than vacuum cleaners with suction only. If a rug is known to contain lead dust and cannot be washed, it should be discarded.
- Wash and dry children's hands and faces frequently, especially before eating.
- Wash toys and pacifiers frequently.
- Wipe your feet on mats before entering the home, especially if you work in occupations where lead is used. Removing your shoes when you are entering the home is a good practice to control lead.
- If soil around home is or is likely to be contaminated with lead (e.g., if the home was built before 1978 or is near a major highway), plant grass or other ground cover; plant bushes around outside of the house so that children cannot play there.
- During remodeling of older homes, follow correct procedures. Be certain children and pregnant women are not in the home, day or night, until the process is completed. After deleading, thoroughly clean the house using cleaning solution to a damp mop and dust before inhabitants return.
- In areas where lead content of water exceeds the drinking water standard and a particular faucet has not been used for 6 hours or more, "flush" the cold-water pipes by running the water until it becomes as cold as it will get (30 seconds to 2 minutes). The more time water has been sitting in pipes, the more lead it may contain.
- *Use only cold water* for consumption (drinking, cooking, and especially for reconstituting powder infant formula). Hot water dissolves lead more quickly than cold water and thus contains higher levels of lead. It is acceptable to use first-flush water for nonconsumption uses (e.g., bathing).
- Have water tested by a competent laboratory. This action is especially important for apartment dwellers; flushing may not be effective in high-rise buildings and in other buildings with lead-soldered central piping.
- Do not store food in open cans, particularly if cans are imported.
- Do not use pottery or ceramic ware that was inadequately fired or is meant for decorative use for food storage or service. Do not store drinks or food in lead crystal.
- Avoid folk remedies or cosmetics that contain lead.
- Avoid candy imported from Mexico (e.g., tamarind hard candy).
- Avoid imported toys and toy jewelry that may contain lead.
- Make certain that home exposure is not occurring from parental occupations or hobbies. Household members employed in occupations such as lead smelting should shower and change into clean clothing before leaving work. Construction and lead abatement workers may also bring home lead contaminants.
- Ensure that children eat regular meals because more lead is absorbed on an empty stomach.
- Ensure that children's diets contain sufficient iron and calcium and not excessive fat.
- Consider iron supplementation if child does not regularly consume foods rich in iron.

Modified from Centers for Disease Control and Prevention. (2013). *Lead home*. Retrieved from http://www.cdc.gov/nceh/lead/

For children who undergo chelation therapy, the nurse prepares them for the injections and makes all efforts to reduce injection pain. Chelating agents are administered deeply into a large muscle mass (see Atraumatic Care box). To lessen the pain from calcium EDTA, the local anesthetic procaine is injected with the drug. Rotation of sites is essential to prevent the formation of painful areas of fibrotic tissue. Because calcium EDTA and lead are toxic to the kidneys, keep records of intake and output, and assess the results of urinalysis to monitor renal functioning.

ATRAUMATIC CARE

Lead Chelation Therapy

To lessen the pain from intramuscular injection of calcium disodium edetate ($CaNa_2EDTA$ or calcium EDTA), the local anesthetic procaine is injected with the drug. Apply topical anesthetic cream such as eutectic mixture of local anesthetics (e.g., lidocaine-prilocaine [EMLA]) or LMX4 (4% lidocaine) over the puncture site before the injection of EDTA and British anti-Lewisite (BAL) (time per manufacturer's guidelines).

! NURSING ALERT

Use extreme caution with chelating agents. Incidences of child death from hypocalcemia have been recorded when Na_2EDTA was substituted for $CaNa_2EDTA$ and used as a chelating agent (Fountain & Reith, 2014).

! NURSING ALERT

Adequate urinary output must be ensured with administration of calcium EDTA. Children receiving the drug intramuscularly must be able to maintain adequate oral intake of fluids.

Discharge planning for children with lead poisoning must include thorough education of families on safety from lead hazards, clear instructions regarding medication administration and follow-up, and confirmation that the child will be discharged to a home without lead hazards. Although the nurse must use caution to avoid alarming parents unnecessarily, it is important that they know the risk implications for their child's behavior and cognitive functions. Nurses should observe the development and behavior of children who are hospitalized. Thoroughly evaluate any concerns that are identified. Referral to a child development or speech and language specialist may be necessary.

As in any situational crisis, parents need support and understanding if their child is treated for lead poisoning. Many families at the highest risk for lead poisoning have the fewest resources to comply with measures such as relocation or removal of lead from the environment where the child experiences exposure.

CHILD MALTREATMENT

The broad term *child maltreatment* includes intentional physical abuse or neglect, emotional abuse or neglect, and sexual abuse of children, usually by adults. It is one of the most significant social problems affecting children. In 2015 Child Protective Service agencies in the United States confirmed that an estimated 683,000 children were victims of one or more types of child maltreatment. Of the confirmed cases, about 17.2% suffered physical abuse, 8.4% sexual abuse, 75.3% neglect, and 6.9% psychologic maltreatment or emotional abuse. In 2015 there were an estimated 1585 child fatalities as a result of child abuse and neglect (US Department of Health and Human Services, 2015). Reported statistics only partially represent the actual incidence of child maltreatment because many cases are believed to go unreported.[c]

CHILD NEGLECT

Child neglect is the most common form of maltreatment, and 74.8% of reported neglect cases involve children 3 years old or younger (US Department of Health and Human Services, 2015). Of the children who died, 72.9% suffered from neglect either exclusively or in combination with another type of maltreatment (US Department of Health and Human Services, 2015). **Neglect** is generally defined as the failure of a parent or other person legally responsible for the child's welfare to provide for the child's basic needs and an adequate level of care.

Important contributing factors for child neglect are lack of knowledge of child's needs, lack of resources, and caregiver substance abuse. For example, neglectful parents often demonstrate poor parenting skills. They may be unaware that an infant needs to be fed every 3 to 4 hours, may not know what to feed the child, and may have insufficient funds to buy food. The most serious lack of knowledge is failure to recognize emotional nurturing as an essential need of children (see also Chapter 10, Failure to Thrive).

Types of Neglect

Neglect takes many forms and can be classified broadly as physical or emotional maltreatment. **Physical neglect** involves the deprivation of necessities, such as food, clothing, shelter, supervision, medical care, and education. **Emotional neglect** generally refers to failure to meet the child's needs for affection, attention, and emotional nurturance.

Neglect may also include lack of intervention for or fostering of maladaptive behavior, such as delinquency or substance abuse. **Emotional abuse** or **psychologic maltreatment**, an even more difficult aspect of maltreatment to define, refers to the deliberate attempt to destroy or significantly impair a child's self-esteem or competence. Emotional abuse may take the form of rejecting, isolating, terrorizing, ignoring, corrupting, verbally assaulting, or overly pressuring the child (Hibbard, Barlow, MacMillan, et al., 2012).

PHYSICAL ABUSE

The deliberate infliction of physical injury on a child, usually by the child's caregiver, is called *physical abuse.* Physical abuse can include anything from bruises and fractures to brain damage. Minor physical injury is responsible for more reported cases of maltreatment than major physical injury, but major physical abuse causes more deaths. In 2015, 43.9% of fatalities from abuse suffered physical abuse alone or in combination with other types of maltreatment (US Department of Health and Human Services, 2015). Despite the importance of the problem, a universally accepted definition of what constitutes minor and major physical abuse does not exist. Rather, each state in the United States defines abuse according to its individual reporting laws.

Abusive Head Trauma

Abusive head trauma (AHT) is a serious form of physical abuse caused by violent shaking of infants and young children. Other commonly used terms include *shaken baby syndrome, inflicted head injury,* or *neuro-inflicted brain injury*. This violent shaking would be easily recognized by others as dangerous (American Academy of Pediatrics Committee on Child Abuse and Neglect, 2009; Kemp, 2011) and is most often a result of the caregiver's frustration with crying, maternal stress, or depression (Kemp, 2011). Every year in the United States, an estimated 1200 to 1400 children are shaken, and of these victims, 25% to 30% die as a result of their injuries. The rest have lifelong complications (National Center on Shaken Baby Syndrome, n.d.).

It is important to understand what happens in AHT. Infants have a large head-to-body ratio, weak neck muscles, and a large amount of water in the brain. Violent shaking causes the brain to rotate within the skull, resulting in shearing forces that tear blood vessels and neurons. The characteristic injuries that occur are intracranial bleeding (subdural and subarachnoid hematomas) and, in approximately 80% of cases, bilateral retinal hemorrhages, which are classic results of repetitive acceleration–deceleration head trauma (Maguire, Watts, Shaw, et al., 2013). Injuries may also include fractures of the ribs and long bones. Most often, there are no signs of external injury, making diagnosis difficult. Clinicians base an abusive diagnosis on patterns of injuries to the infant, but this can be subjective. PredAHT, a prediction tool, assists clinicians with an AHT diagnosis by listing six key clinical features of AHT obtained from high-quality publications (Cowley, Morris, Maguire, et al., 2015). The PredAHT has high sensitivity and specificity in estimating the probability of AHT when three or more of the six features are present in the patient (Cowley et al., 2015).

Traumatic brain injury is often not an isolated event, with a large number of children showing evidence of a previous injury (Kemp, 2011). Victims of AHT can be seen with a variety of symptoms, from generalized flulike symptoms to unresponsiveness with impending death (Altimier, 2008). Many of the presenting symptoms, such as vomiting, irritability, poor feeding, and listlessness, are often mistaken for common infant and childhood ailments. In more severe forms, presenting symptoms may include seizures, posturing, alterations in level of consciousness, apnea, bradycardia, or death. The long-term outcomes of AHT include seizure disorders; visual impairments, including blindness; developmental delays; hearing loss; cerebral palsy; and mild to profound mental, cognitive, or motor impairments (Altimier, 2008). Nurses can take an active role in prevention of AHT by teaching caregivers about care for infants and techniques to cope with inconsolable crying (Barr, 2012).

! NURSING ALERT

Stress to parents the danger of shaking infants (shaking can cause abusive head trauma [AHT]). Education must include coping mechanisms to care for children with inconsolable crying.

Munchausen Syndrome by Proxy

Munchausen syndrome by proxy (MSBP), also known as *medical child abuse* or *factitious disorder by proxy,* is a rare but serious form of child abuse in which caregivers deliberately exaggerate or fabricate histories and symptoms or induce symptoms. It is a form of child maltreatment that may include physical, emotional, and psychologic abuse for the gratification of the caregiver. In most cases, the perpetrator is the biologic mother with some degree of health care knowledge and training. Health care providers can become easily misled and unknowingly enable the perpetrator (Skarsaune & Bondas, 2015; Squires & Squires, 2013). Because of the history of symptoms provided by the caregiver, the child endures painful and unnecessary medical testing and procedures. Common symptoms presented are seizures, nausea and vomiting, diarrhea, and altered mental status; they are usually witnessed only by the perpetrator.

Considerations when determining whether a child is a victim of MSBP include:

- Is the child's condition consistent with the reported history?
- Does diagnostic evidence support the reported history?
- Has anyone other than the caregiver witnessed the symptoms?
- Is treatment being provided primarily because of the caregiver's demands?

The resolution of symptoms after separation from the perpetrator confirms the diagnosis.

Factors Predisposing to Physical Abuse

The causes of child abuse are multifaceted. Child maltreatment occurs across all socioeconomic, religious, cultural, racial, and ethnic groups (US Department of Health and Human Services, 2015). Three risk factors are commonly identified in child abuse: (1) parental characteristics, (2) characteristics of the child, and (3) environmental characteristics. However, no single factor or group of factors is predictive of abuse. Rather, the interaction of these factors is thought to increase the risk of abuse occurring in a particular family.

Parental Characteristics

Some identified characteristics occur more frequently in parents who abuse their children and are therefore considered risk factors. Younger parents more often are abusers of their children. Single-parent families are at higher risk for abuse, and in single-parent families that include an unrelated partner, the partner is sometimes the abuser, although a biologic parent is most commonly the perpetrator (US Department of Health and Human Services, 2015).

Abusive families are often socially isolated and have few supportive relationships. They often have additional stressors, such as low-income circumstances with little education. Parents with substance abuse problems pose a greater risk for abuse and neglect because of a variety of factors. The additional stressors of substance abuse with the demands of normal care of children create situations in which abuse and neglect can occur, because these parents have impaired judgment and may react with violence while under the influence of drugs or alcohol (Lyden, 2011). With little or no available support system and concurrent stressors imposed by the child or environment, these parents are vulnerable to additional crises of any nature and may strike out at the child as a method of releasing their frustration and anxiety.

Other factors identified in abusive parents include low self-esteem and little knowledge of appropriate parenting skills. Parenting skills are learned behaviors, and parents who grew up with poor parental role models may have difficulty parenting their own children. Often child abusers were abused or observed some types of abuse in their home (Lyden, 2011).

Characteristics of the Child

The onus for child abuse is always on the abuser. However, children who are abused do have some common characteristics. Children from birth to 1 year old are at highest risk for being abused (US Department of Health and Human Services, 2015). Infants and small children require constant attention and must have all their needs met by others. This can result in parental or caregiver fatigue that may result in striking out at the child with physical force, shaking the child, or ignoring the child's needs.

The physical and emotional demands placed on the parents or caregiver of an unwanted, brain-damaged, hyperactive, or physically disabled child may overwhelm them, resulting in abuse. Children with disabilities may not understand that abusive behaviors are not appropriate, so they may not tell others or defend themselves. Premature infants may be at risk for maltreatment because of failure of parent-child bonding during early infancy, increased physical needs, or irritability. One child may be singled out in an abusive family. Removing that child from the home often places the other siblings at risk for abuse. No child is safe if left in the abusive environment unless the parents can be helped to learn new parenting skills, to meet the children's needs, and to release their frustration through alternatives other than attacking their children.

Environmental Characteristics

The environment is a significant part of the potentially abusive situation. A typical environment is one of chronic stress, including problems of divorce, poverty, unemployment, poor housing, frequent relocation, alcoholism, and drug addiction. Increased exposure between children and parents, such as that which occurs in crowded living conditions, also increases the likelihood of abuse.

Although most reporting of abuse has been from lower socioeconomic populations, as stated earlier, child abuse is not a problem of any one societal group. Stresses imposed by poverty predispose lower socioeconomic families to abusive situations, and abuse in these groups is more likely to be reported. However, concealed crises may also be present in upper-class families. Families who have substitute caregivers (such as daycare providers and babysitters) may also be at risk for child abuse, especially if the family has not fully evaluated the caregiver. Nurses need to be aware of all these factors to identify the less obvious examples of child abuse and neglect.

SEXUAL ABUSE

Sexual abuse is one of the most devastating types of child maltreatment, and estimates indicate that it has increased significantly during the past decade (US Department of Health and Human Services, 2015). Some of the apparent increase is due to increased awareness and increased reporting (Evans, 2011).

As with all forms of child maltreatment, no universal definition for sexual abuse exists. The Child Abuse Prevention and Treatment Act (CAPTA), amended by the CAPTA Reauthorization Act of 2010, defines **sexual abuse** as "the employment, use, persuasion, inducement, enticement, or coercion of any child to engage in, or assist any other person to engage in, sexually explicit conduct or any simulation of such conduct; or the rape, molestation, prostitution, or other form of sexual exploitation of children, or incest with children" (US Department of Health and Human Services, 2015).

Sexual abuse includes the following types of sexual maltreatment (see also Chapter 16, Sexual Violence):

Incest: Any physical sexual activity between family members; blood relationship is not required (abusers can include stepparents, unrelated siblings, grandparents, uncles, and aunts); does not include sexual relations between legally sanctioned partners, such as spouses

Molestation: A vague term that includes "indecent liberties," such as touching, fondling, kissing, single or mutual masturbation, or oral-genital contact

Exhibitionism: Indecent exposure, usually exposure of the genitalia by an adult man to children or women

Child pornography: Arranging and photographing, in any media, sexual acts involving children, alone or with adults or animals, regardless of consent by the child's legal guardian; also may denote distribution of such material in any form with or without profit

Child prostitution: Involving children in sex acts for profit and usually with changing partners

Pedophilia: Literally means "love of child" and does not denote a type of sexual activity but rather the preference of an adult for prepubertal children as the means of achieving sexual excitement

Characteristics of Abusers and Victims

Anyone, including siblings and mothers, can be sexual abusers, but a typical abuser is a man whom the victim knows. Offenders come from all levels of society; however, a higher risk of child abuse has been noted among families with incomes below the poverty level (Breyer & MacPhee, 2015). In addition, parents with a high school education are more likely than parents with a college education to be abusers (Breyer & MacPhee, 2015). Many offenders hold full-time jobs, are active in community affairs, and may not have prior criminal records. Offenders often are employed (or volunteer) in positions such as teaching or coaching that bring them into contact with young girls and boys. Offenders may commit many assaults before being caught.

Incestuous relationships between father or stepfather and daughter are generally prolonged, and the victims are usually reluctant to report the situation because of fear of retaliation and fear that they will not be believed. Typically, incestuous relationships begin later than other forms of child abuse. The eldest daughter is usually abused, but in her absence another sister may be substituted. Sibling incest may also occur. Sexual abuse by relatives with a strong emotional bond with the victim, such as a parent, is often the most devastating to the child.

Boys are also victims of both intrafamilial and extrafamilial abuse. Compared with female victims, male victims are much less likely to report abuse, and they may suffer much greater emotional harm from incestuous relationships. Boys are likely to be subjected to anal penetration and oral-genital contact. They often have subtle physical findings and are abused by a father, stepfather, or mother's boyfriend.

Significant risk factors for child sexual abuse include parental unavailability, lack of emotional closeness and flexibility, social isolation, emotional deprivation, and communication difficulties. Most sexual abuse is committed by men and by persons known to the child, such as family members (Forsdike, Tarzia, Hindmarsh, et al., 2014). Around 20% to 25% of child sexual abuse cases involve penetration or oral-genital contact. In 2011 more than 26% of sexual abuse victims were between 12 and 14 years old, and nearly 22% were between 15 and 17 years old (US Department of Health and Human Services, 2015).

Initiation and Perpetuation of Sexual Abuse

The cycle of sexual abuse often starts insidiously unless it involves an isolated attack, such as rape. Often offenders spend time with the victims to gain their trust before initiating any sexual contact. Most victims are then pressured into being an accessory to the sexual activity through various means (Box 13.4) and may be unaware that sexual activity is part of the offer. Children may not reveal the truth for fear that their parents would not believe them if they told, especially if the offender is a trusted member of the family. Some fear that they will be blamed for the situation, and many young children with limited vocabulary have difficulty describing the activity when they do have the courage or opportunity to reveal the abuse.

Incest most frequently occurs between siblings, but it may also be between fathers or stepfathers and daughters or between grandfather and granddaughter. Sibling incest has been found to have adverse outcomes during childhood that extend into adulthood and are just as damaging as father-daughter abuse (Krienert & Walsh, 2011). Victims

BOX 13.4 Methods Used to Pressure Children Into Sexual Activity

- The child is offered gifts or privileges or has privileges withheld.
- The adult misrepresents moral standards by telling the child that it is "okay to do."
- Isolated and emotionally and socially impoverished children are enticed by adults who meet their needs for warmth and human contact.
- The successful sex offender pressures the victim into secrecy by describing it as a "secret between us" that other people would take away if they found out.
- The offender plays on the child's fears, including fear of punishment by the offender, fear of repercussions if the child tells, and fear of abandonment or rejection by the family.

may take years to disclose this abuse. However, not all incestuous relationships follow this pattern of silence. Reports of father-daughter incest during child custody conflicts have become more common and have raised serious concerns regarding the possibility of false accusation. Rather than tolerating or denying the child's sexual abuse, the other parent (usually the mother) is typically the chief accuser.

NURSING CARE OF THE MALTREATED CHILD

A critical responsibility of health professionals is identifying abusive situations as early as possible. Nurses who increase their knowledge of the different types of abuse and neglect and underlying causes will enhance their ability to identify, intervene, and prevent children from maltreatment and neglect (Lyden, 2011). The characteristics that may predispose members of some families to commit abuse can serve as a framework for assessing vulnerability but are never predictive of actual abuse. A careful, detailed history and interview combined with a thorough physical examination are the diagnostic tools needed to identify abuse. Nurses have a special role because they may be the first person to see the child and parent and are the consistent caregivers if the child is hospitalized (see Nursing Care Guidelines box).

NURSING CARE GUIDELINES

Talking With Children Who Reveal Abuse

- Provide a private time and place to talk.
- Do not promise not to tell; tell them that you are required by law to report the abuse.
- Do not express shock or criticize their family.
- Use their vocabulary to discuss body parts.
- Avoid using any leading statements that can distort their report.
- Reassure them that they have done the right thing by telling.
- Tell them that the abuse is not their fault and that they are not bad or to blame.
- Determine their immediate need for safety.
- Let the child know what will happen when you report.

In interviewing the child and family, the nurse must be careful to avoid biasing the child's retelling of the events. Some experts suggest that health professionals limit the interview to the child's physical and mental health concerns and leave topics of the family's social, legal, or other problems to the police or Child Protective Services (Mollen, Goyal, & Frioux, 2012). If this is not possible, try to coordinate the interview process so that all pertinent health care professionals can be present for the interview.

BOX 13.5 Warning Signs of Abuse

- Child has physical evidence of abuse or neglect, including previous injuries.
- History is incompatible with the pattern or degree of injury, such as bilateral skull fractures after being dropped.
- Explanation of how injury occurred is vague or the parent or guardian is reluctant to provide information.
- The patient is brought in with a minor, unrelated complaint, and significant trauma is found.
- Histories are contradictory among caregivers.
- The mechanism of injury provided is not possible given age or developmental level of the patient, such as 6-month-old turning on hot water.
- Bruising or other injury is present in a nonmobile patient.
- The patient's affect is inappropriate in relation to the extent of injury.
- Evidence of abusive or neglectful parent-child interaction is present.
- The parent, guardian, or custodian disappears after bringing in the patient for trauma, or a patient with suspicious injury is brought in by an unrelated adult.
- The patient has multiple fractures of differing ages.
- There was a delay in seeking care.
- The parent or caregiver discloses that abuse has or may have occurred.
- The patient makes an outcry of abuse or neglect.

Recognition of abuse or neglect necessitates a familiarity with both physical and behavioral signs that suggest maltreatment (Box 13.5). No one indicator can be used to diagnose maltreatment. It is a pattern or combination of indicators that should arouse suspicion and lead to further investigation. It is important to note that some situations (such as bleeding disorders, osteogenesis imperfecta, or sudden infant death syndrome) may be misinterpreted as abuse. Also, some cultural practices, such as cupping or coin rubbing, may mimic physical abuse. Unintentional injuries, such as burns from metal buckles on car seats, bruising from seat belts, or spiral fractures from a twist and fall injury, may also be wrongly diagnosed as abuse. Normal variants, such as mongolian spots and congenital anomalies of genitalia, can be mistaken for abuse.

Caregiver-Child Interaction

The nurse can use the initial contact with the family to assess the interaction between the caregiver and the child. Observations of the caregivers should include emotional support for the child, attentiveness to the child's needs, and concern for the child's injury. Although caregivers and children may vary in responses to a stressful event, note an unusual caregiver-child relationship and factor this into the overall evaluation of the child.

Certain behavioral responses of the parents to their child and to the interviewer should alert the nurse to the possibility of maltreatment. Abusive parents may have difficulty showing concern toward their child. They may be unable or unwilling to comfort the child. Abusers may blame the child for the injuries or belittle him or her for being clumsy or stupid. When interacting with health care workers, the parent may become hostile or uncooperative. During the child's hospitalization, they may not participate in the child's care and may show little concern for his or her progress, eventual discharge, or need for follow-up care.

Abused children's responses to their parents or the injury may also support the suspicion of abuse. Although no one pattern is typical, extremes of behavior may be observed. Children may be unresponsive to the parent or excessively clinging and intolerant of separation. They may be overly attached to the abusive parent, possibly in the hope of preventing any upset that may precipitate anger and another attack.

During care of the injury, children may be passive and accepting of the discomfort or uncooperative and fearful of any physical contact. They may avoid eye contact. Some children maintain a wary watchfulness of all strangers; some shy away from strangers as if frightened; others are unusually affectionate and outgoing.

History and Interview

Child Physical Abuse

It is often difficult to distinguish child maltreatment from accidental injuries. Caregivers whose history of events may be deceptive or incomplete and children who are nonverbal may make the assessment more complex. A purposeful, skilled history and appropriate interview questions help the nurse ensure the right course of action. Knowledge of mechanism of injury and child development is essential. Cases of abuse are often detected when the child or caregiver history of events does not match the physical findings. Children who are verbal can often give a history of the injury. Separating the child from the caregiver may provide a more reliable history. It is important to ask nonleading, open-ended questions. The history should include a narrative of the injury from both caregiver and child (if verbal). Date, time, and location where the injury took place along with who was present at the time of the injury are essential questions. Family history for bleeding and bone disorders is important. Box 13.5 outlines areas of history that are concerning for abuse.

Neglect and Emotional Abuse

Each child may manifest different responses to neglect, depending on the situation and developmental age of the child. The goal of the interview is to determine whether the child is in a safe environment and whether the caregiver has the skills and resources to care for the child. It is often difficult to determine whether the circumstances constitute poor parenting skills or true neglect. Box 13.6 lists flags for behaviors to look for in neglected and abused children.

Sexual Abuse

An essential component to identifying sexual abuse is the interview. Several dynamics may impede the child's revelation of sexual abuse. Child sexual abuse is often perpetrated by someone known to the child, including family members. In some cases, the child may have been sworn to secrecy. The child may have been told that no one will believe the story or that his or her family would be harmed if he or she told someone about the abuse. Small children may imitate behaviors they have had perpetrated on themselves or have seen others do. The nurse must be able to recognize normal, age-related sexual curiosity and self-stimulating behaviors. Typically, children do not act out specific details of the sexual act or perform intrusive acts on others unless they have sexual knowledge beyond their normal age-related development (Dubowitz & Lane, 2016).

Children's reports of sexual abuse may vary from contradictory stories to unwavering versions of the experience. Stories that sound contradictory may reflect the child's experiences in several instances of abuse. Also, children who repeatedly tell identical facts may have been prompted to do so.

Increasing evidence suggests that the types of interrogation children are exposed to after reports of sexual abuse shape their thinking. To avoid biasing the interaction, nurses must be skillful interviewers when questioning children who may be victims of abuse. Medical records should include verbatim statements made by the child and interviewer that reflect appropriate nonleading questions and statements (Lyden, 2011). The child may not be emotionally ready to discuss the abuse. Establishing rapport with the child is essential to gaining his or her trust. Interviews should not be rushed. Engaging the child in play activities while encouraging conversation may help the child discuss the abuse. It may take several interviews or psychologic counseling for the child to be forthcoming about the abuse. Information regarding the last sexual contact is important because it determines the need for a forensic evaluation. Children who have been sexually abused within the past 72 to 96 hours should be considered for forensic testing.

Unfortunately, there is no typical profile of the victim, and the nurse must have a high index of suspicion to identify these children. Physical signs vary and may include any of those listed for sexual abuse. The victim may exhibit various behavioral manifestations, but none of these behaviors is diagnostic. When abused children exhibit these behaviors, the signs may be incorrectly attributed to the normal stresses of childhood, especially in older school-age children or adolescents. Even signs considered most predictive of sexual abuse (such as certain genital findings, sexually inappropriate behavior for age, enactment of adult sexual activity, and intense focus on sexual activity [e.g., masturbation]) do not always indicate that sexual abuse has occurred. Conversely, abused children may not demonstrate more knowledge of sexual activity than nonabused children. However, one difference in the abused children's explanation of sexual activity may be unusual affective responses. For example, abused children have an increased risk for conduct disorders, aggressive behavior, and poor academic performance (Dubowitz & Lane, 2016).

! NURSING ALERT

When children report potentially sexually abusive experiences, take their reports seriously but also cautiously to avoid alarming the child or falsely accusing someone.

PHYSICAL ASSESSMENT

Child Physical Abuse

The goal of the physical assessment for child physical abuse is identification of all injuries. A system approach ensures that the whole body is evaluated. In instances of severe abuse and injuries, the assessment should begin with a rapid assessment of airway, breathing, circulation, and neurologic systems. A systematic head-to-toe examination follows. Attention to areas often overlooked, such as the scalp, behind the ears, and the frenulum, is essential. The child's exterior genital area and posterior surface should be completely examined.

Record the location and a detailed description of all injuries. Note the color, size, and location of all bruising. Burn documentation should include the location, pattern, demarcation lines, and presence of eschar or blisters. Diagrams of the injuries using a body diagram form are helpful. If possible, obtain photographs of the injuries using a measurement tool.

Not all forms of physical abuse have obvious signs. Intra-abdominal organ injury from blunt trauma to the abdomen can occur without signs of external abdominal bruising. Nurses should consider intra-abdominal injury in infants and children who have any other signs of abuse.

! NURSING ALERT

Incompatibility between the history and the injury is probably the most important criterion on which to base the decision to report suspected abuse.

BOX 13.6 Clinical Manifestations of Potential Child Maltreatment

Physical Neglect

Suggestive Physical Findings

Growth failures
Signs of malnutrition, such as thin extremities, abdominal distention, lack of subcutaneous fat
Poor personal hygiene
Unclean or inappropriate dress
Evidence of poor health care, such as delayed immunization, untreated infections, frequent colds
Frequent injuries from lack of supervision

Suggestive Behaviors

Dull and inactive affect; excessively passive or sleepy
Self-stimulatory behaviors, such as finger sucking or rocking
Begging or stealing food
Absenteeism from school
Substance abuse
Vandalism or shoplifting

Emotional Abuse and Neglect

Suggestive Physical Findings

Growth failure (failure to thrive)
Eating or feeding disorder
Enuresis
Sleep disorder

Suggestive Behaviors

Self-stimulatory behaviors, such as biting, rocking, or sucking
During infancy, lack of social smile and stranger anxiety
Withdrawal from environment and people
Unusual fearfulness
Antisocial behavior, such as destructiveness, stealing, cruelty to animals or people
Extremes of behavior, such as overly compliant and passive or aggressive and demanding
Lags in emotional and intellectual development, especially language
Suicide attempts

Physical Abuse

Suggestive Physical Findings

Bruises and welts (may be in various stages of healing)
- On face, lips, mouth, back, buttocks, thighs, or areas of torso
- Regular patterns descriptive of object used, such as belt buckle, hand, wire hanger, chain, wooden spoon, squeeze or pinch marks
- May be present in various stages of healing

Burns
- On soles, palms, back, or buttocks
- Patterns descriptive of object used, such as round cigar or cigarette burns; sharply demarcated areas from immersion in scalding water; rope burns on wrists or ankles from being bound; burns in the shape of an iron, radiator, or electric stove burner
- Absence of "splash" marks and presence of symmetric burns
- Stun gun injury: Lesions circular, fairly uniform (≤0.5 cm), and paired about 5 cm apart

Fractures and dislocations
- Skull, nose, or facial structures
- Injury denoting type of abuse, such as spiral fracture or dislocation from twisting of an extremity or whiplash from shaking the child
- Multiple new or old fractures in various stages of healing

Lacerations and abrasions
- On backs of arms, legs, torso, face, or external genitalia
- Unusual symptoms, such as abdominal swelling, pain, and vomiting from punching
- Descriptive marks, such as from human bites or pulling out of hair

Chemical
- Unexplained repeated poisoning, especially drug overdose
- Unexplained sudden illness, such as hypoglycemia from insulin administration

Suggestive Behaviors

Wary of physical contact with adults
Apparent fear of parents or going home
Lying very still while surveying environment
Inappropriate reaction to injury, such as failure to cry from pain
Lack of reaction to frightening events
Apprehensive when hearing other children cry
Indiscriminate friendliness and displays of affection
Superficial relationships
Acting-out behavior, such as aggression, to seek attention
Withdrawal behavior

Sexual Abuse

Suggestive Physical Findings

Bruises, bleeding, lacerations, or irritation of external genitalia, anus, mouth, or throat
Torn, stained, or bloody underclothing
Pain on urination or pain, swelling, and itching of genital area
Penile discharge
Sexually transmitted disease, nonspecific vaginitis
Difficulty in walking or sitting
Unusual odor in the genital area
Recurrent urinary tract infections
Presence of sperm
Pregnancy in young adolescent

Suggestive Behaviors

Sudden emergence of sexually related problems, including excessive or public masturbation, age-inappropriate sexual play, promiscuity, or overtly seductive behavior
Withdrawn behavior, excessive daydreaming
Preoccupation with fantasies, especially in play
Poor relationships with peers
Sudden changes, such as anxiety, loss or gain of weight, clinging behavior
In incestuous relationships, excessive anger at mother for not protecting daughter
Regressive behavior, such as bedwetting or thumb sucking
Sudden onset of phobias or fears, particularly fears of the dark, men, strangers, or particular settings or situations (e.g., undue fear of leaving the house or staying at the daycare center or the babysitter's house)
Running away from home
Substance abuse, particularly of alcohol or mood-elevating drugs
Profound and rapid personality changes, especially extreme depression, hostility, and aggression (often accompanied by social withdrawal)
Rapidly declining school performance
Suicidal attempts or ideation

All evidence collected must adhere to strict guidelines for legal purposes; the chain of custody must be appropriately maintained with local law enforcement personnel. Documentation on the chain of custody form should include the names of persons collecting and receiving evidence (e.g., photographs, DNA samples), types of evidence collected and received, and date of receipt (Lyden, 2011).

Neglect and Emotional Abuse

Neglect from deprivation of necessities is easier to identify than emotional neglect or psychologic maltreatment because physical signs are usually evident. Assessment of the child's height, weight, nutritional status, hygiene, and age-appropriate interactions is important for the overall picture of potential neglect. Emotional maltreatment may be readily suspected, but it is difficult to substantiate. Physical signs are often nonspecific, and nurses must rely on behavioral indicators, which range from depression to acting-out behavior, to help identify a possibly abusive situation. Any persistent and unexplained change in the child's behavior is an important clue to possible emotional abuse.

Sexual Abuse

Identifying instances of sexual abuse is particularly difficult because, often, few if any obvious physical indications of the activity exist. Physical signs vary and may include any of those listed in Box 13.6 for sexual abuse. The goal of the physical examination is to document genital findings. In most cases, the genital examination findings are normal, which does not mean that sexual abuse did not occur. Fondling or genital-to-genital contact without penetration may leave no physical findings. Forensic evidence obtained directly from a prepubertal victim's body diminishes greatly after 24 hours, with the best chance for evidence collection coming from bed linens or the child's underwear (Girardet, Bolton, Lohoti, et al., 2011). The female genital examination should include a description of the vulva, hymen, and surrounding tissue. Abnormal findings of concern are injuries to the posterior vulva or the lower half of the hymeneal ring or abrasions, bruising, or bleeding of the genital or anal tissue. It is often helpful to use a magnifying instrument (colposcope) to detect subtle injuries. There are many variants of normal findings for female genital anatomy, so it is recommended that the examination be done by a practitioner experienced with these types of cases. Contrary to popular myth, the size of the hymeneal opening is not predictive of the likelihood of sexual abuse (Adams, 2011). For male victims, swelling, abrasions, or bruising of the genital tissue raises concerns for abuse. Examine the anal area for symmetry, tone, fissures, or scars. Genital tissue heals very quickly and most often without scars. Therefore unless the child is seen within a few days of injury, the genital tissue may appear normal. In addition, the vaginal and anal mucosa is elastic; therefore penetration without disruption of tissue is possible. This defies another myth that there is always evidence of female virginity. Consider the collection of specimens for determining the presence of sexually transmitted infections, which may have been contracted during the sexual contact.

Nursing Care Management

Protect the Child From Further Abuse

Initially, identification of instances of suspected abuse or neglect is essential. The nurse may come in contact with abused children in an emergency department, practitioner's office, home, daycare center, or school.

! NURSING ALERT

The priority is to remove the child from the abusive situation to prevent further injury.

All states and provinces in North America have laws for mandatory reporting of child maltreatment. Suspected child abuse is reported to the local authorities.[d] Referrals usually come to the state child welfare department and are assigned to a caseworker in an agency, such as Child Protective Services. After a referral has been made, a caseworker is assigned to investigate the report. Based on the findings, the child is left in the home or temporarily removed.

A court proceeding may be necessary before the child can be placed outside the home or when parental rights are to be terminated. When the courts are involved, they usually require firsthand testimony by the referring parties. Nurses may be subpoenaed to appear in court, or their notes may be introduced as evidence in court hearings. Accurate and factual documentation is essential. Behaviors are described, not interpreted, and are recorded daily to establish a progress record (see Nursing Care Guidelines box). Conversations among the nurse, child, and parent are recorded verbatim as much as possible.

NURSING CARE GUIDELINES

Recording Assessment Data in Suspected Abuse

History of Injury

Date, time, and place of occurrence
Sequence of events with recorded times
Presence of witnesses, especially person caring for child at time of incident
Time lapse between occurrence of injury and initiation of treatment
Interview with child when appropriate, including verbal quotations and information from drawing or other play activities
Interview with parent, witnesses, and other significant persons, including verbal quotations
Description of parent-child interactions (verbal interactions, eye contact, touching, parental concern)
Name, age, and condition of other children in home (if possible)

Physical Examination

Location, size, shape, and color of bruises; approximate location, size, and shape on drawing of body outline
Distinguishing characteristics, such as a bruise in the shape of a hand or a round burn (possibly caused by cigarette)
Symmetry or asymmetry of injury; presence of other injuries
Degree of pain; any bone tenderness
Evidence of past injuries; general state of health and hygiene
Developmental level of child; screening test (see Chapter 3, Developmental Assessment)

Support the Child

Children suspected of being abused are often hospitalized for medical management of their injuries and to allow further assessment of their safety needs. The needs of these children are the same as those of any hospitalized child. The child should be treated as a child with the usual physical needs, developmental tasks, and play interests—not as a victim of abuse. The goal of the nurse-child relationship is to provide a role model for the parents in helping them to relate positively and constructively to their child and to foster a therapeutic environment for the child in his or her reprieve from the abusing situation.

[d]Telephone numbers are usually listed under "Child Abuse" in the business white pages of the local directory, or you can call the emergency child abuse hotline: 800-422-4453 (800-4-A-CHILD).

Support the Family

The nurse also encourages the child's relationship with nonoffending parents. The nurse does not become a substitute parent but rather acts as a role model for parents in helping them to relate positively and constructively to their child. When parental ignorance of childrearing practices has played a part in the abuse, the nurse can educate the parents on children's physical and emotional needs. Because of the parents' own childrearing, they may not be aware of nonviolent methods of discipline, such as time-outs. They may also need help in dealing with their frustration so that they do not vent anger on the child. Because these parents may be sensitive to criticism or resistant to authority figures, teaching is implemented through demonstration and example rather than through lecturing. Praise any competent parenting abilities they demonstrate to promote their sense of parental adequacy.

Advise family members to encourage the child to resume normal activities and observe the child for signs of distress (see Chapter 16, Posttraumatic Stress Disorder). Children express their feelings primarily through behavior. Parents should be alert for changes in behavior that indicate distress resulting from the incident, such as remaining in the house, refusing to go to school, changes in sleeping patterns, and frequency of dreams and nightmares.

Referral to appropriate social service agencies is also essential. Many abusive parents live in poverty, and the daily stresses imposed by their circumstances are overwhelming. Seek resources for financial aid, improved housing, and child care. Self-help groups also provide important services. Groups such as Parents Anonymous[e] (a group for parents who have abused or fear that they may abuse their child but only in terms of physical abuse, not sexual abuse) are accepting and nonjudgmental.

Plan for Discharge

Discharge planning should begin as soon as the legal disposition for placement has been decided, which may be temporary foster home placement, return to the parents, or permanent termination of parental rights. The latter is the most drastic solution, but it is necessary in situations of life-threatening abuse. Whenever children are sent to a foster home or juvenile institution, they must be allowed an opportunity to express their feelings. No matter how severe the abuse, they usually mourn the loss of their parents. They need help to understand why they must not return home and that this new home is in no way a punishment. Whenever possible, foster parents are encouraged to visit in the hospital, and the nurse should take an active role in helping the new parents understand the child, as well as the child's health care needs, because studies have shown that the health care needs of children in foster care often go unmet (Schneiderman, Smith, & Palinkas, 2012).

Prevent Abuse

Prevention of child maltreatment has been an extremely difficult goal. However, nurses have played an important role in such programs. For example, home visits based on identified risk factors (such as mothers who are teenagers, unmarried, or of low socioeconomic status) were noted to be an effective preventive measure (Selph, Bougatsos, Blazina, et al., 2013). The nurses provided information on normal child growth and development and routine health care needs, served as informal support persons, and referred families to appropriate services when a need for assistance was identified. The Nurse-Family Partnership is one program that has demonstrated evidence-based interventions resulting in the prevention of child maltreatment (Lane, 2014).

Nurses in a variety of settings can implement similar activities. For example, nurses in prenatal clinics can prepare expectant families for adjustment to parenthood. Nursery and postpartum nurses can foster the attachment process by encouraging parents to hold and look at their infant, as well as teach coping mechanisms for prolonged crying. Nurses in neonatal intensive care units can minimize the effects of separation by encouraging parents to visit and can help parents become comfortable caring for their child. Nurses in ambulatory settings can teach parents appropriate methods of bathing, feeding, toileting, disciplining, and preventing injuries while stressing the normal needs and developmental characteristics of children. Nurses must be sensitive to parental needs for attention, reassurance, and reinforcement, and should refer parents to community services and self-help groups.

Unlike preventive efforts for neglect and physical abuse, which have been aimed at the potential offender, prevention of child sexual abuse has centered on education of children to protect themselves. Materials that describe sexual abuse and its prevention are available for parents.[f] Helpful games such as "What if the babysitter wants to wrestle and hug but tells you to keep it a secret?" can be used to explore dangerous situations in advance and help children learn the importance of saying "no." They need reassurance that no matter what the other person says or does, the parents want to know about it and will not punish them. Even if children participate in the activity before telling their parents, they must be reassured that it was not their fault. It is equally important to teach children safety in terms of potential risk situations. Several suggestions for parents regarding protecting and educating children against possible molestation are presented in the Family-Centered Care box. The nurse is frequently in a position to discuss the topic of abuse with parents and to provide guidelines. In addition, parents need to be made aware that "nice" people, including friends and relatives, can be offenders; parents should carefully observe how others act toward the child. A sudden change in the child's behavior and a response such as "I don't like Uncle Bob anymore" are clues to investigate the relationship. In the event of any doubt, prevent further solitary encounters with this person and the child. It is sometimes to the child's great misfortune that parents do not take certain comments seriously, such as "He hugs me too tight" or "I don't want to go with him." Casual parental statements such as "He just loves you" or "You do whatever adults tell you to do" can place children in jeopardy. Health professionals must alert parents to such dangers and guide them toward an appreciation of the problem, providing concrete guidelines toward child education and protection.

FAMILY-CENTERED CARE

Preventing and Dealing With Sexual Abuse of Children

Sexual assault of children is much more common than most people realize. It may be preventable if children have good preparation. *To provide protection and preparation:*

- Pay careful attention to who is around children. (Unwanted touch may come from someone liked and trusted.)
- Back up a child's right to say no.
- Encourage communication by taking seriously what children say.
- Take a second look at signals of potential danger.
- Refuse to leave children in the company of those who are not trusted.
- Include information about sexual assault when teaching about safety.
- Provide specific definitions and examples of sexual assault.
- Remind children that even "nice" people sometimes do mean things.
- Urge children to tell about *anybody* who causes them to be uncomfortable.
- Prepare children to deal with bribes, threats, and possible physical force.
- Virtually eliminate secrets between children and parents.
- Teach children how to say no, ask for help, and control who touches them and how.
- Model self-protective and limit-setting behavior for children.

If it ever becomes necessary to help a child recover from a sexual assault:

- Listen carefully to understand the child.
- Support the child for telling through praise, belief, sympathy, and lack of blame.
- Know local resources and choose help carefully.
- Provide opportunities to talk about the assault.
- Provide opportunities for the entire family to go through a recovery process.

Sexual assault affects everyone. To help deal with this social problem:

- Provide care and support to those who have been victimized.
- Recognize that offenders may not change behavior even with intervention.
- Organize neighborhood programs to support each other's efforts to protect children.
- Encourage schools to provide information about sexual assault as a problem of health and safety.
- Organize community groups to support educational treatment and law enforcement programs.

Modified from Adams, C., & Fay, J. (1981). *No more secrets: Protecting your child from sexual assault.* San Luis Obispo, CA: Impact.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A mother expresses concerns about her 4-year-old son experiencing "terrible dreams". The nurse conducts a health history and assessment on the child relating to the mother's concern and notes the findings below. **Select all the history and assessment findings that require follow-up. Select all that apply.**

A. The child awakens at night, cries and screams while being unaware of his mother by his side.
B. The mother believes the child will grow out of this stage when he is a little older.
C. The child has a specific nighttime routine that is helpful in calming the child.
D. The mother watches frightening TV shows with him to help him understand what is real.
E. The mother admits giving the child a "medication" to help him calm down when this occurs.
F. The child likes to color and draw pictures of his dreams.

2. A 3-year-old boy is brought to the emergency department by his parents after he was noted to be "acting differently than normal" a few hours ago while he was being cared for by his grandmother. When she went to take her evening medication, the grandmother noted that her pill container had been opened and some pills were missing. The parents state that the grandmother has a heart condition. The nurse conducts a history and assessment and notes the findings below. **Select all the history and assessment findings that would require the nurse to follow-up immediately. Select all that apply.**

A. The child has nausea and vomiting that began an hour ago
B. Temperature is 36.8°C (98.4°F).
C. Pulse is 48 beats/min
D. Respiration rate is 20 breaths/min
E. Heart rate is irregular
F. Child is irritable

3. The nurse is working with the family of a 4-year-old girl and have concerns about possible exposure to lead poisoning. The mother states they live in an old house, built in 1975 that has paint that is peeling off the side. The child frequently plays in the dirt where there were loose paint chips found. A lead blood level was obtained with a result of 8 mcg/dL. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**

Based on the child's history and assessment data, the nurse determines that the laboratory findings reflect the need for ____1____. The nurse would educate the mother to complete follow-up lead testing within ____2____ .

Options for 1	Options for 2
surveillance	1 month
treatment	1 week
chelation	6 months
nutrition	6 weeks
iron supplements	1 year

4. An 8-month-old infant girl is seen in the Emergency Department (ED), because the mother states the child fell down the stairs yesterday and hit her head. The infant presents with vomiting for the past 2 hours, refusing to eat or drink, and has become more listless and tired since the fall. While reading the infant's electronic medical record, the nurse notes a previous ED visit two months for a burn incident, and there is a history of maternal drug abuse also documented. **Select all the additional history and assessment findings below that require the nurse to intervene. Select all that apply.**

A. Bruises on her arms and legs
B. No other siblings
C. Mother is unable to provide details on how the infant fell down the stairs
D. Infant is wrapped warmly in a blanket and being held by the mother
E. Weight loss since last visit

PROMOTING OPTIMAL GROWTH AND DEVELOPMENT

The segment of the life span that extends from age 6 to approximately age 12 has a variety of labels, each of which describes an important characteristic of the period. These middle years are most often referred to as *school-age years* or *the school years*. This period begins with entrance into the school environment, which has a significant impact on development and relationships.

Physiologically, the middle years begin with the shedding of the first deciduous tooth and end at puberty with the acquisition of the final permanent teeth (with the exception of the wisdom teeth). Before 5 or 6 years old, children have progressed from helpless infants to sturdy, complicated individuals with an ability to communicate, conceptualize in a limited way, and become involved in complex social and motor behaviors. Physical growth has been equally rapid during the preschool-age years. In contrast, the period of middle childhood, between the rapid growth of early childhood and the prepubescent growth spurt, is a time of gradual growth and development with more even progress in both physical and emotional aspects.

BIOLOGIC DEVELOPMENT

During middle childhood, growth in height and weight assumes a slower but steady pace as compared with the earlier years. Between 6 and 12 years old, children grow an average of 5 cm (2 inches) per year to gain 30 to 60 cm (1 to 2 feet) in height and almost double their weight, increasing 2 to 3 kg (4.4 to 6.6 pounds) per year. The average 6-year-old child is about 116 cm (46 inches) tall and weighs about 21 kg (46 pounds); the average 12-year-old child is about 150 cm (59 inches) tall and weighs approximately 40 kg (88 pounds). During this age, girls and boys differ little in size, although boys tend to be slightly taller and somewhat heavier than girls. Toward the end of the school-age years, both boys and girls begin to increase in size, although most girls begin to surpass boys in both height and weight, to the acute discomfort of both girls and boys.

Physical Changes

School-age children are more graceful than they were as preschoolers, and they are steadier on their feet. Their body proportions take on a slimmer look, with longer legs, varying body proportion, and a lower center of gravity. Posture improves over that of the preschool period to facilitate locomotion and efficiency in using the arms and trunk. These proportions make climbing, bicycle riding, and other activities easier. Fat gradually diminishes, and its distribution patterns change, contributing to the thinner appearance of children during these middle years, although as previously stated they continue to gain weight.

Accompanying the skeletal lengthening and fat diminution is an increase in the percentage of body weight represented by muscle tissue. By the end of this age period, both boys and girls double their strength and physical capabilities, and their steady and relatively consistent development of coordination increases their poise and skill. However, this increased strength is often misleading. Although strength increases, muscles are still functionally immature when compared with those of adolescents, and they are more readily damaged by muscular injury caused by overuse. Thus caution must be used in sports activities for children in this age-group.

The most pronounced changes that indicate increasing maturity in children are a decrease in head circumference in relation to standing height, a decrease in waist circumference in relation to height, and an increase in leg length in relation to height. These indicators often provide a clue to a child's degree of physical maturity. There appears to be a correlation between physical indications of maturity and success in school.

Certain physiologic and anatomic characteristics are typical of school-age children. Facial proportions change as the face grows faster in relation to the remainder of the cranium. The skull and brain grow very slowly

Fig. 14.1 Middle childhood is the stage of development when deciduous teeth are shed.

during this period and increase little in size thereafter. Because all of the primary (deciduous) teeth are lost during this age span, middle childhood is sometimes known as the age of the loose tooth (Fig. 14.1). The early years of middle childhood, when the new secondary (permanent) teeth appear too large for the face, are known as the ugly duckling stage.

Maturation of Systems

Maturity of the gastrointestinal system is reflected in fewer stomach upsets, better maintenance of blood glucose levels, and an increased stomach capacity, which permits retention of food for longer periods. School-age children do not need to be fed as promptly or as frequently as preschool-age children. Caloric needs (kcal/kg) are less than they were in the preschool years and lower than they will be during the coming adolescent growth spurt.

Physical maturation is evident in other body tissues and organs. Bladder capacity, although differing widely among individual children, is generally greater in girls than in boys. The heart grows more slowly during the middle years and is smaller in relation to the rest of the body than at any other period of life. Heart and respiratory rates steadily decrease, and blood pressure increases from 6 to 12 years old.

The immune system becomes more competent in its ability to localize infections and to produce an antibody-antigen response. However, children commonly have several infections in the first 1 to 2 years of school because of increased exposure to others in their school classes.

Bones continue to ossify throughout childhood but yield to pressure and muscle pulls more readily than with mature bones. Children need ample opportunity to move around, but they should observe caution in carrying heavy loads. For example, they should shift books or tote bags from one arm to the other. Backpacks, when worn correctly, distribute weight more evenly.

Wider differences between children are observed at the end of middle childhood than at the beginning. These differences become increasingly apparent and, if they are extreme or unique, may create emotional problems. The associated characteristics of height and weight relationships, rapid or slow growth, and other important features of development should be explained to children and their families. Physical maturity is not necessarily correlated with emotional and social maturity. Seven-year-old children who look like 10-year-old children will think and act like 7-year-olds. To expect behaviors appropriate for an older age is unrealistic and can be detrimental to their development of competence and self-esteem. Conversely, to treat 10-year-old children who look young physically as though they were younger is an equal disservice to them.

Prepubescence

Preadolescence is the period that begins toward the end of middle childhood and ends with the 13th birthday. **Puberty** signals the beginning of the development of secondary sex characteristics, and **prepubescence**, the 2-year period that precedes puberty, typically occurs during preadolescence.

Toward the end of middle childhood, the discrepancies in growth and maturation between boys and girls become apparent. On average, there is a difference of approximately 2 years between girls and boys in the age of onset of pubescence. This is a period of rapid growth in height and weight, especially for girls.

There is no universal age at which children assume the characteristics of prepubescence. The first physiologic signs appear at about 9 years old (particularly in girls) and are usually clearly evident in 11- to 12-year-old children. Although preadolescent children do not want to be different, variability in physical growth and physiologic changes among children of the same sex and between the two sexes is often striking at this time. This variability, especially in relation to the onset of secondary sex characteristics, is of great concern to preadolescents. Either early or late appearance of these characteristics is a source of embarrassment and uneasiness to both sexes.

Preadolescence is a time when considerable overlapping of developmental characteristics occurs, with elements of both middle childhood and early adolescence apparent. However, several unique characteristics set this period apart from others. In general, puberty begins at 10 years old in girls and at 12 years old in boys, but it can be normal for either sex after 8 years old. Boys experience little visible sexual maturation during preadolescence, whereas girls' bodies may change quite visibly.

PSYCHOSOCIAL DEVELOPMENT: DEVELOPING A SENSE OF INDUSTRY (ERIKSON)

Freud described middle childhood as the **latency period**, a time of tranquility between the Oedipal phase of early childhood and the eroticism of adolescence. During this time, children experience relationships with same-sex peers following the indifference of earlier years and preceding the heterosexual fascination that occurs for most boys and girls in puberty.

Successful mastery of Erikson's first three stages of psychosocial development is important in terms of development of a healthy personality. Successful completion of these stages requires a loving environment within a stable family unit. These experiences prepare the child to engage in experiences and relationships beyond the intimate family group. Children who do not experience a stable family life often have a difficult time establishing relationships.

A **sense of industry**, or a sense of accomplishment, occurs somewhere between 6 years old and adolescence. School-age children are eager to develop skills and participate in meaningful and socially useful work. Interests expand in the middle years, and with a growing sense of independence, children want to engage in tasks that can be carried through to completion (Fig. 14.2). Failure to develop a sense of accomplishment may result in a feeling of inferiority.

Many aspects of industry contribute to the child's sense of competence and mastery. Children gain satisfaction from independent behavior in exploring and manipulating their environment and from interaction with peers. Reinforcement in the form of grades, material rewards, additional privileges, and recognition provides encouragement and stimulation.

A sense of accomplishment also involves the ability to cooperate, to compete with others, and to cope effectively with people. Middle childhood is the time when children learn the value of doing things with others and the benefits derived from division of labor in the accomplishment of goals. Peer approval is a strong motivating power.

Fig. 14.2 School-age children are motivated to complete tasks. **A,** Working alone. **B,** Working with others.

The danger inherent in this period of development is the occurrence of situations that might result in a sense of inadequacy or **inferiority**. This may happen if the previous stages have not been successfully mastered or if a child is incapable of or unprepared to assume responsibilities associated with developing sense of accomplishment. Children with physical and mental limitations may be at a disadvantage in the acquisition of certain skills. When the reward structure is based on evidence of mastery, children who are incapable of developing these skills risk feeling inadequate and inferior.

Even children without chronic disabilities may experience feelings of inadequacy in some areas. No child is able to do everything well, and children must learn that they will not be able to master every skill they attempt. All children, even children who usually have positive attitudes toward work and their own abilities, will feel some degree of inferiority when they encounter specific skills that they cannot master.

Children need and want real achievement. Children achieve a sense of industry when they have access to tasks that need to be done and they are able to complete the tasks well despite individual differences in their innate capacities and emotional development.

COGNITIVE DEVELOPMENT (PIAGET)

When children enter the school years, they begin to acquire the ability to relate a series of events to mental representations that can be expressed both verbally and symbolically. This is the stage Piaget describes as **concrete operations**, when children can use thought processes to experience events and actions. The rigid, egocentric view of the preschool years is replaced by thought processes that allow children to see things from another's point of view. Their steady reduction in egocentricity helps form the basis for logical thought and the development and maturation of morality.

During this stage, children develop an understanding of relationships between things and ideas. They progress from making judgments based on what they see (perceptual thinking) to making judgments based on what they reason (conceptual thinking). They are increasingly able to master symbols and to use their memories of past experiences to evaluate and interpret the present.

One of the major cognitive tasks of school-age children is mastering the concept of **conservation** (Fig. 14.3). There is a developmental sequence in children's capacity to understand conservation. Children usually grasp conservation of numbers (ages 5 to 6) before conservation of substance. For example, they first recognize that 7 remains 7 whether it is represented by 3 + 4, 2 + 5, 7 buttons, or 7 stars. Conservation of liquids, mass, and length usually is accomplished at about ages 6 to 7. At this time, they recognize that changing the shape of a substance, such as a lump of clay, does not alter its total mass. They learn conservation of weight sometime later (ages 9 to 10) and conservation of volume or displacement last (ages 9 to 12). For example, they no longer perceive a tall, thin glass of water as containing a greater volume than a short, wide glass; they can distinguish between the weights of items regardless of their size. School-age children also develop classification skills. They can group and sort objects according to the attributes these objects share, place things in a sensible and logical order, and hold a concept in mind while making decisions based on that concept. In middle childhood, children derive a great deal of enjoyment from classifying and ordering their environment. They become occupied with collections of objects, such as stickers, shells, dolls, cars, cards, and stuffed animals. They may even begin to order friends and relationships (e.g., best friend, second best friend).

They develop the ability to understand relational terms and concepts, such as yesterday and tomorrow, bigger and smaller, darker and paler, heavier and lighter, to the right of and to the left of, and more than and less than. They view family relationships in terms of reciprocal roles (e.g., to be a brother, one must have a sibling).

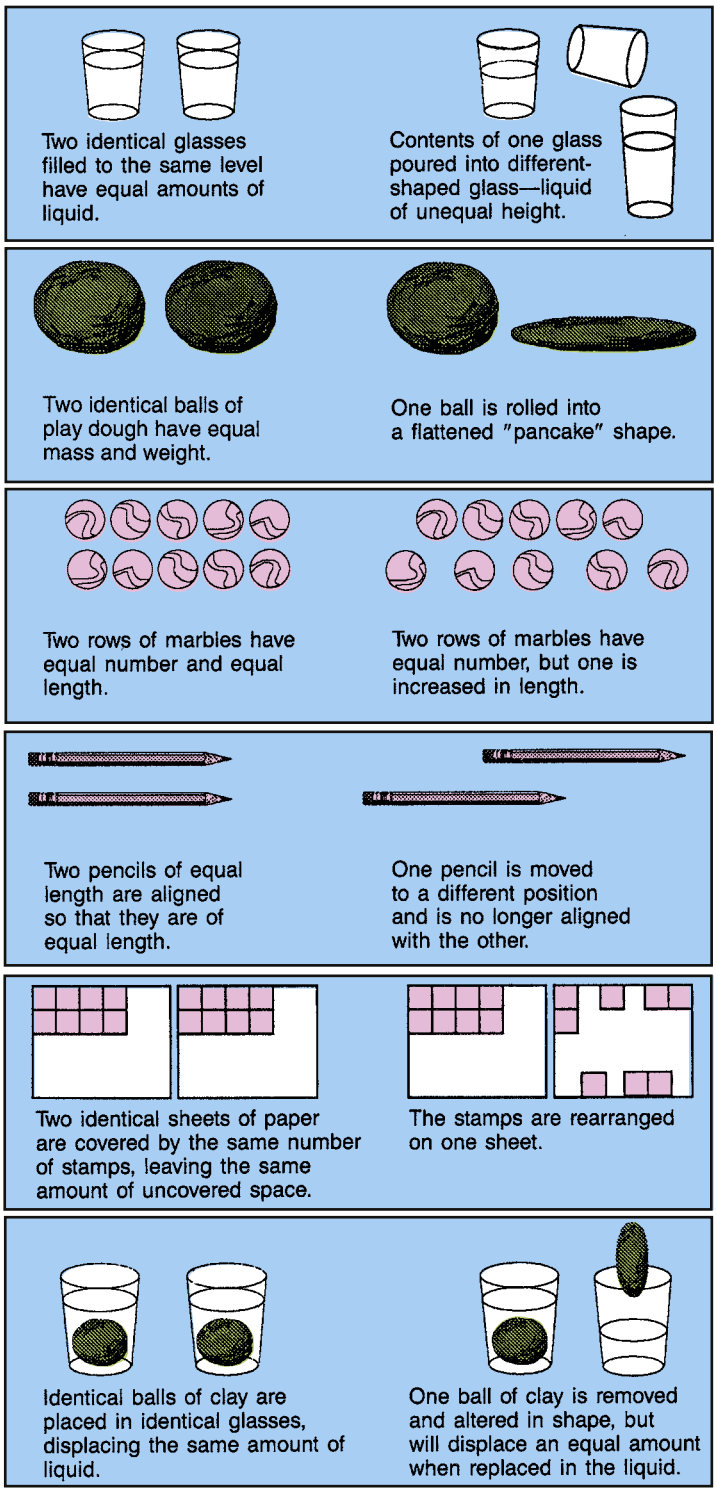
School-age children learn the alphabet and the world of symbols called *words,* which can be arranged in terms of structure and their relationship to the alphabet. They learn to tell time, to see the relationship of events in time (history) and places in space (geography), and to combine time and space relationships (geology and astronomy).

The ability to read is acquired during the school years and becomes the most significant and valuable tool for independent inquiry. Children's capacity to explore, imagine, and expand their knowledge is enhanced by reading.

MORAL DEVELOPMENT (KOHLBERG)

As children move from egocentrism to more logical patterns of thought, they also move through stages in the development of conscience and moral standards. Young children do not believe that standards of behavior come from within themselves but that rules are established and set down by others. During the preschool years, children perceive rules as definite and require no reason or explanation. They learn standards for acceptable behavior, act according to these standards, and feel guilty when they violate them. Although children 6 or 7 years old know the rules and behaviors expected of them, they do not understand the reasons behind them. Rewards and punishments guide their judgment; a "bad act" is one that breaks a rule or causes harm. Young children believe that what other people tell them to do is right and that what they themselves think is wrong. Consequently, children 6 or 7 years old may interpret accidents or misfortunes as punishment for "bad" acts.

Older school-age children are able to judge an act by the intentions that prompted it rather than just its consequences. Rules and judgments become less absolute and authoritarian and begin to be founded



Liquids: Conserving child recognizes that each glass contains the same amount of liquid. Usually attained at age 5 to 7 years.

Mass (continuous substance): Conserving child recognizes that each object contains the same amount of dough. Usually attained at age 5 to 7 years.
Weight: Conserving child recognizes that each object weighs the same. Usually attained at age 9 to 10 years.

Number: Conserving child recognizes that each row contains the same number of marbles. Usually attained at age 5 to 7 years.

Length: Conserving child recognizes that the two pencils are still of equal length. Usually attained at age 6 to 7 years.

Area: Conserving child recognizes that the amount of uncovered area remains the same on each sheet. Usually attained at age 9 to 10 years.

Volume (water displacement): Conserving child recognizes that water levels are the same, since only the shape of the clay has changed. Pieces of clay displace the same volume of liquid. Usually attained at age 9 to 12 years.

Fig. 14.3 Common examples that demonstrate the child's ability to conserve (ages are only approximate).

on the needs and desires of others. For older children, a rule violation is likely to be viewed in relation to the total context in which it appears. The situation, as well as the morality of the rule itself, influences reactions. Although younger children judge an act only according to whether it is right or wrong, older children take into account different points of view. They are able to understand and accept the concept of treating others as they would like to be treated.

SPIRITUAL DEVELOPMENT

Children at this age think in concrete terms but are avid learners and have a great desire to learn about their God or deity. They picture God as human and use adjectives such as "loving" and "helping" to describe their deity. They are fascinated by the concepts of hell and heaven, with a developing conscience and concern about rules, and they may fear going to hell for misbehavior. School-age children want and expect

to be punished for misbehavior and, when given the option, tend to choose a punishment that "fits the crime." Often they view illness or injury as a punishment for a real or imagined misdeed. The beliefs and ideals of family and religious persons are more influential than those of their peers in matters of faith.

School-age children begin to learn the difference between the natural and the supernatural but have difficulty understanding symbols. Consequently, religious concepts must be presented to them in concrete terms. Prayer or other religious rituals comfort them, and if these activities are a part of their daily lives, they can help them cope with threatening situations. Their petitions to their God in prayers tend to be for tangible rewards. Although younger children expect their prayers to be answered, as they get older they begin to recognize that this does not always occur, and they become less concerned when their prayers are not answered. They are able to discuss their feelings about their faith and how it relates to their lives (see Cultural Considerations box).

CULTURAL CONSIDERATIONS

Religious Orientation

Many schools and communities have a Judeo-Christian orientation toward prayer, holidays, and values. This may result in conflict and discomfort for children of other religious or ethnic groups. Sensitivity must be exercised so as not to offend and confuse children from other religious backgrounds, such as the Buddhist, Hindu, and Muslim faiths, and those with no religious backgrounds.

Fig. 14.4 School-age children enjoy engaging in activities with a "best friend."

SOCIAL DEVELOPMENT

Peer group identification is an important factor in gaining independence from parents. Peer groups have a culture of their own with secrets, traditions, and codes of ethics that promote feelings of solidarity and detachment from adults. Through peer relationships, children learn how to deal with dominance and hostility, how to relate to persons in positions of leadership and authority, and how to explore ideas and the physical environment. The aid and support of the group provide children with enough security to risk the moderate parental rejection brought about by small victories in the development of independence.

A child's concept of the appropriate sex role is acquired through relationships with peers. During the early school years, few gender differences exist in the play experiences of children. Both girls and boys share games and other activities. However, in the later school years, the differences in the play of boys and girls become more marked.

Social Relationships and Cooperation

Daily relationships with peers provide important social interactions for school-age children. For the first time, children join group activities with unrestrained enthusiasm and steady participation. Previous interactions were limited to short periods under considerable adult supervision. With increased skills and wider opportunities, children become involved with one or more peer groups in which they can gain status as respected members.

Valuable lessons are learned from daily interaction with age-mates. First, children learn to appreciate the numerous and varied points of view that are represented in the peer group. As children interact with peers who see the world in ways that are somewhat different from their own, they become aware of the limits of their own point of view. Because age-mates are peers and are not forced to accept each other's ideas as they are expected to accept those of adults, other children have a significant influence on decreasing the egocentric outlook of the child. Consequently, children learn to argue, persuade, bargain, cooperate, and compromise to maintain friendships.

Second, children become increasingly sensitive to the social norms and pressures of the peer group. The peer group establishes standards for acceptance and rejection, and children are often willing to modify their behavior to be accepted by the group. The need for peer approval becomes a powerful influence toward conformity. Children learn to dress, talk, and behave in a manner acceptable to the group. A variety of roles, such as class joker or class hero, may be assumed by individual children to gain approval from the group.

Third, the interaction among peers leads to the formation of intimate friendships between same-sex peers. The school-age period is the time when children have "best friends" with whom they share secrets, private jokes, and adventures; they come to one another's aid in times of trouble. In the course of these friendships, children also fight, threaten each other, break up, and reunite. These dyadic relationships, in which the child experiences love and closeness with a peer, seem to be important as a foundation for relationships in adulthood (Fig. 14.4).

Clubs and Peer Groups

One of the outstanding characteristics of middle childhood is the formation of formalized groups, or clubs. A prominent feature of these groups is the code of rigid rules imposed on the members. There is exclusiveness in the selection of persons who have the privilege of joining. Acceptance in the group is often determined on a pass–fail basis according to social or behavioral criteria. Conformity is the core of the group structure. There are often secret codes, shared interests, special styles of dress, and special words that signify membership in the group. Each child must abide by a standard of behavior established by the members. Conforming to the rules provides children with feelings of security and relieves them of the responsibility of making decisions. By merging their identities with those of their peers, children are able

to move from the family group to an outside group as a step toward seeking further independence. Peer groups and clubs allow children to substitute conformity to a peer group for conformity to a family at a time when children are still too insecure to function independently.

During the early school years, groups are usually small and loosely organized, with changing membership and no formal structure. They do not demonstrate the elements of cooperation and order that are seen in groups of older children. In general, girls' groups are less formalized than boys' are, and although there may be a mixture of both sexes in the early school years, the groups of later school years are composed predominantly of children of the same sex. Common interests are the basis around which the group is structured.

Poor relationships with peers and a lack of group identification can contribute to bullying. **Bullying** is any recurring activity that intends to cause harm, distress, or control toward another in which there is a perceived imbalance of power between the aggressor(s) and the victim (Hensley, 2013). Although bullying can occur in any setting, it most often occurs in school hallways or on the playground where supervision is minimal but peers are present to witness the attack (Shetgiri, 2013). Cyber-bullying involves an electronic medium to harm or bother another individual and can be more harmful than traditional bullying, because the attack can instantly reach a wider audience while allowing the bully to remain anonymous (Sticca & Perren, 2013). Children who are targeted for bullying often have internalizing characteristics such as withdrawal, anxiety, depression, low self-esteem, and reduced assertiveness that may make them an easy target for bullying (Arseneault, Bowes, & Shakoor, 2010). Bullies are generally defiant toward adults, manipulative, and likely to break school rules. They have aggressive attitudes, a positive view of violence, and a lack of empathy and may experience or witness violence or abuse at home (Hensley, 2013). Boys who bully tend to use physical force, referred to as *direct bullying*, but girls usually use bullying methods, such as exclusion, gossip, or rumors, which are referred to as *indirect bullying* (Shetgiri, 2013).

The long-term consequences of bullying are significant. Future problems of bullies include a higher risk for conduct problems, hyperactivity, school dropout, unemployment, and participation in criminal behavior (Shetgiri, Lin, & Flores, 2012). Chronic bullies seem to continue their behaviors into adulthood, negatively influencing their ability to develop and maintain relationships. Victims of bullying are at increased risk for low self-esteem, anxiety, depression, feelings of insecurity, loneliness, poor academic performance, and psychosomatic complaints, such as feeling tense, tired, or dizzy (Giesbrecht, Leadbeater, & Macdonald, 2011). School personnel play an important role in implementing anti-bullying interventions in schools; however, research has recognized that involving the whole family in anti-bullying programs greatly increases success (Arseneault et al., 2010).

There are also dangers in peer group attachments that are too strong. Peer pressures force some children to take risks or engage in behaviors that are against their better judgment. A child's membership in a gang is associated with marked increases in serious delinquent behavior (Bradshaw, Waasdorp, Goldweber, et al., 2013). Peer group activities that result in unlawful or criminal **gang violence** are increasing in the United States (US Department of Justice, 2011). An integration of family-centered and school-based programs is needed to reduce the influences for children to become affiliated with gangs.

Relationships With Families

Although the peer group is influential and necessary for normal child development, parents are the primary influence in shaping their children's personalities, setting standards for behavior, and establishing value systems. Family values usually take precedence over peer value systems. Although children may appear to reject parental values while testing the new values of the peer group, ultimately they retain and incorporate into their own value systems the parental values they have found to be of worth.

In the middle school years, children want to spend more time in the company of peers, and they often prefer peer group activities to family activities. This can be disturbing to parents. Children become intolerant and critical of their parents, especially when their parents' ways deviate from those of the group. They discover that parents can be wrong, and they begin to question the knowledge and authority of their parents, who were previously considered to be all-knowing and all-powerful. Parents can best serve the interests of their children through tolerant understanding and support.

Although increased independence is the goal of middle childhood, children are not prepared to abandon all parental control. They need and want restrictions placed on their behavior, and they are not prepared to cope with all of the problems of their expanding environment. They feel more secure knowing there is an authority figure to implement controls and restrictions. Children may complain loudly about restrictions and try to break down parental barriers, but they are uneasy if they succeed in doing so. They respect adults who prevent them from acting on every urge. Children view this behavior as an expression of love and concern for their welfare.

Children also need their parents to be adults, not "pals." Sometimes parents, hurt by their children's rejection, attempt to maintain their love and gratitude by assuming the role of pal. Children need the stable, secure strength provided by mature adults to whom they can turn during troubled relationships with peers or stressful changes in their world. With a secure base in a loving family, children are able to develop the self-confidence and maturity needed to break loose from the group and stand independently.

Play

Play takes on new dimensions that reflect a new stage of development in the school years. Play involves increased physical skill, intellectual ability, and fantasy. In addition, children develop a sense of belonging to a team or club by forming groups and cliques. Belonging to a group is of vital importance.

Rules and Rituals

The need for conformity in middle childhood is strongly manifested in the activities and games of school-age children. In the preschool years, children's games were either invented for them or played in the company of a friend or an adult, and rules evolved with the game. Now children begin to see the need for rules, and their games have fixed and unvarying rules that may be bizarre and extraordinarily rigid. Part of the enjoyment of the game is knowing the rules because knowing means belonging. Conformity and ritual permeate their play and are also evident in their behavior and language. Childhood is full of chants and taunts, such as "Eeeny, meeny, miney, mo," "Last one is a rotten egg," and "Step on a crack, break your mother's back." Children derive a sense of pleasure and power from such sayings, which have been handed down with few changes through generations.

Team Play

A more complex form of play that evolves from the need for peer interaction is team games and sports. A referee, umpire, or person of authority may be required so that the rules can be followed more accurately. Team play teaches children to modify or exchange personal goals for goals of the group; it also teaches them that division of labor is an effective strategy for attaining a goal.

Team play can also contribute to children's social, intellectual, and skill growth (Eime, Young, Harvey, et al., 2013). Children work hard to

Fig. 14.5 Selecting a book with the assistance of an adult.

Fig. 14.6 School-age children take pride in learning new skills.

develop the skills needed to become team members, to improve their contribution to the group, and to anticipate the consequences of their behavior for the group. Team play helps stimulate cognitive growth because children are called on to learn many complex rules, make judgments about those rules, plan strategies, and assess the strengths and weaknesses of members of their own team and members of the opposing team.

Quiet Games and Activities

Although the play of school-age children can be highly active, they also enjoy many quiet and solitary activities. The middle years are the time for collections, and young school-age children's collections are an odd assortment of unrelated objects in messy, disorganized piles. Collections of later school years are more orderly and selective and often are organized in scrapbooks, on shelves, or in boxes.

School-age children become fascinated with complex board, card, or computer games that they can play alone or in groups. As in all games, adherence to the rules is fanatic. Disagreements over rules can cause much discussion and argument but are easily resolved by reading the rules of the game.

The newly acquired skill of reading becomes increasingly satisfying as school-age children expand their knowledge of the world through books (Fig. 14.5). School-age children never tire of stories and, as with preschool children, love to have stories read aloud. They also enjoy sewing, cooking, carpentry, gardening, and creative activities, such as painting. Many creative skills, such as music and art, as well as athletic skills such as swimming, karate, dancing, and skating, are learned during these years and continue to be enjoyed into adolescence and adulthood (Fig. 14.6).

Ego Mastery

Play affords children the means to acquire representational mastery over themselves, their environment, and others. Through play, children can feel as big, as powerful, and as skillful as their imaginations will allow. They can also feel in control and attain vicarious mastery and power over whomever and whatever they choose. School-age children still need the opportunity to use large muscles in exuberant outdoor play and the freedom to exert their newfound autonomy and initiative. They need space in which to exercise large muscles and to deal with tensions, frustrations, and hostility. Physical skills practiced and mastered in play help to develop a feeling of personal competence, which contributes to a sense of accomplishment and provides status in their peer group.

DEVELOPING A SELF-CONCEPT

The term **self-concept** refers to a conscious awareness of self-perceptions, such as one's physical characteristics, abilities, values, self-ideals and expectancy, and idea of self in relation to others. It also includes one's body image, sexuality, and self-esteem. Although primary caregivers continue to exert influence on children's self-evaluation, the opinions of peers and teachers provide valuable input during middle childhood. With the emphasis on skill building and broadened social relationships, children are continually engaged in the process of self-evaluation.

Body Image

Body image is what children think about their bodies and is influenced, but not solely determined, by significant others. The number of significant others that influences children's perception of themselves increases with age. Children are acutely aware of their own bodies, the bodies of their peers, and those of adults. They are also aware of deviations from the norm. Physical impairments, such as hearing or visual defects, ears that "stick out," or birthmarks, assume great importance. Increasing awareness of these differences, especially when accompanied by unkind comments and taunts from others, may cause a child to feel inferior and less desirable. This is especially true if the defect interferes with the child's ability to participate in games and activities.

DEVELOPMENT OF SEXUALITY

Many children experience some form of sex play during or before preadolescence as a response to normal curiosity, not as a result of love or sexual urges. Children are experimentalists by nature, and sex play is incidental and transitory. Any adverse emotional consequences or guilt feelings depend on how the behavior is managed by the parents. Many parents discourage sexual exploration, either through subtle cues or expressions of anger or disgust at their child's behavior. These tactics clearly communicate to children that they should not engage in such activities, discourage questions about sex, and limit the sources of information.

Sex Education

An important component of ongoing sex education is effective communication with parents. If parents either repress the child's sexual curiosity or avoid dealing with it, the sexual information that the child receives may be acquired almost entirely from peers. A recent study found that the majority of parents of preadolescent

and adolescent children believed they were open with sex education discussions; however, only a few parents communicated direct information about safe sex practices (Hyde, Drennan, Butler, et al., 2013). When peers are the primary source of sexual information, it is often transmitted and exchanged in secret conversation and contains misinformation.

Although middle childhood is an ideal time for formal sex education, this subject has created considerable controversy. Many parents and groups are unconditionally opposed to the inclusion of sex education in schools. When sex education is presented from a life span perspective and treated as a normal part of growth and development, the information is less likely to contain overtones of uncertainty, guilt, or embarrassment that could in turn produce anxiety in children.

Nurse's Role in Sex Education

No matter where nurses practice, they can provide information on human sexuality to both parents and children. To discuss the topic adequately, nurses must have an understanding of the physiologic aspects of sexuality, know the common myths and misconceptions associated with sex and the reproductive process, understand cultural and societal values, and be aware of their own attitudes, feelings, and biases about sexuality.

When presenting sexual information to school-age children, nurses should treat sex as a normal part of growth and development. Questions should be answered honestly, in a matter-of-fact manner, and at the child's level of understanding. There may be times when boys and girls should be taught content separately; however, each group needs information about both sexes.

Children need help to differentiate sex and sexuality. Exercises on clarifying values, identifying role models, engaging in problem-solving skills, and practicing responsibility are important to prepare children for early adolescence and puberty. In addition, children need explanations of sexual information that is provided via the media or jokes. Information about anatomy, pregnancy, contraceptives, and sexually transmitted infections, including human immunodeficiency virus and human papillomavirus, should be presented in simple, accurate terms. Preadolescents need precise and concrete information that will allow them to answer questions such as, "What if I start my period in the middle of class?" or "How can I keep people from telling I have an erection?" It is important to tell children what they want to know and what they can expect to happen as they become mature sexually.

During encounters with parents, nurses can be open and available for questions and discussion. They can set an example by the language they use in discussing body parts and their function and by the way in which they deal with problems that have emotional overtones, such as exploratory sex play and masturbation. Parents need help to understand normal behaviors and to view sexual curiosity in their children as a part of the developmental process. Assessing the parents' level of knowledge and understanding of sexuality provides cues to their need for supplemental information that will prepare them for the increasingly complex explanations they will need to provide as their children grow older.

COPING WITH CONCERNS RELATED TO NORMAL GROWTH AND DEVELOPMENT

Table 14.1 summarizes the major developmental achievements of the school-age years.

School Experience

School serves as the agent for transmitting the values of society to each succeeding generation of children and as a setting for many peer relationships. After the family, schools are the second most important socializing agent in the lives of children.

Entrance into school causes a sharp break in the structure of the child's world. For many children, it is their first experience in conforming to a group pattern imposed by an adult who is not a parent and who has responsibility for too many children to be constantly aware of each child as an individual. Children want to go to school and usually adapt to the new conditions with little difficulty. Successful adjustment is related to the child's physical and emotional maturity and the parent's readiness to accept the separation associated with school entrance. Unfortunately, some parents express their unconscious attempts to delay the child's maturity by clinging behavior, particularly with their youngest child.

By the time they enter school, most children have a fairly realistic concept of what school involves. They receive information regarding the role of a student from parents, siblings, playmates, and the media. In addition, most children have had some experience with daycare, preschool, or kindergarten. Middle-class children have fewer adjustments to make and less to learn about expected behavior because schools tend to reflect dominant middle-class customs and values. If the child has attended a preschool program, the focus of the preschool program also affects the child's adjustment. Some preschool programs provide custodial care only, but others emphasize emotional, social, and intellectual development.

Role of Teachers

Teachers, like parents, are concerned about the child's psychologic and emotional welfare. Although the functions of teachers and parents differ, both place constraints on behavior and both are in a position to enforce standards of conduct. However, the teacher's primary responsibility involves stimulating and guiding children's intellectual development, as opposed to providing for their physical welfare beyond the school setting.

Children respond best to teachers who possess the characteristics of a warm, loving parent. Teachers in the early grades perform many of the activities formerly assumed by the parent, such as recognizing the child's personal needs (e.g., the need to go to the bathroom, need for help with clothing) and helping to develop their social behavior (e.g., manners).

Teachers serve as models with whom children can identify and whom they try to emulate. Children seek their teachers' approval and avoid their disapproval. The teacher is a significant person in the life of the early school-age child, and hero worship of a teacher may extend into late childhood and preadolescence. Teachers who make supportive statements that reassure or commend children, use accepting and clarifying statements that help children refine ideas and feelings, and provide assistance that aids children with their own problem solving contribute to the development of a positive self-concept in the school-age child.

Role of Parents

Parents share responsibility for helping children achieve their maximum potential. Parents can supplement the school program in numerous ways (see Family-Centered Care box). Cultivating responsibility is the goal of parental assistance. Being responsible for schoolwork helps children learn to keep promises, meet deadlines, and succeed at their jobs as adults. Responsible children may occasionally ask for help (e.g., with a spelling list), but usually they prefer to think through their work by themselves. Excessive pressure or lack of encouragement from parents may inhibit the development of these desirable traits.

TABLE 14.1 Growth and Development During the School-Age Years (ages are approximate)

Physical and Motor	Mental	Adaptive	Personal-Social
Age 6 Years			
Height and weight gain continues slowly Weight: 16-26.3 kg (35.5-58 pounds) Height: 106.7-123.5 cm (42-49 inches) Central mandibular incisors erupt Loses first tooth Demonstrates gradual increase in dexterity Active age; constant activity Often returns to finger feeding More aware of hand as a tool Likes to draw, print, color Vision reaches maturity	Develops concept of numbers Can count 13 pennies Knows whether it is morning or afternoon Defines common objects (such as fork and chair) in terms of their use Obeys triple commands in succession Knows right and left hands Says which is pretty and which is ugly of a series of drawings of faces Describes the objects in a picture rather than simply enumerating them Attends first grade	At table, uses knife to spread butter or jam on bread At play, cuts, folds, pastes paper; sews crudely if needle is threaded Takes bath without supervision; performs bedtime activities alone Reads from memory; enjoys oral spelling game Likes table games, checkers, simple card games Giggles a lot Sometimes steals money or attractive items Has difficulty owning up to misdeeds Tries out own abilities	Can share and cooperate better Has great need for children of own age Will cheat to win Often engages in rough play Often jealous of younger brother or sister Does what adults are seen doing May have occasional temper tantrums Is a boaster Is more independent, probably an influence of school Has own way of doing things Increases socialization
Age 7 Years			
Begins to grow at least 5 cm (2 inches) in height per year Weight: 17.7-30 kg (39-66 pounds) Height: 111.8-129.5 cm (44-51 inches) Maxillary central incisors and lateral mandibular incisors erupt More cautious in approaches to new performances Repeats performances to master them Jaw begins to expand to accommodate permanent teeth	Notices that certain items are missing from pictures Can copy a diamond Repeats three numbers backward Develops concept of time; reads ordinary clock or watch correctly to nearest quarter-hour; uses clock for practical purposes Attends second grade More mechanical in reading; often does not stop at the end of a sentence; skips words such as "it," "the," and "he"	Uses table knife for cutting meat; may need help with tough or difficult pieces Brushes and combs hair acceptably without help May steal Likes to help and have a choice Is less resistant and stubborn	Is becoming a real member of the family group Takes part in group play Boys prefer playing with boys; girls prefer playing with girls Spends a lot of time alone; does not require a lot of companionship
Ages 8 to 9 Years			
Continues to gain 5 cm (2 inches) in height per year Weight: 19.6-39.6 kg (43-87 pounds) Height: 116.8-141.8 cm (46-56 inches) Lateral incisors (maxillary) and mandibular cuspids erupt Movement fluid; often graceful and poised Always on the go; jumps, chases, skips Increased smoothness and speed in fine motor control; uses cursive writing Dresses self completely Likely to overdo; hard to quiet down after recess More limber; bones grow faster than ligaments	Gives similarities and differences between two things from memory Counts backward from 20 to 1; understands concept of reversibility Repeats days of the week and months in order; knows the date Describes common objects in detail, not merely their use Makes change out of a quarter Attends third and fourth grades Reads more; may plan to wake up early just to read Reads classic books but also enjoys comics More aware of time; can be relied on to get to school on time Can grasp concepts of parts and whole (fractions) Understands concepts of space, cause and effect, nesting (puzzles), conservation (permanence of mass and volume) Classifies objects by more than one quality; has collections Produces simple paintings or drawings	Makes use of common tools such as hammer, saw, screwdriver Uses household and sewing utensils Helps with routine household tasks, such as dusting, sweeping Assumes responsibility for share of household chores Looks after all of own needs at table Buys useful articles; exercises some choice in making purchases Runs useful errands Likes pictorial magazines Likes school; wants to answer all questions Is afraid of failing a grade; is ashamed of bad grades Is more critical of self Takes music and sports lessons	Is easy to get along with at home Likes the reward system Dramatizes Is more sociable Is better behaved Is interested in boy-girl relationships but will not admit it Goes about home and community freely, alone or with friends Likes to compete and play games Shows preference in friends and groups Plays mostly with groups of own sex but is beginning to mix Develops modesty Compares self with others Enjoys organizations, clubs, and group sports

Continued

TABLE 14.1 Growth and Development During the School-Age Years (ages are approximate)—cont'd

Physical and Motor	Mental	Adaptive	Personal-Social
Ages 10 to 12 Years			
Weight: 24.3-58 kg (54-128 pounds) Height: 127-162.5 cm (50-64 inches) Remainder of teeth will erupt and tend toward full development (except wisdom teeth) **Girls:** Pubescent changes may begin to appear; body lines soften and round out **Boys:** Slow growth in height and rapid weight gain; may become obese in this period	Writes brief stories Attends fifth to seventh grades Writes occasional short letters to friends or relatives on own initiative Uses telephone for practical purposes Responds to magazine, radio, or other advertising Reads for practical information or own enjoyment—stories or library books of adventure or romance, animal stories	Makes useful tools or does easy repair work Cooks or sews in small ways Raises pets Washes and dries own hair; is responsible for a thorough job of cleaning hair but may need reminding to do so Is sometimes left alone at home for an hour or so Is successful in looking after own needs or those of other children left in his or her care	Loves friends; talks about them constantly Chooses friends more selectively; may have a "best friend" Enjoys conversation Develops beginning interest in opposite sex Is more diplomatic Likes family; family really has meaning Likes mother and wants to please her in many ways Demonstrates affection Likes father, who is admired and may be idolized Respects parents

FAMILY-CENTERED CARE

Helping Children in School

General Guidelines

Be supportive: Provide companionship; share ideas and thoughts.
Be positive: Every child should experience some success each day.
Share an interest in reading: Use the library; discuss books they are reading.
Support and encourage activity rather than passivity.
Encourage originality: Help children make their own projects from discarded articles or other available materials.
Foster the development of hobbies and collections.
Encourage children to wonder and reflect during free time.
Encourage family experiences and trips to places of interest.
Encourage questions: Help children discover sources for information or places to explore and investigate.
Stimulate creative thinking and problem solving: Help children try out new solutions to problems without fear of making mistakes.
Use rewards rather than punishment.

Specific Guidelines

Meet the teacher at the beginning of school and plan to visit the school to see what is taught and expected.
Send the child to school every day. Teachers are concerned when parents make other plans for their children; it conveys the impression that school is unimportant.
Demonstrate an interest in what the child is learning.
Demonstrate an interest in content and growth more than in grades.
Make it clear to the child that schoolwork is between the child and the teacher; the teacher and child should set goals for better school performance to allow the child to feel responsible for school successes and failures.
Take advantage of situations that support and reinforce school learning.
Share information with teachers that will help them understand the child better.
Communicate with the teacher if there appears to be a problem; avoid waiting for a scheduled conference.
Provide a quiet, well-lit area for study that is safe from interruption; do not allow television or music.
Avoid dictating a study time but do enforce rules, such as no video games until homework is done; accept the child's word that work is complete.
Help with homework should focus on explaining the question, not giving the answer.
Teach the child to break large tasks (such as a report) into smaller, manageable tasks spread over the allotted time rather than attempting the entire project the night before it is due.
Request special help for children with learning problems.
Support the school staff by showing respect for both the school system and the teacher, at least in the child's presence.

Latchkey Children

The term **latchkey children** is used to describe children in elementary school who are left to care for themselves before or after school without the supervision of an adult. The large numbers of single-parent families and working parents, together with the lack of available child care, have created a stress-provoking situation for many school-age children. Some of these children may have a chronic illness as well.

Inadequate adult supervision after school leaves children at greater risk for injury and delinquent behavior. In some instances, outside activities are curtailed, and relationships with peers may be significantly diminished. Most school-age children feel more lonely, isolated, and fearful when left home alone than children who have someone to care for them (Ruiz-Casares, Rousseau, Currie, et al., 2012). To cope with their fears and anxieties while alone, these children may devise strategies, such as hiding (in a bathroom, in a closet, or under a bed), playing the television loudly to drown out noises, and using pets for comfort.

Many communities and persons concerned about the welfare of latchkey children are trying to help these children and their parents deal with this potentially serious problem. Some communities and employers have implemented after-school programs. Other types of programs include those designed to teach self-help skills to children, hotlines to provide telephone check-in and reassurance programs for children, and

programs that link latchkey children with reassuring older persons in their community. Nurses should be aware of these community services and encourage parents to teach self-help skills to these children.

Discipline

Many factors influence the amount and manner of discipline and limit setting imposed on school-age children, including the parents' psychosocial maturity, their own childrearing experiences during childhood, the children's temperaments, the context of the children's misconduct, and the children's responses to rewards and punishments. Discipline serves many purposes: (1) to help the child interrupt or inhibit a forbidden action; (2) to point out a more acceptable form of behavior so that the child knows what is right in a future situation; (3) to provide some reason, understandable to the child, that explains why one action is inappropriate and another action is more desirable; and (4) to stimulate the child's ability to empathize with the victim of a misdeed.

To be effective, discipline should take place in a positive, supportive environment with the use of strategies to instruct and guide desired behaviors and eliminate undesired behaviors (Owen, Slep, & Heyman, 2012). Physically aggressive practices, such as spanking, are linked to children with poor internalizing behaviors, including depression, anxiety, hopelessness, and poor external behaviors, such as aggression and violence (Ferguson, 2013). Reasoning, on the other hand, is an effective disciplinary technique for school-age children. With advancing cognitive skills, they are able to benefit from more complex disciplinary strategies. For example, withholding privileges, requiring compensation, imposing penalties, and contracting can be used with great success. Problem solving is the best approach to limit setting, and children themselves can be included in the process of determining appropriate disciplinary measures.

Dishonest Behavior

During middle childhood, children may engage in what is considered to be antisocial behavior. Previously well-behaved children may engage in lying, stealing, and cheating. Such behaviors are disturbing and challenging to parents.

Lying can occur for a number of reasons. By the time children enter school, they still "tell stories," often exaggerating a story or situation as a means of impressing their family or friends, but can distinguish between fact and fantasy. If children do not develop this characteristic, parents need to teach them what is real and what is make-believe.

Young children may lie to escape punishment or to get out of some difficulty even when their misbehavior is evident. Older children may lie to meet expectations set by others to which they have been unable to measure up. However, most children know that lying and cheating are wrong, and they are concerned when it is observed in their friends. They are quick to tell on others when they detect cheating.

Parents need to be reassured that all children lie occasionally and that sometimes children may have difficulty separating fantasy from reality. Parents should be helped to understand the importance of their own behavior as role models and of being truthful in their relationships with children.

Cheating is most common in young children 5 to 6 years old. They find it difficult to lose at a game or contest, so they may cheat to win. They have not yet realized that this behavior is wrong, and they do it almost automatically. This behavior usually disappears as they mature. However, when children observe parental behaviors such as boasting about cheating, they assume this to be appropriate behavior. When parents set examples of honesty, children are more likely to conform to these standards.

As with other ethically related behavior, stealing is not unexpected in younger children. Between 5 and 8 years old, children's sense of property rights is limited, and they tend to take things simply because they are attracted to them or to take money for what it will buy. They are equally likely to give away something valuable that belongs to them. When young children are caught and punished, they are penitent—they "didn't mean to" and "promise to never do it again"—but they may repeat the performance the following day. Often they not only steal but also lie about their behavior or attempt to justify it with excuses. It is seldom helpful to trap children into admission by asking directly if they committed the offense. Children do not take responsibility for these behaviors until the end of middle childhood. Stealing can sometimes be an indication that something is seriously wrong or lacking in the child's life. For example, children may steal to make up for love or another satisfaction that they feel is lacking. In most situations, it is wise not to attempt to attach a hidden or deep meaning to the stealing. An admonition, together with an appropriate and reasonable punishment, such as having the older child pay back the money or return the stolen items, will ordinarily take care of most cases. Most children can be taught to respect the property rights of others with little difficulty despite numerous temptations and opportunities. If children's personal rights are respected, they are likely to respect the rights of others. Some children simply need more time to learn the rules regarding private property.

Stress and Fear

Children today experience significant amounts of stress. Stress in childhood comes from a variety of sources, such as conflict within the family, parental criminality or psychiatric disorder, and low socioeconomic status (Riley, Scaramella, & McGoron, 2014). The school environment and participation in multiple organized activities can be additional sources of stress. The demands from teachers and parents with school work and standardized proficiency testing, in addition to peer pressure, can cause stress on school-age children (White, 2012). In addition, children in the middle school years are often overcommitted with activities such as dance, music, athletics, and other activities until the cumulative effect is overwhelming.

The increasing violence in society has infiltrated the school setting. In the present information age, in which tragedy is broadcast daily in the media, children come to school knowing more about the latest world events than any previous generation of children. Many children know other children who have been killed or children who have brought weapons to school. School-age children can be victims of bullying, verbal insults, unwanted sexual remarks, damaged or stolen property, and physical abuse in the school environment (King, 2014). Furthermore, children are stressed by conflict within the home, and the high number of single-parent families result in altered relationships and increasing responsibilities for children.

To help children cope with stress, parents, teachers, and health care providers must recognize signs that indicate a child is undergoing stress, identify the source of the stress promptly, and refer those children who need specialized treatment. They need to frequently reassure children that they are safe, have honest and open communication, and encourage children to express their feelings.

! NURSING ALERT

The nurse who observes the following signs of stress in a child should explore the situation further:

- Stomach pains or headache
- Sleep problems
- Bedwetting
- Changes in eating habits
- Aggressive or stubborn behavior
- Withdrawal or reluctance to participate
- Regression to earlier behaviors (e.g., thumb sucking)
- Trouble concentrating or changes in academic performance

Children 7 to 12 years old are capable of identifying their own physiologic responses to stress. Children should be taught to recognize the signs as indicators of stress and to use techniques to manage their stress. Children can learn relaxation techniques such as deep-breathing exercises, progressive relaxation of muscle groups, yoga, and positive imagery to reduce stress (Bothe, Grignon, & Olness, 2014; White, 2012). Encouraging them to "blow off steam" through physical activity reduces tension and anxiety. Children can be encouraged to observe effective coping strategies in others and adopt them for their own use. When an effective strategy has been developed for one situation, parents and teachers can show the child how to transfer the coping strategy or technique to other situations.

In addition to stress, school-age children experience a wide variety of fears, including fear of the dark, excessive worry about past behavior, self-consciousness, social withdrawal, and an excessive need for reassurance. These fears are considered normal for children this age. During the middle-school years, children become less fearful of body safety than they were as preschoolers, but they still fear being hurt, being kidnapped, or having to undergo surgery. They also fear death and are fascinated by all aspects of death and dying. The fears of noises, darkness, storms, and dogs lessen, but new fears related predominantly to school and family bother children (e.g., fear of failing, fear of bullies, fear of something bad happening to their parents) during this time.

PROMOTING OPTIMAL HEALTH DURING THE SCHOOL YEARS

Nutrition

Although caloric needs are diminished in relation to body size during middle childhood, resources are being laid down at this time for the increased growth needs of adolescence. Parents and children need to be aware of the value of a balanced diet to promote growth. The quality of the child's diet depends on the family's pattern of eating.

Likes and dislikes established at an early age continue in middle childhood, although preferences for single foods subside, and children develop a taste for a variety of foods. However, the easy availability of fast-food restaurants, the influence of the mass media, and the temptation of "junk food" make it easy for children to fill up on empty calories. Foods that do not promote growth, such as sugars, starches, and excess fats, are common in school-age children's diets. The easy availability of high-calorie foods, combined with the tendency toward more sedentary activities, has also contributed to an epidemic of childhood obesity. This problem is discussed further in Chapter 16.

Parents are unable to monitor what their children eat when they are away from home. A parent may pack a lunch for school but is unaware of how much is eaten, traded, sold, or thrown away. Nutrition education can and should be integrated in the curriculum throughout the school years. Important aspects of nutrition education include the US Food and Drug Administration's MyPlate; elements of a wholesome diet; and how food products are grown, processed, and prepared. School cafeterias may not always provide healthy, nutritious meals; however, parents should advocate for the availability of nutritious food options and the elimination of unhealthy foods at schools.

SLEEP AND REST

The amount of sleep and rest required during middle childhood is highly individualized. The amount of sleep depends on the child's age, activity level, and other factors, such as health status. The growth rate slows in the school-age years, and less energy is expended in growth than during preceding years.

School-age children usually do not require naps, but they do need to sleep approximately 11.5 hours at 5 years old and 9 hours at 11 years old each night (Galland, Taylor, Elder, et al., 2012). Although fewer bedtime problems occur during these years, occasional difficulties are still associated with the bedtime ritual. Usually children 6 or 7 years old exhibit few bedtime problems, and encouraging quiet activity before bedtime (such as coloring or reading) facilitates the task of going to bed. However, most children in middle childhood must be reminded frequently to go to bed; 8- to 9-year-old children and 11-year-old children are particularly resistant (Bhargava, 2011). Often these children are unaware that they are tired; if they are allowed to remain awake later than usual, they are fatigued the following day. Sometimes bedtime resistance can be resolved by allowing a later bedtime as the child gets older. Twelve-year-old children usually offer no resistance at bedtime; some even retire early to read or listen to music.

EXERCISE AND ACTIVITY

The improved capabilities and adaptability of school-age children permit greater speed and effort in motor activities. Larger, stronger muscles permit longer and increasingly strenuous play without exhaustion. School-age children acquire the coordination, timing, and concentration that are required to participate in adult-type activities, but they may lack the strength, stamina, and control of adolescents and adults. They can engage in a greater amount of physical activity during the school years. However, parents, teachers, and coaches must remember that although children this age are large and appear strong, they may not be ready for strenuous competitive athletics.

All growing children need regular exercise and opportunities for satisfying experiences consistent with individual likes and dislikes. Appropriate activities during the school-age years include running, jumping rope, swimming, roller skating, ice skating, dancing, and bicycle riding. Positive reinforcement achieved by experiencing increasingly smooth, rhythmic, and efficient use of the body conditions the child toward regular physical activity. Exercise is essential for muscle development and tone, refinement of balance and coordination, increased strength and endurance, and stimulation of body functions and metabolic processes. Children need ample space to run, jump, skip, and climb in addition to safe indoor and outdoor facilities and equipment. Most children have abundant energy and need little encouragement to engage in physical activity. Children with disabling conditions or those who hesitate to become involved in active play (e.g., obese children) require special assessment and help so that activities appeal to them and are compatible with their limitations while also meeting their developmental needs.

Sports

Considerable controversy surrounds the trend toward early participation in competitive athletics and the amount and type of competitive sports that are appropriate for children in the elementary grades. The current view is that virtually every child is suited for some sport, and authorities do not discourage participation if children are matched to the type of sport appropriate to their abilities and to their physical and emotional constitution. School-age children enjoy competition (Fig. 14.7). However, teachers and coaches must understand the physical limitations of children this age and teach them the proper techniques and safety measures needed to avoid injuries. A safe and appropriate sport can be identified for even the most unskilled and uncompetitive child, including children with chronic illnesses and intellectual disability. Common sporting activities for school-age children include baseball, soccer, gymnastics, and swimming. Equipment must be

Fig. 14.7 The activities engaged in by school-age children vary according to interest and opportunity. **A,** Little League competitors. **B,** Playing tug-of-war.

maintained in safe condition, and protective apparatus should be worn to prevent serious injury (see Chapter 29, Traumatic Injury).

During the school-age years, girls have the same basic body structure as boys and have a similar response to systematic exercise training. However, at puberty, boys become larger and have more muscle mass, and at this stage, it is usually recommended that girls compete only against other girls. Before puberty, there is no essential difference in strength and size between girls and boys, making these precautions unnecessary.

Preadolescence is a time to teach fundamental motor skills; develop fitness in a practical, safe, and gradual manner; and promote healthy attitudes and values. Activities should include both practice sessions and unstructured play; the actual game or event should be managed in a manner that stresses mastery of the sport and enhancement of self-image rather than winning or pleasing others. All children should have an opportunity to participate, and special ceremonies should recognize all participants, not just individuals who excel in sports or athletics.

Acquisition of Skills

School-age children demonstrate increasing fine motor abilities and complex artistic skills. Handedness is well established by the beginning of the school years, and children make great strides in writing and drawing during this period. It is a time of energetic and vibrant creative productivity. With the tools of language and reading, children create poems, stories, and plays. With more advanced fine motor skills, they are able to master an unlimited variety of handicrafts, such as ceramics, needlework, woodworking, and beadwork. They avidly pursue these skills in solitude, with a friend, or through organized groups such as boys' or girls' clubs or special interest groups that use crafts or other activities as a means to occupy, entertain, and educate children.

School-age children are capable of assuming responsibility for their own needs, although their distaste for soap and water and "dress" clothes is legendary. School-age children can and want to assume their share of household tasks, which usually are related to the male and female roles that have been defined by their culture. Many children also assume responsibility for tasks outside the home, such as babysitting, yard work, or paper routes.

Television, Video Games, and the Internet

Children spend a significant amount of time each day involved in media-related activities, including the use of tablets, video games, and cell phones. Children 8 to 10 years old spend at least 8 hours every day with various forms of media, and teenagers spend more than 11 hours per day (American Academy of Pediatrics, Council on Communications and Media, 2013). Because of the long periods of exposure, media have more time to develop children's attitudes than do parents and teachers.

There is no doubt that children learn from various forms of media, but the values and attitudes depicted on these are not always realistic and may conflict with previously taught values. Violence is common in various forms of media, and significant exposure to media violence increases aggressive behavior in some children (American Academy of Pediatrics, Council on Communications and Media, 2013). In addition, repeated exposure to violence can desensitize children to violence, convey a message that violence is acceptable, and teach children that initiating violent behavior is an appropriate form of protection (Brown & Tierney, 2011). Parents should make the ultimate decision about which programs their child will watch, which video games they are allowed to play, and what Internet sites they can access. These forms of media have valuable educational opportunities, but there are also risks that parents must acknowledge.

DENTAL HEALTH

The first permanent (secondary) teeth erupt at about 6 years old, beginning with the 6-year molar, which erupts posterior to the deciduous molars. Other permanent teeth appear in approximately the same order as eruption of the primary teeth and follow shedding of the deciduous teeth (Fig. 14.8). With the appearance of the second permanent (12-year) molar, most permanent teeth are present. Permanent dentition is more advanced in girls than in boys.

Because the permanent teeth erupt during the school-age years, dental hygiene and regular attention to dental caries are important parts of health supervision during this period. Correct brushing techniques should be taught or reinforced, and the role that fermentable carbohydrates play in production of dental caries should be emphasized. It is important to be alert to possible malocclusion problems that may result from irregular eruption of permanent teeth and that may impair function. Regular dental supervision and continued fluoride supplementation are integral parts of the health maintenance program.

The most effective means of preventing dental caries is proper oral hygiene. Children should be taught to perform their own dental care with the supervision and guidance of the parents. Parents should learn the correct brushing technique with their children, and they should monitor their child's efforts until the child can assume full responsibility.

Teeth should be brushed after meals, after snacks, and at bedtime. Children who brush their teeth frequently and become accustomed to the feel of a clean mouth at an early age usually maintain the habit throughout life. For school-age children with mixed and permanent dentition,

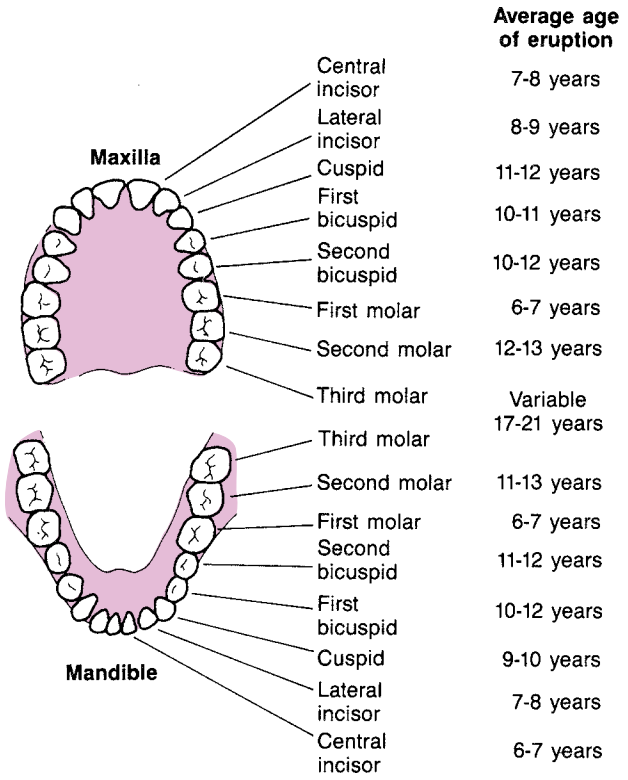


Fig. 14.8 Sequence of eruption of the secondary teeth. (Data from Dean, J. A. [2016]. *McDonald and Avery's dentistry for the child and adolescent* [10th ed.]. St Louis, MO: Mosby/Elsevier.)

the best toothbrush is one with soft nylon bristles and an overall length of about 21 cm (8 inches). Several methods of brushing have been described and recommended for children, but there is no conclusive evidence that one method is superior to another. Thorough cleaning is more important than the specific technique used. The dentist should assess factors, such as the manipulative skills and special needs of the child, and suggest the most appropriate brushing technique and regimen. Flossing follows brushing. Parents should perform the flossing until children acquire the manual dexterity required (usually at about 8 or 9 years old).

Dental Problems

Limited or inadequate dental care results in the most common dental problems: dental caries, malocclusion, and periodontal disease. Trauma, especially tooth avulsion, is another important dental problem. All of these conditions benefit from early intervention to prevent tooth loss.

Dental caries (cavities) is the principal oral problem in children and adolescents. Reducing the incidence and consequences of dental caries is extremely important in childhood. If untreated, dental caries can result in total destruction of the involved teeth. The prevalence rate of caries increases steadily across the life span; whereas 25% of children younger than 5 years old have caries, 68% of children have caries by 19 years old (Mahat, Lyons, & Bowen, 2014).

Dental caries is a multifactorial disease involving susceptible teeth, cariogenic microflora, and an appropriate oral environment. The incidence of lesions and the likelihood of progressive invasion vary considerably and depend on a number of factors being present in the right combination. Because many children are exposed to health care but not dental care, oral inspection is an integral part of the physical assessment of every child. If there is any evidence of dental caries or other unhealthy dental state, the child should be referred for dental services. An alarming number of children do not receive regular dental supervision, and a significant number reach adulthood without dental examinations or treatment by a dentist.

Periodontal disease, an inflammatory and degenerative condition involving the gums and tissues supporting the teeth, often begins in childhood and accounts for a significant amount of tooth loss in adulthood. The more common periodontal problems are **gingivitis** (simple inflammation of the gums) and **periodontitis** (inflammation of the gums and loss of connective tissue and bone in the supporting structures of the teeth). Gingivitis, the most prevalent periodontal disease, is a reversible inflammatory disease that can begin in early childhood and is most often associated with the buildup of plaque on the teeth. Management is directed toward prevention by conscientious brushing and flossing, including the use of fluoride. Children should see a dentist at any signs of inflammation or irritation.

Malocclusion occurs when teeth of the upper and lower dental arches do not approximate in the proper relationships. As a result, the physiologic function of chewing is less effective, and the cosmetic effect is displeasing. Teeth that are uneven, crowded, or overlapping are unable to meet their counterparts in the opposite jaw in the appropriate relationships and may be predisposed to disease in later years.

Orthodontic treatment is most successful when it is started in the late school-age or early teenage years after the last primary teeth have been shed and before growth ceases. However, referral should be made as soon as malocclusion is evident because some deformities can be corrected at an earlier age.

Dental injury may occur in childhood and includes fractures of varying degrees of severity, chipping, dislocation, or avulsion. All tooth injuries require prompt treatment by a competent dentist to prevent permanent displacement or loss. Delayed examination and diagnosis of tooth damage can result in infection or pulp involvement. Because it can affect the remaining teeth, replacement of the lost tooth is needed to maintain normal alignment and position of the other teeth.

A tooth that is **avulsed** (exarticulated, or "knocked out") should be replanted by the child, parent, or nurse and stabilized as soon as possible so that the blood supply to the tooth can be reestablished and the tooth kept alive (see Emergency Treatment box). A tooth that is replanted promptly has a good survival rate. Avulsed primary teeth are usually not reimplanted.

EMERGENCY TREATMENT

Avulsed Permanent Tooth

Recover tooth.
Hold tooth by crown; avoid touching root area.
If tooth is dirty, rinse it gently under running water or saline; be certain to insert stopper in sink or basin (to avoid tooth loss).

To Reimplant the Tooth

Insert tooth into socket; be certain that the lip side (or convex surface) is facing front.
Have child maintain tooth in place by slowly biting down on a piece of gauze.
Transport child to dentist immediately.
Avoid sudden stops or sharp turns to prevent dislodging tooth.

If Reluctant to Reimplant the Tooth

Place avulsed tooth in suitable medium for transport:

- Cold milk
- Saliva—under child's or parent's tongue

If child is holding tooth in the mouth, avoid sudden stops to prevent swallowing tooth.

Do not forget to take the tooth.

As with all injuries to the mouth, an avulsed tooth causes a large amount of bleeding, which is frightening to children and their families; therefore the nurse or anyone faced with dental trauma should be prepared to provide support and reassurance during the trauma.

SCHOOL HEALTH

Child health maintenance is ultimately the responsibility of the parents; however, the public schools and health departments in the United States have contributed to the improvement of child health by providing a healthful school environment, health services, and health education that emphasize sound health practices. Most of these functions constitute major components of community health services and involve large amounts of public funds and large numbers of health professionals, including nurses.

A school health program is involved in ongoing health maintenance through assessment, screening, and referral activities. Routine health services provided by most schools include health appraisal, emergency care, safety education, communicable disease control, counseling, and follow-up care. Health education of school-age children is directed toward providing knowledge of health and influencing habits, attitudes, and conduct in relation to health and injury prevention.

Traditionally, school nurses were viewed from a limited perspective as the individuals who detected diseases in the school, applied bandages, and cared for students who were ill or injured. Although these are important functions, this traditional role has acquired much broader dimensions. School nurses develop, implement, and evaluate health care plans and programs. In some settings, school health services have enlarged into family health centers that meet the needs of not only school-age children but also their families and the community. In these settings, school nurse practitioners provide health care that includes assessment of physical, psychomedical, psychoeducational, behavioral, and learning problems, as well as comprehensive well-child care.

The passage of Public Laws 94-142 and 99-457 requires the integration of children with chronic illnesses and disabilities into the least restrictive environments, including regular classrooms whenever possible. School nurses are responsible for the medical and nursing needs of these children while they are in the school setting. School nurses develop, implement, and evaluate individualized health care plans for these children. Not all schools have a school nurse, and unlicensed assistive personnel (UAP) are used in some cases. After appropriate training and certification, UAP can provide standardized routine health care to students but must be overseen by a school nurse (Resha, 2010). Delegation and supervision of UAP requires skillful nursing assessment, effective communication, and professional judgment.

INJURY PREVENTION

Because school-age children have developed more refined muscular coordination and control and can apply their cognitive capacities to their behavior, the number of injuries in middle childhood is diminished compared with the number in early childhood. The most common cause of severe injury and death in children older than 4 years of age is motor vehicle crashes—either as a pedestrian or passenger (National Highway Traffic Safety Administration, 2013). It is important that nurses continue to emphasize three automobile safety measures that have been found to reduce the severity of injuries: effective car restraint systems, door-lock mechanisms, and appropriate passenger seating locations in the motor vehicle. The rear vehicle seat is the safest place for children younger than 13 years old, and booster seats should be used until the child is 57 inches tall (Centers for Disease Control and Prevention, National Center for Injury Prevention and Control, 2015).

Fig. 14.9 The right-size bike is important. The child should be able to sit on the bike and place the balls of both feet on the ground. Each foot should comfortably reach and manipulate the pedal in the down position. Wearing a protective helmet is mandatory. The helmet should be positioned so that it sits low on the forehead and parallel to the ground when the head is held upright. It should not rock back and forth or shift from side to side. The strap should fasten securely under the chin.

School-age children's desire for riding bicycles increases the risk of injury on streets. Other serious injuries include accidents on skateboards, roller skates, in-line skates, scooters, and other sports equipment. All-terrain vehicles (ATVs) are responsible for a large number of childhood injuries because they are unstable, not easily seen by others, and able to obtain substantial speed. Several national organizations have developed policy and position statements to discourage the use of ATVs in any child younger than 16 years old (Campbell, Kelliher, Borrup, et al., 2010).

Most injuries occur in or near the home or school. The most effective means of prevention is education of the child and family regarding the hazards of risk taking and the improper use of equipment. Safety helmets, protective eye and mouth shields, and protective padding are strongly recommended for children engaging in active sports, even though they may not be required equipment. Falls from bicycles are the cause of a significant number of head injuries in school-age children, and the most important aspect of bicycle safety is to encourage children to wear protective helmets (Fig. 14.9) (Meehan, Lee, Fischer, et al., 2013).

Physically active school-age children are also highly susceptible to cuts and abrasions, and the incidence of childhood fractures, strains, and sprains is high. Trampoline injuries are highest in children 5 through 14 years old and account for numerous fractures, sprains, and head injuries. Trampolines in the home environment, routine physical education classes, or outdoor playgrounds are not recommended for children younger than 6 years old (American Academy of Pediatrics, Council on Sports Medicine and Fitness, 2012). Serious injuries are discussed elsewhere in the book: burns (Chapter 31), eye trauma (Chapter 18), submersive injury (Chapter 27), and head injuries (Chapter 27). The prevalence of injuries depends on the dangers present in the environment, the protection offered by adults, and children's behavior patterns. Table 14.2 lists characteristics of school-age children that make them prone to injury and suggestions for injury prevention. Family-Centered Care boxes provide safety guidelines for bicycle, skateboard, in-line skate, and scooter guidance during the school years.

TABLE 14.2 Injury Prevention During the School-Age Years

Developmental Abilities Related to Risk of Injury	Injury Prevention
Motor Vehicle Accidents	
Is increasingly involved in activities away from home Is excited by speed and motion Is easily distracted by environment Can be reasoned with	Educate child on proper use of seat belts while a passenger in a vehicle. Maintain discipline while the child is a passenger in a vehicle (e.g., ensure that children keep arms inside, do not lean against doors, and do not interfere with driver). Remind parents and children that no one should ride in the bed of a pickup truck. Emphasize safe pedestrian behavior. Insist on child wearing safety apparel (e.g., helmet) when applicable, such as while riding bicycle, motorcycle, moped, or ATV (see Family-Centered Care boxes).
Drowning	
Is apt to overdo May work hard to perfect a skill Has cautious, but not fearful, gross motor actions Likes swimming	Teach child to swim. Teach basic rules of water safety. Select safe and supervised places to swim. Check sufficient water depth for diving. Caution child to swim with a companion. Ensure that child uses an approved flotation device in water or boat. Advocate for legislation requiring fencing around pools. Learn cardiopulmonary resuscitation.
Burns	
Has increasing independence Is adventurous Enjoys trying new things	Make certain home has smoke detectors. Set water heaters to 48.9°C (120°F) to avoid scald burns. Instruct child on behavior in areas involving contact with potential burn hazards (e.g., gasoline, matches, bonfires or barbecues, lighter fluid, firecrackers, cigarette lighters, cooking utensils, chemistry sets). Instruct child to avoid climbing or flying kite around high-tension wires. Instruct child in proper behavior in the event of fire (e.g., fire drills at home and school). Teach child safe cooking (use low heat; avoid any frying; be careful of steam burns, scalds, or exploding foods, especially from microwaving).
Poisoning	
Adheres to group rules May be easily influenced by peers Has strong allegiance to friends	Educate child on hazards of taking nonprescription drugs and chemicals, including aspirin and alcohol. Teach child to say "no" if offered illegal or dangerous drugs or alcohol. Keep potentially dangerous products in properly labeled receptacles, preferably out of reach.
Bodily Damage	
Has increased physical skills Needs strenuous physical activity Is interested in acquiring new skills and perfecting attained skills Is daring and adventurous, especially with peers Frequently plays in hazardous places Confidence often exceeds physical capacity Desires group loyalty and has strong need for friends' approval Delights in physical activity Attempts hazardous feats Accompanies friends to potentially hazardous facilities Is likely to overdo Growth in height exceeds muscular growth and coordination	Help provide facilities for supervised activities. Encourage playing in safe places. Keep firearms safely locked up except under adult supervision. Teach proper care of, use of, and respect for potentially dangerous devices (e.g., power tools, firecrackers). Teach children not to tease or surprise dogs, invade their territory, take dogs' toys, or interfere with dogs' feeding. Stress use of eye, ear, or mouth protection when using potentially hazardous objects or devices or when engaging in potentially hazardous sports. Do not permit use of trampolines except as part of supervised training. Teach safety regarding use of corrective devices (glasses); if child wears contact lenses, monitor duration of wear to prevent corneal damage. Stress careful selection, use, and maintenance of sports and recreation equipment, such as skateboards and in-line skates (see Family-Centered Care boxes). Emphasize proper conditioning, safe practices, and use of safety equipment for sports or recreational activities. Caution against engaging in hazardous sports, such as those involving trampolines. Use safety glass and decals on large glassed areas, such as sliding glass doors. Use window guards to prevent falls. Teach name, address, and phone number, and emphasize that child should ask for help from appropriate people (e.g., cashier, security guard, police) if lost; have identification on child (e.g., sewn in clothes, inside shoe). Teach safety and stranger safety: Avoid personalized clothing in public places. Never go with a stranger. Have child tell parents if anyone makes child feel uncomfortable in any way. Teach child to say "no" when confronted by uncomfortable situations. Always listen to child's concerns regarding others' behavior.

ATV, All-terrain vehicle.

FAMILY-CENTERED CARE

Bicycle Safety

- Always wear a properly fitted bicycle helmet that is approved by the US Consumer Product Safety Commission; replace a damaged or outgrown helmet.
- Ride bicycles with traffic and away from parked cars.
- Ride single file.
- Walk bicycles through busy intersections only at crosswalks.
- Give hand signals well in advance of turning or stopping.
- Keep as close to the curb as practical.
- Watch for drain grates, potholes, soft shoulders, loose dirt, and gravel.
- Keep both hands on handlebars except when signaling.
- Never ride double on a bicycle.
- Do not carry packages that interfere with vision or control; do not drag objects behind a bike.
- Watch for and yield to pedestrians.
- Watch for cars backing up or pulling out of driveways; be especially careful at intersections.
- Look left, right, and then left before turning into traffic or roadway.
- Never hitch a ride on a truck or other vehicle.
- Learn rules of the road and respect for traffic officers.
- Obey all local ordinances.
- Wear shoes that fit securely while riding.
- Wear light colors at night and attach fluorescent material to clothing and bicycle.
- Equip the bicycle with proper lights and reflectors.
- Be certain the bicycle is the correct size for rider (see Fig. 14.9).
- Equip the bicycle with proper lights and reflectors.
- Children riding as passengers must wear appropriate-size helmets and sit in specially designed protective seats.

Modified from American Academy of Pediatrics, Committee on Injury and Poison Prevention. (2008). Bicycle helmets. *Pediatrics, 122*(2), 450.

FAMILY-CENTERED CARE

Skateboard, In-Line Skate, and Scooter Safety

- Children younger than 5 years old should not use skateboards or in-line skates because they are not developmentally prepared to protect themselves from injury. Children ages 6 to 10 years should use these only with close adult supervision.
- The age when children are ready to use in-line skates safely is not known because of differences in the ability to acquire the skills needed to participate in the sport. Novice skaters should learn indoors on a flat, smooth surface. Children who ride skateboards, in-line skates, or scooters should wear helmets and other protective equipment, especially on their knees, wrists, and elbows, to prevent injury.
- Skateboards, in-line skates, and scooters should never be used near traffic or in streets. Their use should be prohibited on streets and highways. Activities that bring skateboards together (e.g., "catching a ride") are especially dangerous.
- Some types of use, such as riding homemade ramps on hard surfaces, may be particularly hazardous.

Data from Brudvik, C. (2006). Injuries caused by small wheel devices. *Prevention Science, 7*, 313–320; and American Academy of Pediatrics, Committee on Injury and Poison Prevention. (2009). In-line skating injuries in children and adolescents. *Pediatrics, 123*(5), 1421–1422.

FAMILY-CENTERED CARE

Guidance During School Years

Age 6 Years

Prepare parents to expect strong food preferences and frequent refusal of specific food items.
Prepare parents to expect an increasingly ravenous appetite.
Prepare parents for emotional reactions as child experiences erratic mood changes.
Help parents anticipate continued susceptibility to illness.
Teach injury prevention and safety, especially bicycle safety.
Encourage parents to respect child's need for privacy and to provide a separate bedroom for child, if possible.
Prepare parents for child's increasing interests outside the home.
Help parents understand the need to encourage child's interactions with peers.

Ages 7 to 10 Years

Prepare parents to expect improvement in health with fewer illnesses but warn them that allergies may increase or become apparent.
Prepare parents to expect an increase in minor injuries.
Emphasize caution in selecting and maintaining sports equipment and reemphasize safety.
Prepare parents to expect increased involvement with peers and interest in activities outside the home.
Emphasize the need to encourage independence while maintaining limit setting and discipline.
Prepare mothers to expect more demands at 8 years old.
Prepare fathers to expect increasing admiration at 10 years old; encourage father-child activities.
Prepare parents for prepubescent changes in girls.

Ages 11 to 12 Years

Help parents prepare child for body changes of pubescence.
Prepare parents to expect a growth spurt in girls.
Make certain child's sex education is adequate with accurate information.
Prepare parents to expect energetic but stormy behavior at 11 years old and child becoming more even-tempered at 12 years old.
Encourage parents to support child's desire to "grow up" but to allow regressive behavior when needed.
Prepare parents to expect an increase in child's masturbation.
Instruct parents that the child may need more rest.
Help parents educate child on experimentation with potentially harmful activities.

Health Guidance

Help parents understand the importance of regular health and dental care for the child.
Encourage parents to teach and model sound health practices, including diet, rest, activity, and exercise.
Stress the need to encourage children to engage in appropriate physical activities.
Emphasize providing a safe physical and emotional environment.
Encourage parents to teach and model safety practices.

ANTICIPATORY GUIDANCE—CARE OF FAMILIES

Parents of the school-age child must share their child's time with the increasingly important peer group. Experiences with the peer group prepare school-age children for the broader world of relationships and increased independence from their parents. Parents must learn to provide support as unobtrusively as possible without feeling rejected, hurt, or angry. The nurse can help parents of the school-age child by providing anticipatory guidance and reassurance throughout this period (see Family-Centered Care box).

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. An 8-year-old boy and his family have recently moved, and he is attending a new school. He states he is unhappy and has difficulty with his classes. He has made no new friends. The mother has talked with his teachers and they are not concerned; he is engaged in the classroom. The nurse performs a complete history and physical examination and finds no areas of concern except that he is in a new school with no friends. Using the principles of Piaget's cognitive development, the nurse would discuss which of the following? **Use an X for the health teaching statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
"Children this age are able to see things from another's point of view and it is important to keep communication open with your son."			
"He may be having difficulty making judgments about his surroundings and may need further evaluation."			
"It would be helpful to sit beside him and watch a favorite movie to show support."			
"School-age children often use their past experiences to evaluate their present situation and moving to a new school is a tough adjustment for him ."			

2. A 9-year-old boy is seen by the school nurse for the third time this week with reports of a stomachache and requests to go home. The child tells the nurse that he has been bullied for the past month by a group of boys in the school because his father is out of work and he has no money for lunch. The group found this out and continues to make fun of him in the cafeteria and on the playground. The nurse determines it would be important to talk with his teacher, cafeteria staff, and playground staff about bullying. Which characteristic of bullying would the nurse share with the teacher, cafeteria staff, and playground staff? **Select all the apply.**

A. Unintentional harm is inflicted upon another person that is part of the socialization process in childhood.
B. The infliction of repetitive physical, verbal, or emotional abuse upon another person with intent to harm.
C. Attempt to gain acceptance and be liked by same-sex peers.
D. Attempt to intimidate someone who is seen as vulnerable.
E. An early sign of a severely disturbed personality disorder that escalates in adulthood.
F. Emotional abuse can be as harmful as any other type of abuse.

3. A school nurse in middle school (grades 6, 7, and 8) is preparing an outline for a sex education class. Which statements represent important concepts to be covered in discussing this topic with this age group? **For each nursing action, use an X to indicate whether it was Effective (helped to meet expected quality patient outcomes), Ineffective (did not help to meet expected quality patient outcomes), or Unrelated (not related to the quality patient outcomes).**

Sex Education Nursing Action	Effective	Ineffective	Unrelated
Separating the boys and girls into same-sex groups with a leader of the same sex.			
Answer questions in a matter-of-fact way that is honest and appropriate to the children's level of understanding.			
Use vernacular or slang terms to describe human physiologic functions.			
Avoid discussing sexually transmitted diseases in this age group.			
Discuss what it is like to have your first boyfriend or girlfriend.			
Discuss common myths and misconceptions associated with sex and the reproductive process.			

4. A 10-year-old boy's mother says he is "prone" to injury because he is always taking chances on his skateboard and bicycle. Injury prevention is an important area for nursing education. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**

The nurse educates the mother that injury primarily occurs because of ____1____ and ____2____.

Options for 1	Options for 2
peer pressure	bullying
physical awkwardness	clumsiness
parents' lack of supervision	feeling small
wanting to impress the opposite sex	risk-taking behaviors
hormones	feeling invincible
underdeveloped skeletal muscles	showing off

PROMOTING OPTIMAL GROWTH AND DEVELOPMENT

Adolescence is a period of transition between childhood and adulthood—a time of rapid physical, cognitive, social, and emotional maturation.

Several terms are used to refer to this stage of growth and development. **Puberty** refers to the maturational, hormonal, and growth process that occurs when the reproductive organs begin to function and the secondary sex characteristics develop. This process is sometimes divided into three stages: **prepubescence**, the period of about 2 years immediately before puberty when the child is developing preliminary physical changes that herald sexual maturity; **puberty**, the point at which sexual maturity is achieved, marked by the first menstrual flow in girls but by less obvious indications in boys; and **postpubescence**, a 1- to 2-year period after puberty during which skeletal growth is completed and reproductive functions become fairly well established. **Adolescence**, which literally means "to grow into maturity," is generally regarded as the psychologic, social, and maturational process initiated by the pubertal changes. It involves three distinct subphases: **early adolescence** (ages 11 to 14), **middle adolescence** (ages 15 to 17), and **late adolescence** (ages 18 to 20). The term **teenage years** is used synonymously with *adolescence* to describe ages 13 through 19 years. The changes that occur during the early, middle, and late phases of adolescence are summarized in Table 15.1.

BIOLOGIC DEVELOPMENT

The physical changes of puberty are primarily the result of hormonal activity and are controlled by the anterior pituitary gland in response to a stimulus from the hypothalamus. The obvious physical changes are noted in increased physical growth and in the appearance and development of secondary sex characteristics; less obvious are physiologic alterations and neurogonadal maturity, accompanied by the ability to procreate. Physical distinction between the sexes is made on the basis of distinguishing characteristics. **Primary sex characteristics** are the external and internal organs that carry out the reproductive functions (e.g., ovaries, uterus, breasts, penis). **Secondary sex characteristics** are the changes that occur throughout the body as a result of hormonal changes (e.g., voice alterations, development of facial and pubertal hair, fat deposits) but that play no direct part in reproduction.

Neuroendocrine Events of Puberty

The events of puberty are caused by a cluster of events that trigger the production of gonadotropin-releasing hormone (GnRH) by the hypothalamus. GnRH travels to the anterior pituitary gland, where it stimulates the production and secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Increasing levels of FSH and LH stimulate a gonadal response, which for females consists of growth of ovarian follicles, production of estrogen, and initiation of ovulation; for males, it consists of maturation of the testicles and testosterone and stimulation of sperm production.

The ovaries, testes, and adrenals secrete sex hormones. These hormones are produced in varying amounts by both sexes throughout the life span. The adrenal cortex is responsible for the small amounts secreted before the pubescent years, but the sex hormone production that accompanies maturation of the gonads is responsible for the biologic changes observed during puberty.

Estrogen, the feminizing hormone, is found in low quantities during childhood. Beginning in early puberty, FSH stimulates estrogen production by the ovaries; however, estrogen levels are not high enough to cause ovulation until mid-puberty. The increasing quantity of estrogen in early puberty causes a building of the endometrial lining of the uterus and first menstruation, or menarche. As puberty progresses, one ovarian follicle becomes dominant during each menstrual cycle and produces increasing amounts of estrogen that releases an ovum, a process called *ovulation.* After ovulation, the follicle involutes and estrogen production decreases. The pituitary gland responds to the decreased estrogen production by increasing production of FSH, which initiates a new menstrual cycle. **Androgens**, the masculinizing hormones, are also secreted in small and gradually increasing amounts up to about 7 or 9 years old, at which time there is a more

TABLE 15.1 Growth and Development During Adolescence

Early Adolescence (11 to 14 Years Old)	Middle Adolescence (15 to 17 Years Old)	Late Adolescence (18 to 20 Years Old)
Growth		
Rapidly accelerating growth Reaches peak velocity Secondary sex characteristics appear	Growth decelerating in girls Stature reaches 95% of adult height Secondary sex characteristics well advanced	Physically mature Structure and reproductive growth almost complete
Cognition		
Explores newfound ability for limited abstract thought Clumsy groping for new values and energies Comparison of "normality" with peers of same sex	Developing capacity for abstract thinking Enjoys intellectual powers, often in idealistic terms Concern with philosophic, political, and social problems	Established abstract thought Can perceive and act on long-range options Able to view problems comprehensively Intellectual and functional identity established
Identity		
Preoccupied with rapid body changes Trying out various roles Measurement of attractiveness by acceptance or rejection of peers Conformity to group norms Decline in self-esteem	Modifies body image Self-centered; increased narcissism Tendency toward inner experience and self-discovery Has a rich fantasy life Idealistic Able to perceive future implications of current behavior and decisions; variable application	Body image and gender role definition nearly secured Mature sexual identity Phase of consolidation of identity Increase in self-esteem Comfortable with physical growth Social roles defined and articulated
Relationships With Parents		
Defining independence–dependence boundaries Strong desire to remain dependent on parents while trying to detach No major conflicts over parental control	Major conflicts over independence and control Low point in parent-child relationship Greatest push for emancipation; disengagement Final and irreversible emotional detachment from parents; mourning	Emotional and physical separation from parents completed Independence from family with less conflict Emancipation nearly secured
Relationships With Peers		
Seeks peer affiliations to counter instability generated by rapid change Upsurge of close, idealized friendships with members of the same sex Struggle for mastery within peer group	Strong need for identity to affirm self-image Behavioral standards set by peer group Acceptance by peers extremely important—fear of rejection Exploration of ability to attract opposite sex	Peer group recedes in importance in favor of individual friendship Testing of romantic relationships against possibility of permanent alliance Relationships characterized by giving and sharing
Sexuality		
Self-exploration and evaluation Limited dating, usually group Limited intimacy	Multiple plural relationships Internal identification of heterosexual, homosexual, or bisexual attractions Exploration of "self appeal" Feeling of "being in love" Tentative establishment of relationships	Forms stable relationships and attachment to another Growing capacity for mutuality and reciprocity Dating as a romantic pair May publicly identify as gay, lesbian, or bisexual Intimacy involves commitment rather than exploration and romanticism
Psychologic Health		
Wide mood swings Intense daydreaming Anger outwardly expressed with moodiness, temper outbursts, and verbal insults and name calling	Tendency toward inner experiences; more introspective Tendency to withdraw when upset or feelings are hurt Vacillation of emotions in time and range Feelings of inadequacy common; difficulty in asking for help	More constancy of emotion Anger more likely to be concealed

rapid increase in both sexes, especially boys, until about 15 years old. These hormones have tremendous growth-promoting properties that result in rapid increases of muscle mass, skeletal growth, and bone density. Androgens are responsible for the development of pubic, axillary, facial, and body hair; acne; body odor; and an increase in height.

Boys do not experience a discrete event analogous to menstruation or ovulation in girls; however, FSH and LH act on testicular cells to stimulate production of testosterone and sperm. The production of viable sperm tends to follow boys' first ejaculation. The capacity to ejaculate occurs approximately 1 year after initial testicular enlargement and pubic hair appearance.

Sexual Maturation

The visible evidence of sexual maturation is achieved in an orderly sequence, and the state of maturity can be estimated on the basis of the appearance of these external manifestations. The age at which these

BOX 15.1 Tanner Stages

The Tanner stages were developed by Dr. J. M. Tanner and colleagues. Tanner stages describe the stages of pubertal growth and are numbered from stage 1 (immature) to stage 5 (mature) for both males and females. In girls and young women, the Tanner stages describe pubertal development based on breast size and the shape and distribution of pubic hair. In boys and young men, the Tanner stages describe pubertal development based on the size and shape of the penis and scrotum and the shape and distribution of pubic hair.

Data from Tanner, J. M. (1962). *Growth of adolescents.* Oxford, England: Blackwell Scientific Publications.

BOX 15.2 Usual Sequence of Maturational Changes

Girls

Breast changes
Rapid increase in height and weight
Growth of pubic hair
Appearance of axillary hair
Menstruation (usually begins 2 years after first signs)
Abrupt deceleration of linear growth

Boys

Enlargement of testicles
Growth of pubic hair, axillary hair, hair on upper lip, hair on face and elsewhere on body (facial hair usually appears about 2 years after appearance of pubic hair)
Rapid increase in height
Changes in the larynx and consequently the voice (usually take place along with growth of penis)
Nocturnal emissions
Abrupt deceleration of linear growth

changes are observed and the time required to progress from one stage to another may vary among children. The time from the appearance of breast buds to full maturity may be 1½ to 6 years for adolescent girls. It may take 2 to 5 years for male genitalia to reach adult size. The stages of development of secondary sex characteristics and genital development have been defined as a guide for estimating sexual maturity and are referred to as the **Tanner stages** (Box 15.1). The usual sequence of appearance of maturational changes is presented in Box 15.2.

Sexual Maturation in Girls

In most girls, the initial indication of puberty is the appearance of breast buds, an event known as **thelarche**, which occurs between 8 and 13 years old (Fig. 15.1). In a minority of normally developing girls, however, pubic hair may precede breast development. The average age of thelarche varies among ethnic groups: African American girls have an average age of 8.8 years, white girls' average is 9.7 years, and Hispanic girls' average is 9.3 years (Herman-Giddens, 2013). This is followed in approximately 2 to 6 months by growth of pubic hair on the mons pubis, known as **adrenarche** (Fig. 15.2).

The initial appearance of menstruation, or **menarche**, occurs about 2 years after the appearance of the first pubescent changes, approximately 9 months after attainment of peak height velocity, and 3 months after attainment of peak weight velocity. The mean age of menarche ranges from 10½ to 15 years, with the average age being 12 years, 8 months for non-Hispanic white girls, and 12 years, 2 months for African American girls (Cabrera, Bright, Frane, et al., 2014). Ovulation and regular menstrual periods usually occur 6 to 14 months after menarche. Girls may be considered to have **pubertal delay** if breast development has not occurred by 13 years old (Villanueva & Argente, 2014).

There is evidence that the mean age of menarche has gradually decreased over the past century in the United States and other developing countries. Females are experiencing puberty at younger ages, with differences noted between white and African American girls. The explanation for this is not yet clear but appears to be influenced by complex physiologic, psychologic, and environmental interrelationships and the reduced rates of disease as technology and medicine advances. This decline in the average age of menarche appears to have leveled off in recent years but continues to be studied (Papadimitriou, 2016).

Sexual Maturation in Boys

The first pubescent changes in boys are testicular enlargement accompanied by thinning, reddening, and increased looseness of the scrotum (Fig. 15.3). These events usually occur between 9½ and 14 years old. Early puberty is also characterized by the initial appearance of pubic hair. Penile enlargement begins, and testicular enlargement and pubic hair growth continue throughout mid-puberty. During this period, there is also increasing muscularity, early voice changes, and development of early facial hair. Temporary breast enlargement and tenderness, **gynecomastia**, are common during early to mid-puberty, occurring in up to 70% of boys (Ali & Donohoue, 2020). The spurts in height and weight occur concurrently toward the end of mid-puberty. For most boys, breast enlargement disappears within 2 years; however, gynecomastia may persist in obese individuals. By late puberty, there is a definite increase in the length and width of the penis, testicular enlargement continues, and first ejaculation occurs. Axillary hair develops, and facial hair extends to cover the anterior neck. Final voice changes occur secondary to the growth of the larynx. Concerns about **pubertal delay** should be considered for boys who exhibit no enlargement of the testes or scrotal changes by 14 years old (Villanueva & Argente, 2014).

Physical Growth During Puberty

Along with increases in reproductive hormones and sexual maturation, a dramatic increase in growth occurs. The final 20% to 25% of linear growth is achieved during puberty, and up to 50% of ideal adult body weight is gained during this time as well. Most of this growth of skeletal muscles and internal organs occurs during a 24- to 36-month period—the adolescent **growth spurt**. This accelerated growth occurs in all children but, as in other areas of development, is highly variable in age of onset, duration, and extent. The growth spurt begins earlier in girls, usually between 9½ and 14½ years old; on average it begins between 10½ and 16 years old in boys. During this period, the average boy gains 10 to 30 cm (4 to 12 inches) in height and 7 to 30 kg (15.5 to 66 pounds) in weight. The average girl, in whom the growth spurt is slower and less extensive, gains 5 to 20 cm (2 to 8 inches) in height and 7 to 25 kg (15.5 to 55 pounds) in weight. Growth in height typically ceases 2 to 2½ years after menarche in girls and at 18 to 20 years old in boys.

This increase in size is acquired in a characteristic sequence. Growth in length of the extremities and neck precedes growth in other areas, and because these parts are the first to reach adult length, the hands and feet appear larger than normal during adolescence. Increases in hip and chest breadth take place in a few months, followed several months later by an increase in shoulder width. These changes are followed by increases in length of the trunk and depth of the chest. This sequence of changes is responsible for the characteristic long-legged, gawky appearance of early adolescent children.

Sex Differences in General Growth Patterns

Sex differences in general growth and distribution patterns are apparent in skeletal growth, muscle mass, adipose tissue, and skin. **Skeletal growth** differences between boys and girls are apparently a function of hormonal effects at puberty. The earlier cessation of growth in girls is caused by epiphyseal unity under the potent effect of estrogen secretion, and the hormonal effect on female bone growth is much stronger than the similar effect of testosterone in boys. In boys, the prolonged growth period before puberty and the less rapid epiphyseal closure are reflected in their greater overall height and longer arms and legs. Other skeletal differences are increased shoulder width in boys and broader hip development in girls.

Hypertrophy of the laryngeal mucosa and enlargement of the larynx and vocal cords occur in both boys and girls to produce **voice changes**. Girls' voices become slightly deeper and considerably fuller, but the effect in boys is striking. The change in the voice of adolescent boys occurs between Tanner stages 3 and 4, with the voice often shifting uncontrollably from deep to high tones in the middle of a sentence. The average lengthening of the vocal cords is 10.9 mm (0.4 inch) for boys and 4.2 mm (0.17 inch) for girls.

Growth of **lean body mass**, principally muscle, which tends to occur after the bone growth spurt, takes place steadily during adolescence. Lean body mass is both quantitatively and qualitatively greater in boys than in girls at comparable stages of pubertal development. **Nonlean body mass**, primarily fat, is also increased but follows a less orderly pattern. There may be a transient increase in subcutaneous fat just before the skeletal growth spurt, especially in boys. This is followed 1 to 2 years later by a modest to marked decrease, which is again more marked in boys. Later, variable amounts of fat are deposited to fill out and contour the mature physique in patterns characteristic of the adolescent's sex, particularly in the regions over the thighs, hips, and buttocks and around the breast tissue. It should be noted, however, that pediatric obesity is steadily on the increase in the United States, and obesity can change the timing and sequence of puberty. This may have long-term effects for increased risk of adult adiposity and obesity (Nokoff, Thurston, Hilkin, et al., 2019). A review of recent evidence indicates an association between obesity and onset of early puberty in girls rather than a causal relationship, and other factors such as hormones and insulin resistance may account for early onset puberty as well. A large, racially diverse sample of boys found evidence of earlier puberty for overweight boys compared with normal or obese boys, and later puberty for obese boys compared with normal or overweight boys (Lee, Wasserman, Kaciroti, et al., 2016)

Other Physiologic Changes

A number of physiologic functions are altered in response to some of the pubertal changes. The size and strength of the heart, blood volume, and systolic blood pressure increase, whereas the heart rate decreases. Blood volume, which has increased steadily during childhood, reaches a higher value in boys than in girls, a fact that may be related to the increased muscle mass in pubertal boys. Adult values are reached for all formed elements of the blood. The lungs increase in both diameter and length during puberty. Respiratory rate decreases steadily throughout childhood and reaches the adult rate in adolescence. Respiratory volume and vital capacity are increased, and to a far greater extent in males than in females. The rate of steady decline in basal metabolic rate from birth to adulthood slows during puberty. During this period, physiologic responses to exercise change drastically: performance improves, especially in boys, and the body is able to make the physiologic adjustments needed for normal functioning after exercise is completed. These capabilities are a result of the increased size and strength of muscles and the increased level of cardiac, respiratory, and metabolic functioning.

COGNITIVE DEVELOPMENT EMERGENCE OF FORMAL OPERATIONAL THOUGHT (PIAGET)

Cognitive thinking culminates with the capacity for **abstract thinking**. This stage, the period of **formal operations**, is Piaget's fourth and last stage. Adolescents are no longer restricted to the real and actual, which was typical of the period of concrete thought; now they are also concerned with the possible. They think beyond the present. Without having to center attention on the immediate situation, they can imagine a sequence of future events that might occur, including college and occupational possibilities; how things might change in the future, such as relationships with parents; and the consequences of their actions, such as dropping out of school. At this time, their thoughts can be influenced by logical principles rather than just their own perceptions and experiences. They become increasingly capable of scientific reasoning and formal logic.

Adolescents are capable of mentally manipulating more than two categories of variables at the same time. For example, they can consider the relationship between speed, distance, and time in planning a trip. They can detect logical consistency or inconsistency in a set of statements and evaluate a system or set of values in a more analytic manner. For instance, they question the parent who insists on honesty in the youngster but at the same time cheats on an income tax report or expense account.

In adolescence, young people begin to consider both their own thinking and the thinking of others. They wonder what opinion others have of them, and they are able to imagine the thoughts of others. With this capacity comes the ability to differentiate between others' thoughts and their own and to interpret the thoughts of others more accurately. They are able to understand that few concepts are absolute or independent of other influencing factors. As they become aware that other cultures and communities have different norms and standards from their own, it becomes easier for them to accept members of these other cultures, and the decision to behave in their own culture in an accepted manner becomes a more conscious commitment.

MORAL DEVELOPMENT (KOHLBERG)

Although younger children merely accept the decisions or points of view of adults, adolescents question absolutes and rules, and they view moral standards as subjective and based on points of view that are subject to disagreement. There are occasions when social conventions are questioned and principles of justice, caring, and quality of life take precedence over established social norms. Aspects of conventional and **principled moral reasoning** are present in adolescence and used at different times in different situations.

Late adolescence is characterized by serious questioning of existing moral values and their relevance to society and the individual. Adolescents can easily take the role of another. They understand duty and obligation based on reciprocal rights of others and the concept of justice that is founded on making amends for misdeeds and repairing or replacing what has been spoiled by wrongdoing. However, they seriously question established moral codes, often as a result of observing that adults verbally ascribe to a code but do not adhere to it.

SPIRITUAL DEVELOPMENT

Religious beliefs also become more abstract and principled during the adolescent years. Specifically, adolescents' beliefs become more oriented toward spiritual and ideological matters and less oriented toward rituals, practice, and the strict observance of religious customs. Compared to children, adolescents place more emphasis on the internal aspects of religion and less emphasis on external manifestations.

Generally, the stated importance of participation in organized religion declines somewhat during the adolescent years. More high school students than postsecondary students attend religious services regularly, and, not surprisingly, the younger the adolescents, the more likely they are to view religion as being important to them. Among older adolescents, the importance of organized religion declines more among college students than among those not in college. Late adolescence appears to be a time when individuals reexamine and reevaluate many of the beliefs and values of their childhood. Consistent with developmental changes in value autonomy, the religious beliefs of young people are likely to become more personalized and less bound to the traditional religious practices they may have been exposed to when they were younger. As adolescents mature and form an identity, they may either reject their family's traditional beliefs or decide to conform to those beliefs (Neuman, 2011).

Nurses play an important role for teens by providing an opportunity to discuss issues regarding spirituality. These aspects are especially important to younger and middle-age adolescents who may be contemplating or participating in risky behaviors because greater levels of religiosity and spirituality are associated with protective, health-promoting behaviors, especially for youth living in environments that lack positive influences (Horton, 2015).

PSYCHOSOCIAL DEVELOPMENT

Identity Development (Erikson)

The task of **identity** formation is to develop a stable, coherent picture of oneself that includes integrating one's past and present experiences with a sense of where one is headed in the future. Throughout childhood, individuals have been going through the process of identification as they concentrate on various parts of the body at specific times. During infancy, children identify themselves as being separate from the mother; during early childhood, they establish gender role identification with the appropriate-sex parent; and in later childhood, they establish who they are in relation to others. In adolescence, they come to see themselves as distinct individuals, somehow unique and separate from every other individual.

Adolescence begins with the onset of puberty and extends to relative physical and emotional stability at or near graduation from high school. During this time, adolescents are faced with the crisis of **group identity versus alienation**. In the period that follows, individuals strive to attain autonomy from the family and develop a sense of **personal identity** as opposed to **role diffusion**. A sense of group identity appears to be essential to the development of a personal identity. Young adolescents must resolve questions concerning relationships with a peer group before they are able to resolve questions about who they are in relation to family and society.

Group Identity

During the early stage of adolescence, pressure to belong to a group is intensified. Teenagers find it essential to belong to a group from which they can derive status. Belonging to a crowd helps adolescents establish the differences between themselves and their parents. They dress as the group dresses and wear makeup and hairstyles according to group criteria, all of which are different from those of the parental generation. Language, music, and dancing reflect a culture that is exclusive to adolescents. If adults begin to emulate these fashions and interests, the style changes immediately. The evidence of adolescent conformity to the peer group and nonconformity to the adult group provides teenagers with a frame of reference for self-assertion and rejection of the identity of their parents' generation. To be different is to be unaccepted and alienated from the group.

Individual Identity

The quest for personal identity is part of the ongoing identification process. As adolescents establish identity within a group, they also attempt to

incorporate multiple body changes into a concept of the self. Body awareness is part of self-awareness. In their search for identity, adolescents consider the relationships that have developed between themselves and others in the past, as well as the directions they hope to take in the future.

Significant others hold expectations for the behavior of adolescents. Often these expectations or demands are persistent enough that individuals make certain decisions that they would not make if they were solely responsible for identity formation. Adolescents may find it too easy to slip into the roles expected by others without incorporating their own personal goals or questioning decisions. Thus individuals may become what parents or others wish them to be based on these premature decisions. Young persons might form a negative identity when society or their culture provides them with a self-image that is contrary to the values of the community. Labels such as "juvenile delinquent," "hoodlum," or "failure" are applied to certain adolescents, who then accept and live up to these labels with behaviors that validate and strengthen them.

The process of evolving a personal identity is time consuming and fraught with periods of confusion, depression, and discouragement. Parents provide models for coping during stressful encounters, which likely influence adolescent's social relationships within and outside the family setting (Marceau, Zahn-Waxler, Shirtcliff, et al., 2015). Adolescents still need monitoring and input from parents during their search for identity; total abandonment during this phase is undesirable and may leave the adolescent feeling fragmented, alone, and adrift, resulting in the development of psychopathology. Determining an identity and a place in the world is a critical and perilous feature of adolescence (see Critical Thinking Case Study box). However, as the pieces gradually shift and settle into place, a positive identity emerges. Role diffusion results when the individual is unable to formulate a satisfactory identity from the multiplicity of aspirations, roles, and identifications.

CRITICAL THINKING CASE STUDY

Discussing the Future

Jeremy, 17 years old, will be graduating from high school in the spring. His mother, a single parent, tells you that she is concerned because graduation is quickly approaching, and Jeremy has made no plans for what he will do with his life after graduation. Whenever Jeremy mentions the topic, his mother tells him, "This is what you must do" and begins to outline the steps he must take. Jeremy just walks away. She asks, "What should I do?" What advice should you give Jeremy's mother?

Initial Assessment. What could be occurring in this family as Jeremy nears graduation?

Clinical Reasoning. What developmental considerations are important for the nurse to understand before responding to the mother?

Teaching Points

- High school graduation is an important milestone for an adolescent.
- Uncertainty about the future is commonly experienced by adolescents, and parents should be made aware of this.
- Parents often need support in helping their adolescents to develop their future goals without pressuring them and increasing their stress.

Critical Thinking Answers

Initial Assessment. Jeremy could be anxious about graduation and feeling pressure from his mother. The mother may be feeling the loss of her son as he nears this important milestone in his life.

Clinical Reasoning. The following should be considered before responding to Jeremy's mother:

- Adolescents and the search for personal identity
- The influence of others on the adolescent's search for personal identity
- Ways to communicate with adolescents

Fig. 15.4 Romantic relationships are important for most adolescents. (©2011 Photos.com, a division of Getty Images. All rights reserved.)

Sex-Role Identity

Adolescence represents a critical time in the development of sexuality and a sex-role identity. Hormonal, physical, cognitive, and social changes that occur during adolescence all have an impact on sexual development. Of all the developmental changes that affect adolescent sexuality, none is more obvious than the impact of puberty. Adolescents must come to terms with hormonal influences, physiologic manifestations such as menstruation and ejaculation, and physical changes such as breast and genital development. All of these changes have a profound impact on the way teenagers perceive their bodies (i.e., body image). In addition to transitions in body image, increasing levels of pubertal hormones contribute to increased levels of sexual motivation among both boys and girls. The emergence of formal operational thinking also increases adolescents' decision-making capabilities concerning sexual issues. As they mature, teenagers become better able to think through potential risks and benefits of sexual behaviors before they engage in any behavior. Older adolescents may also be able to conceptualize more long-term consequences of present behaviors. One of the important tasks of adolescence is to incorporate sexuality successfully into close, intimate relationships. This task is made possible by the advanced cognitive abilities that emerge over the course of adolescence.

Part of adolescent identity formation involves the development of **sexual identity**. As they begin to integrate changes involved with puberty, young adolescents also develop emotional and social identities separate from their families'. For young adolescents, the process of sexual identity development usually involves forming close friendships with same-sex peers. Many teenagers begin to make a shift from relationships with same-sex peers to intimate relationships with members of the opposite sex during middle adolescence (Fig. 15.4). Opposite-sex relationships typically begin with peer activities involving both boys and girls. Pairing off as couples becomes more common as middle adolescence progresses. The type and degree of seriousness

of partner relationships vary. Initial relationships are usually noncommittal, extremely mobile, and seldom characterized by any deep romantic attachments. Sexual activity becomes more common during middle adolescence. The relationship between love and sexual expression is brought into focus during middle adolescence. Most young people oppose exploitation, pressure, or force in sex, as well as sex solely for the sake of physical enjoyment without a personal relationship. Adolescents find it hard to believe that sex can exist without love; therefore they view each relationship as real love.

An integrated sexual identity often emerges during late adolescence as individuals incorporate sexual experiences, feelings, and knowledge. For most, this identity is consistent with their own physical and mental capacities and with societal limits and expectations. Whatever their sexual orientation, most teenagers possess the capacity to have intimate relationships that satisfy the emotional and sexual needs of both partners.

Sexual orientation is an important aspect of sexual identity. **Sexual orientation** is defined as a pattern of sexual arousal or romantic attraction toward persons of the opposite gender (heterosexual), of the same gender (homosexual, often called gay, lesbian, or queer), or of both genders (bisexual), or it may involve the process of gender transition (transgender) or an asexual orientation (not sexually aroused by either gender). Sexual orientation encompasses several dimensions: (1) sexual orientation identity, which consists of how an individual defines his or her sexual orientation; (2) sexual attraction, which includes the gender to which the individual is romantically and physically attracted; and (3) sexual behavior, which consists of whom an individual has sexual relationships with (O'Neill & Wakefield, 2017). In individuals, the direction and intensity of each dimension are not necessarily consistent with any of the others. For example, individuals may be attracted most strongly to their same gender, fantasize about both genders, have sexual activity only with the opposite gender, and identify as gay or lesbian. Other individuals may engage in same-gender sexual behavior and fantasize about both genders but identify as heterosexual. As with all aspects of sexual identity, the dimensions of sexual orientation are influenced by cultural meaning and expectation, by gender, by peer groups, and by other environmental contexts.

Adolescence is the period during which individuals commonly begin to identify their sexual orientation as part of their developing sexual identity. However, this identification process can be profoundly influenced by cultural beliefs and values, by societal and family pressures, or by a lack of similar peers. Most adolescents eventually report an orientation toward exclusively heterosexual relationships. For adolescents whose orientation encompasses any same-gender dimensions, the identity process during adolescence can be complicated, especially when community norms disapprove of orientations other than heterosexual. Adolescents who have witnessed harassment or violence directed at gay, lesbian, and bisexual people, for example, may be reluctant to self-identify with these orientations even when their attractions and behaviors are exclusively same-gender or bisexual.

The development of sexual orientation as part of sexual identity includes several developmental milestones during late childhood and throughout adolescence. These milestones do not necessarily occur in the same order for everyone, nor are they completed in the same amount of time. They include (1) the realization of romantic or erotic attraction to people of one (or both) genders; (2) erotic daydreaming about one or both genders; (3) romantic partners or dates without sexual activity; (4) sexual activity with people of the preferred gender or genders (also, for some teens, sexual activity with a nonpreferred gender, out of curiosity or through social pressure); (5) self-identification of the orientation that best fits one's current circumstances and understanding; (6) publicly self-identifying that orientation, usually to intimate friends and family first and then the wider social group; and (7) an intimate, committed sexual relationship with a person of the gender appropriate to one's orientation.

There is no evidence that homosexual or bisexual adults are more or less likely to create long-term, stable relationships than are heterosexual couples. It should be noted that bisexual adolescents and adults do not generally engage in sexual relationships with both genders concurrently; self-identification as bisexual usually refers to the ability to be attracted to either gender but does not imply that such a person requires partners of both genders or that one must be equally attracted to and have sexual experience with both genders in order to be bisexual.

Although the order of these milestones varies greatly among adolescents, adolescents who identify as gay, lesbian, or bisexual tend to publicly self-identify later than heterosexual peers. Without positive gay, lesbian, or bisexual role models or a supportive peer group, sexual-minority teens can feel isolated, and they may not share their orientation with anyone for fear of rejection or violence.

SOCIAL ENVIRONMENTS

The biologic, cognitive, and social changes of adolescence are shaped by the social environment in which the changes take place. The social environment provides opportunities, barriers, role models, and support for individuals' development and health. Systems within the social environment, including family, peers, schools, community (including the Internet-based community), and the larger society, all contribute uniquely to an adolescent's development and health.

Families

During adolescence, the parent-child relationship changes from one of protection and dependency to one of mutual affection and equality. The process of achieving independence often involves turmoil and ambiguity as both parent and adolescent learn to play new roles and work toward establishing the ultimate relationship. As teenagers assert their rights for grown-up privileges, they frequently create tensions within the home. They resist parental control, and conflicts can arise from almost any situation or any subject. Favorite topics of dispute include Internet use, the need for a personal cell phone, manners, dress, chores and duties, homework, disrespectful behavior, friendships, dating and relationships, money, automobiles, alcohol and other substance abuse, and time schedules.

Teenagers' earliest attempts to achieve emancipation from parental controls are manifested in a period of rejection of the parents. They absent themselves from home and family activities and spend an increasing amount of time with the peer group. They confide less in their parents, but parents continue to play an important role in the personal and health-related decision making of adolescents. With advancing adolescence, teenagers become more competent, and with this competence comes a need for more autonomy. Although they may be psychologically prepared for independence, they are often thwarted in their efforts by lack of money or other parental barriers. Conflict arises in relation to the teenagers' outside activities and the elements of privacy and trust. Parental monitoring remains important throughout adolescence and may have a direct influence on adolescent sexual and substance use behavior. Parents should be guided toward **authoritative parenting** in which authority is used to guide the adolescent while allowing developmentally appropriate levels of freedom and providing clear, consistent messages regarding expectations. However, to gain the trust of adolescents, parents must respect their adolescent's privacy and show an honest and sincere interest in what the adolescent believes and feels (see Family-Centered Care box).

FAMILY-CENTERED CARE

Communication With Adolescents: The Art of Listening

Conflicts between parents and their adolescents are often a result of a natural characteristic of parenthood: the desire to protect one's offspring from harm or from simply doing something "stupid," something embarrassing, or something they may later regret. Teens sometimes bounce their thoughts and ideas off adults. At times, they really want some feedback, but sometimes they simply want to elicit a reaction.

I found it easy to listen openly, thoughtfully, and without interrupting when my teenagers' friends discussed troublesome topics. However, one day, when one of my own teenagers had a similar conversation with me, the parent part kicked in. I felt responsible and spoke my piece on the spot. This brought communication to a halt and resulted in defensiveness. It was a long time before my child tried to talk to me about anything controversial again.

The next time one of my teenagers started a similar conversation, I decided to try to trick myself. Throughout the entire conversation, I told myself over and over again to act as if this were not my teenager but rather someone else's child. I found this actually worked quite well, and I was able to listen without interrupting. I continue to use the system, sometimes with more success than at other times.

—Mother of four

Over the past several decades, changes have taken place within the family microsystem that have important implications for adolescent health. Higher rates of divorce and remarriage, increasing numbers of single-parent or blended families, and greater percentages of working mothers have become characteristic of contemporary US society. Changes in family structure and parent employment have resulted in adolescents having more time unsupervised by adults and increased time alone or with peers. Decreased adult supervision may result in more risk-taking behaviors, such as substance use and sexual intercourse, and decreased opportunities to develop a supportive relationship with parents. Consistently, adolescents with a sense of family belonging along with connectedness with school and community show less susceptibility to negative peer pressure and lower tendencies to be involved in risk-taking behaviors (Brooks, Magnusson, Spencer, et al., 2012).

Peer Groups

For most teenagers, peers assume a more significant role in adolescence than they did during childhood. The peer group serves as a strong support to adolescents, individually and collectively, providing them with a sense of belonging and a feeling of strength and power. The peer group forms the transitional world between dependence and autonomy.

The peer group has an intense influence on adolescents' self-evaluation and behavior. Peers serve as credible sources of information, role models of new social behaviors, sources of social reinforcement, and bridges to alternative lifestyles. To gain acceptance by a group, younger adolescents tend to conform completely in such things as mode of dress, hairstyle, taste in music, and vocabulary. Peers can also be a positive force in health promotion by encouraging healthy behaviors, serving as role models, and promoting positive health norms.

Schools

In contemporary society, schools play an increasingly important role in preparing young people for adulthood. Schooling is essential for a successful future. Failure to complete high school reduces employment opportunities and the probability of earning an adequate income. The dropout rate among minority students is higher than that among nonminority students; however, in 2016, 94.8% of white individuals and 93.8% of African American individuals16 to 24 years old had graduated from high school (Child Trends Data Bank, 2018).

Fig. 15.5 Teenagers like to gather in small groups. (©2011 Photos.com, a division of Getty Images. All rights reserved.)

The school is psychologically important to adolescents as a focus of social life. Teenagers usually distribute themselves into a relatively predictable social hierarchy. They know to which groups they and others belong. A sense of school connectedness and optimal social connectedness is associated with positive outcomes for school completion, positive mood, and decreased high-risk behavior in adolescents (Chapman, Buckley, Reveruzzi, et al., 2014). School connectedness is correlated with caring teachers and the absence of prejudice or discrimination from peers.

Within the larger groups are smaller, distinct, and exclusive crowds or cliques of selected close friends who are emotionally attached to one another. The selection is based on common tastes, interests, and background. Although cliques may become formalized, most remain informal and small. However, each has an identifying feature that proclaims its difference from others and its solidarity within itself in much the same manner as the adolescent generation as a whole sets itself apart from the adult generation. Cliques are usually made up of one sex, and girls tend to be more cliquish than boys and to have a greater need for close friendships (Fig. 15.5). Within the intimacy of the group, adolescents gain support in learning about themselves, consideration for the feelings of others, and increased ego development and self-reliance. To belong is of utmost importance; thus adolescents behave in a way that will ensure their establishment in a group. Adolescents are highly susceptible to social approval, acceptance, and demands. To be ignored or criticized by peers creates feelings of inferiority, inadequacy, and incompetence.

Work

For the majority of young people in the United States, the workplace becomes a fourth microsystem. Most adolescents are employed in an array of jobs as restaurant workers, cashiers, sales clerks, clerical assistants, and unskilled laborers. The jobs tend to require little initiative or decision making and rarely use skills learned in school. Adolescent work may negatively affect development, as it fails to link adolescents to vocational mentors; is not intellectually stimulating; may take time away from other activities that could contribute to identity development; and can lead to fatigue, decreased interest in school, and poorer grades. These detrimental effects are likely to affect adolescents who work more than 20 hours a week.

Fig. 15.6 Cell phones allow adolescents to talk for hours with their peers. (©2011 Photos.com, a division of Getty Images. All rights reserved.)

Interests and Activities

Adolescents spend a large amount of time engaged in leisure-time activities. These leisure-time activities move from being family centered to being peer centered. In addition to providing teenagers with fun and enjoyment, leisure-time activities assist in the development of social, physical, and cognitive skills. Leisure-time activities also allow teenagers the opportunity to learn to set priorities and structure their time.

The role of social media and advanced technology are nowhere more prominent than in the lives of today's adolescents. The widespread availability of the Internet and access to social networking websites such as Facebook, Snapchat, Instagram, email, blogs, and Twitter have created "virtual" communities and ways for young people to interact with others; web cameras even allow those interactions to include real-time video communication. Cellular telephones offer more mobile opportunities to talk on the phone, send text messages or instant messaging, send photos, or use video phone capabilities (Fig. 15.6).

Social networking websites have created a more public arena for trying out identities and developing interpersonal skills with a wider network of people, occasionally with anonymity. This can create opportunities for young people who have limited access to friends (because of rural location, shyness, or rare chronic conditions) to interact with people like themselves. However, most adolescents appear to be using the online social environment to interact with the same peers that they spend their day with at school.

Text messaging has become a common activity and can sometimes be disruptive. In addition, both the online and the text environment can create opportunities for **cyberbullying**, where teens engage in insults, harassment, and publicly humiliating statements online or on cell phones. There is a recognized danger of adolescents coming in contact and sharing personal information with sexual predators who pose as adolescents in an attempt to make personal contact with underage victims or engage them in "sexting" (i.e., sending sexually explicit or suggestive pictures or messages online). Adolescent sexting, rather than being an innocent anonymous activity, has been linked to risky sexual behaviors (Morelli, Bianchi, Baiocco, et al., 2016). Studies have noted not only that adolescents are enthusiastic technology users, but also that they frequently use multiple types of media at the same time. They may be listening to music on their digital music player while the television is on and they are surfing the Internet and texting friends on their cell phone. In addition, there are some demonstrated affective and behavioral effects among adolescents who are exposed to high levels of violence or sexual content in the technology sources they use, which can become a cause of concern for health promotion (Jacobson, Bailin, Milanaik, et al., 2016). There is increased concern focusing on adolescent vehicle driving and distractions, such as texting or cell phone usage. In 2017, 39.2% of adolescents reported having texted or emailed someone while driving on at least 1 day in the 30 days before the survey (Kann, McManus, & Harris, 2018). Many states have outlawed the use of handheld mobile devices while actively operating a vehicle (Chase, 2014).

PROMOTING OPTIMAL HEALTH DURING ADOLESCENCE

For adolescents, health promotion involves helping youth acquire the power (including knowledge, attitudes, and skills), authority (permission to use their power), and opportunities to make choices that increase the likelihood of positive expressions of health for themselves. A comprehensive approach to health promotion combines activities aimed at individuals with interventions focused on changing norms, attitudes, and behaviors of peer groups, families, communities, and society at large.

The rationale for focusing on health issues becomes obvious when one examines the major sources of mortality and morbidity during adolescence. The leading causes of mortality during adolescence in the United States are motor vehicle crashes, other accidental injuries, homicide, and suicide, which together are responsible for approximately 70% of all adolescent deaths (Kann, McManus, Harris, et al., 2016). The sources of morbidity in adolescence include injury (primarily motor vehicle related), depression, eating disorders, substance use, sexually transmitted infections (STIs), and pregnancy; obesity may begin in childhood or adolescence, with secondary health consequences becoming evident in adolescence. Health promotion for this age-group consists mainly of teaching and guidance to avoid risk-taking activities and health-damaging behaviors. Adolescence provides an opportunity for teenagers to incorporate healthy lifestyle behaviors that will benefit them not only during the teenage years but also throughout the life span.

Effective health promotion for adolescents should incorporate a developmentally appropriate, multifaceted approach and incorporate adolescents' perspectives on what health means. One strategy for health promotion used by nurses and other professionals in health care settings is the one-on-one health screening (see Nursing Care Guidelines box). Through a health screening interview, the health professional can identify both assets and threats to an adolescent's health and well-being; this interview also provides an opportunity to build a trusting relationship with the adolescent. In addition, the health screening interview provides an opportunity for teaching adolescents self-advocacy skills.

ADOLESCENTS' PERSPECTIVES ON HEALTH

To be most effective, adolescent health promotion efforts must incorporate adolescents' perspectives on what health means. Such efforts also must focus on adolescents' concerns and priorities related to health and health care services. From a positive perspective, adolescents' developmentally based sense of curiosity and movement toward autonomy provide opportunities for health promotion.

Adolescents' health-related interests and concerns include stress and anxiety, relationships with adults and peers, weight, acne, and feelings of sadness or depression. Health concerns are often consistent with the immediate developmental task that teenagers face. For example, younger adolescents have a particular interest in issues related to growth and development, whereas middle adolescents have questions and concerns related to peer-group acceptance, relationships with friends, and physical appearance. Older adolescents focus increasingly on school performance, future career and employment plans, and emotional health issues.

Among the behaviors that adolescents view as risky are substance use, sexual activity, and the use of recreational and motor vehicles. Adolescents identify health threats that primarily involve psychologic issues, such as clinical depression and eating or weight problems. The availability of confidential services is particularly important to adolescents, especially when they have concerns related to sensitive issues. Adolescents are more likely to participate in health care services when services are delivered by caring, respectful providers.

HEALTH CONCERNS OF ADOLESCENCE

As adolescents develop, they are able to assume additional responsibility for their own health, including maintaining health practices, taking prescribed medications, keeping appointments, and performing procedures when necessary. Health professionals who work with adolescents should consider their increasing independence and responsibility while maintaining privacy and ensuring confidentiality (see Nursing Care Guidelines box). Parents should also respect their teenager's independence and move toward the role of consultant about health issues while maintaining some level of involvement throughout adolescence.

Several professional organizations have published guidelines aimed at improving and maintaining health care for adolescents and young adults. The American Academy of Pediatrics, American Academy of Family Physicians, American Medical Association, and US Preventive Services Task Force have similar guidelines for health supervision of adolescents. These guidelines emphasize the need to provide health services to adolescents that meet their physical and emotional needs. They place great importance on the provision of health care by providers who are trained in meeting the adolescents' needs. Bright Futures (American Academy of Pediatrics, 2017a) emphasizes that the following issues should be addressed with adolescents over the course of multiple visits:

- Emotional well-being (coping, mood regulation, mental health, sexuality)
- Physical growth and development (physical and dental health, body image, healthy nutrition, physical activity)
- Social and academic competence (relationships with peers and family, school performance, interpersonal relationships)
- Risk reduction (tobacco, alcohol, other drugs, pregnancy, STIs)
- Violence and injury prevention (safety belt and helmet use, substance abuse and riding in a vehicle, interpersonal violence, bullying)

The following sections focus on some of the Bright Futures topics; other adolescent health issues are discussed later in the chapter.

Emotional Well-Being

Adolescents vacillate in their emotional states between considerable maturity and childlike behavior. One minute they are exuberant and enthusiastic; the next minute they are depressed and withdrawn. Unpredictable but essentially normal, mood swings are common during this time. As the tension is relieved, emotion is brought under control, and individuals retreat to review what has happened, to attempt to master their anger and to grow in their ability to control their emotions and gain from the new experience. Because of these mood swings, adolescents are frequently labeled as unstable, inconsistent, and unpredictable. Little things can cause an emotional upheaval and, depending on the teenager's interpretation, can mean a great deal.

Teenagers are better able to control their emotions in later adolescence, when they can approach problems more calmly and rationally. Although they are still subject to periods of sadness, their feelings are less vulnerable, and they begin to demonstrate the more mature emotions of later adolescence. Whereas early adolescents react immediately and emotionally, older adolescents can control their emotions until socially acceptable times and places for expression present themselves. They are still subject to heightened emotion, and when it is expressed, their behavior reflects feelings of insecurity, tension, and indecision.

As sources of credible information, support, and encouragement, nurses can help adolescents cope with the changes and challenges they face. To promote both emotional health and psychosocial adjustment, nurses and other health care professionals can encourage adolescents to develop (1) skills to cope with stress and change and, (2) skills to become involved in personally meaningful activities.

Intentional and Unintentional Injury

The rationale for focusing on health issues becomes obvious when one examines the major sources of mortality and morbidity during adolescence. Motor vehicle crashes are the single greatest source of unintentional injury and death in young people. Many factors contribute to the higher rate of crashes among teen drivers, including the lack of driving experience and maturity, driving too fast, using alcohol, and using cell phones to talk or text. Suicide, a form of intentional injury, is the second leading cause of death among all adolescents in the United States. Homicide is the third leading cause of death among adolescents, mostly involving firearms; many adolescents report easy access to a gun (Centers for Disease Control and Prevention, 2017a).

Injuries also account for substantial morbidity among adolescents. During adolescence, peak physical, sensory, and psychomotor

NURSING CARE GUIDELINES

Interviewing Adolescents

- Ensure confidentiality and privacy; interview adolescent without parents.
- Explain the limits of confidentiality (e.g., legal duty to report physical or sexual abuse or to get others involved if patient is suicidal).
- Show concern for adolescent's perspective, saying, "First, I'd like to talk about your main concerns" and "I'd like to know what you think is happening."
- Offer a nonthreatening explanation for the questions you ask, such as "I'm going to ask a number of questions to help me better understand your health."
- Maintain objectivity; avoid assumptions, judgments, and lectures.
- Ask open-ended questions when possible; move to more directive questions if necessary.
- Begin with less sensitive issues and proceed to more sensitive ones.
- Use language that both the adolescent and you understand.
- Restate: Reflect back to adolescents what they have said, along with feelings that may be associated with their descriptions.

BOX 15.3 Injury Prevention During Adolescence

Developmental Abilities Related to Risk of Injury

Need for independence and freedom
Testing independence
Age permitted to drive a motor vehicle (varies from state to state)
Inclination for risk taking
Feeling of indestructibility
Need for discharging energy, often at expense of logical thinking and other control mechanisms
Strong need for peer approval
Attempting hazardous maneuvers
Peak incidence for practice and participation in sports
Access to more complex tools, objects, and locations
Can assume responsibility for own actions

Injury Prevention

Motor or Nonmotor Vehicles

Pedestrian

Emphasize and encourage safe pedestrian behavior.

- Use crosswalks.
- At night, walk with a friend.
- If someone is following you, go to nearest public place with people.
- Do not walk in secluded areas; take well-traveled walkways.

Passenger

Promote appropriate behavior while riding in a motor vehicle. Refuse to ride with an impaired person or one who is driving recklessly.

Driver

Provide competent driver education; encourage judicious use of vehicle; discourage drag racing or playing chicken; maintain vehicle in proper condition (e.g., brakes, tires).
Teach and promote safety and maintenance of two- and three-wheeled vehicles.
Promote and encourage wearing of safety apparel, such as a helmet and long trousers.
Reinforce the dangers of drugs, including alcohol, when operating a motor vehicle.
Discourage distractions while driving—cell phone talking or texting, eating, smoking, or reading.

Drowning

Teach nonswimmers to swim.
Teach basic rules of water safety.

- Judicious selection of places to swim
- Sufficient water depth for diving
- Swimming with a companion
- No alcohol with water sports

Burns

Reinforce proper behavior in areas with burn hazards (gasoline, electric wires, and fires).
Advise against excessive exposure to natural or artificial sunlight (ultraviolet burn).
Discourage smoking.
Encourage use of sunscreen.

Poisoning

Educate in hazards of drug use, including alcohol.

Falls

Teach and encourage general safety measures in all activities.

Bodily Damage

Promote acquisition of proper instruction in sports and use of sports equipment.
Instruct in safe use of and respect for firearms and other devices with potential danger (e.g., power tools, firecrackers).
Provide and encourage use of protective equipment when using potentially hazardous devices.
Promote access to or provision of safe sports and recreational facilities.
Be alert for signs of depression (potential suicide).
Instruct regarding proper use of corrective devices (e.g., glasses, contact lenses, hearing aids).
Encourage and foster judicious application of safety principles and prevention.

function gives teenagers a feeling of strength and confidence that they have never experienced before. Their propensity for risk-taking behavior plus feelings of indestructibility make adolescents especially prone to injuries. The leading causes of injury-related morbidity among adolescents include vehicular crashes, firearms, drowning, poisoning, burns, and falls. Some of the developmental characteristics of teenagers and injury prevention suggestions are outlined in Box 15.3.

Dietary Habits, Eating Disorders, and Obesity

Puberty marks the beginning of accelerated physical growth, which can double some adolescents' nutritional requirements. At the same time, growing independence, the need for peer acceptance, concern with physical appearance, and an active lifestyle may affect eating habits, food choices, nutrient intake, and nutritional status.

Pressure for time and commitments to activities adversely affect teenagers' eating habits. Omitting breakfast or eating a breakfast that is nutritionally poor in quality is frequently a problem. Snacks, usually selected for accessibility rather than nutritional merit, become increasingly a part of the habitual eating pattern during adolescence (Fig. 15.7). Excess intake of calories, sugar, fat, cholesterol, and

Fig. 15.7 Snacking on empty calories is common among adolescents, especially during inactivity. (©2015 iStock.com.)

sodium is common among adolescents and is found in all income and racial or ethnic groups and both genders. Inadequate intake of certain vitamins (folic acid, vitamin B_6, vitamin A) and minerals (iron, calcium, zinc) is also evident, particularly among girls and teenagers of low socioeconomic status. In combination with other factors, these dietary patterns could result in increased risk for obesity and chronic diseases, such as heart disease, osteoporosis, and some types of cancer later in life. Maximum bone mass is also acquired during adolescence; the calcium deposited during these years determines the risk of osteoporosis. Milk is usually passed over in favor of soft drinks.

Overeating or undereating during adolescence presents special problems. When they experience the normal increase in weight and fat deposition of the growth spurt, teenage girls often resort to dieting. The desire for a slim figure and a fear of becoming "fat" prompt teenage girls to embark on nutritionally inadequate reducing regimens that drain their energy and deprive their growing bodies of essential nutrients. Nationwide, 47.1% of adolescents are trying to lose weight (Kann et al., 2018). Although most teens try to lose weight through exercise and diet, a small percentage engage in risky weight loss practices such as vomiting after meals or taking laxatives. Boys are less inclined to undereat or adopt risky weight loss practices. They are more concerned about gaining size and strength. However, they tend to eat foods high in calories but low in other essential nutrients.

Obesity is increasing among both children and adolescents in the United States. Poor dietary habits and increasingly sedentary lifestyles have caused this obesity epidemic. Results from the 2015–16 National Health and Nutrition Examination Survey (NHANES) estimate that 18.5% of US children and adolescents ages 2 to 19 years are obese, including 5.6% who are severely obesity, and another 16.6% are overweight (Fryar, Carrol, & Ogden, 2018).

Health problems traditionally thought of as adult comorbidities of obesity, including type 2 diabetes mellitus, obstructive sleep apnea, and nonalcoholic steatohepatitis, are occurring in adolescents. Routine nutrition screening for all adolescents should include questions about meal patterns, dieting behaviors, consumption of high-fat and high-salt foods, and recent changes in weight. Discuss healthy dietary habits with all adolescents, including the benefits of a healthy diet; ways to consume foods rich in calcium, iron, and other vitamins and minerals; and safe weight management. Lifestyle changes necessary for adolescents to lose weight require the involvement of family members who provide support and encourage active participation.

Physical Fitness

Although today's youth are less fit than children 20 years ago, adolescents probably spend more time and energy practicing and participating in sports activities than members of any other age-group. In 2017 nearly one-half (46.5%) of all high school students reported that they participated in activities that made them "sweat and breathe hard for at least 20 minutes" three or more times in the past week (Kann et al., 2018). Many adolescents participate in sports within school settings (Fig. 15.8). School-based, health-oriented physical education may provide both immediate effects of the activity and sustained effects through encouragement of lifelong activity patterns. Participation in school physical education classes declines with age because schools often do not have mandatory requirements past grade 9 or 10. Health care organizations such as the American Academy of Pediatrics (2017b) recommend discussing the emotional, social, and physical benefits of exercise with all adolescents. Furthermore, encourage all adolescents to engage in physical activity on a regular basis.

The practice of sports, games, and even dancing contributes significantly to growth and development, the education process, and better

Fig. 15.8 Adolescents should be encouraged to participate in activities that contribute to lifelong physical fitness. (©2011 Photos.com, a division of Getty Images. All rights reserved.)

health. These activities provide exercise for growing muscles, interactions with peers, and a socially acceptable means of enjoying stimulation and conflict. In addition, competitive activities help teenagers in the process of self-appraisal and the development of self-respect and concern for others. Because physical fitness appears to be a major influence on one's lifelong health status, children should be encouraged to participate in activities that contribute to lifelong physical fitness. Nurses can encourage participation as a way to promote health and build self-esteem. However, adolescents should not be encouraged to engage in physical activities that are beyond their physical or emotional capacity.

Sexual Behavior, Sexually Transmitted Infections, and Unintended Pregnancy

Sexual activity significantly decreased among US youth in the 1990s and through 2015, with 61.8 live births per 1000 teens in 1991, 39.1 live births per 1000 teens in 2009, and 22.3 live births per 1000 teens in 2015 (Centers for Disease Control and Prevention, 2017b). Despite this decline, less than 5% of teens use the most effective types of birth control (long-acting reversible contraceptives) and instead rely on condoms or birth control pills, which require consist and correct use (Centers for Disease Control and Prevention, 2017b). Rates of STIs and human immunodeficiency virus (HIV) infection among teens have increased, although this may be due to increased testing and better sensitivity of STI testing. However, many sexually active young people engage in behaviors that put them at risk for STIs or pregnancy, such as having sex with multiple partners and having sex without using contraception.

Obtaining a sexual history can be an important step in promoting sexual health and preventing STIs and unintended pregnancies among young people. Questions about sexuality should be prefaced by an

explanation of the purpose and limits of confidentiality. Initially questions can cover less sensitive topics, such as pubertal development, and then address dating behaviors, gender attractions, and sexual activity. Screening questions regarding sexual attractions and experiences should be phrased in ways that allow adolescents to discuss same- and opposite-gender attractions, such as using the term *partner* instead of *boyfriend* or *girlfriend.* Sexually active youth should be asked about their motivation to use condoms or other barrier methods to prevent STIs and their consistency in doing so; use of birth control pills or other forms of hormonal contraception; the number of sexual partners over the past 6 months; and the use of alcohol or other substances in connection with sexual activity.

Sexually active adolescents should be screened for STIs with laboratory tests for gonorrhea, chlamydia, and, if applicable, syphilis. For females, a Papanicolaou (Pap) test should be done to detect human papillomavirus (HPV) infection or other cervical dysplasia. Both males and females should be evaluated for HPV by visual inspection and should also be asked about whether they have received the HPV vaccine series. Adolescents at risk for HIV infection should be offered confidential HIV screening tests. The frequency of laboratory screening for STIs and HIV depends on sexual practices and STI history of individual adolescents.

All adolescents should receive medically accurate health guidance regarding responsible sexual behaviors, including abstinence. Counsel sexually active adolescents about ways to reduce their risk of STIs and unwanted pregnancy and provide positive reinforcement for responsible sexual behaviors. Gay, lesbian, and bisexual adolescents need the same sexuality education and information as heterosexual adolescents. All adolescents should be counseled on ways to reduce their risk of sexual exploitation.

Gay, Lesbian, and Bisexual Adolescents

The population of gay, lesbian, and bisexual adolescents has unique developmental issues and health challenges. Although adolescents may participate in same-gender sexual activity or have same-gender attractions, they do not necessarily become gay, lesbian, or bisexual adults. Assigning sexual orientation labels to adolescents is complex and should be approached cautiously.

Most of the health challenges of sexual minority teens are responses to negative societal attitudes and messages about homosexual or bisexual orientation. They may use alcohol and other substances to escape their anxieties, and they are at much greater risk for suicidal behaviors than their heterosexual peers. Although nurses should screen all youth for suicidal thoughts and history of suicide attempts, it is especially critical for an adolescent who identifies as gay, lesbian, or bisexual or one who is questioning his or her orientation.

Publicly disclosing a gay, lesbian, or bisexual orientation during adolescence ("coming out") brings additional challenges. Many adolescents disclose their orientation to a close peer, then to a sibling, and finally to a parent (Steever, Francis, Gordon, et al., 2014). Adolescents face hostility, violence, and even rejection from their families. Nurses should not encourage teens to disclose their sexual orientation to their families without first forming a safety plan in case the reaction is not supportive. For most young people, referral to an agency that provides support services or social opportunities for gay, lesbian, and bisexual adolescents is appropriate. Parents who seek assistance in adjusting to their child's disclosure can be referred to a local chapter of Parents, Families and Friends of Lesbians and Gays. Adolescents who acknowledge same-gender attractions or relationships are also at risk for violence and harassment from schoolmates, neighbors, and even strangers. Sexual minority adolescents may fear similar uncaring attitudes among health care providers and might avoid disclosing their orientation during health assessments. To provide sensitive, professional care for gay, lesbian, and bisexual adolescents, nurses should be sensitive in their choice of language and be nonjudgmental and caring in their communication.

Fig. 15.9 Adolescents use being alone as a method of coping with stress. Health care professionals need to assess whether this indicates clinical depression. (©2011 Photos.com, a division of Getty Images. All rights reserved.)

BOX 15.4 Areas of Stress in Adolescence

- Body image
- Sexuality conflicts
- Academic pressures
- Competitive pressures
- Relationships with parents
- Relationships with siblings
- Relationships with peers
- Finances
- Decisions about present and future roles
- Career planning
- Ideologic conflicts

Use of Tobacco, Alcohol, and Other Substances

Statistically, experimentation with substances is common among US adolescents. By the 12th grade, 60.4% of students have used alcohol, 28.9% have smoked cigarettes, and 35.6% have tried cannibus in the past 30 days (Kann et al., 2018). Many adolescents use these substances because they provide an opportunity to challenge authority, demonstrate autonomy, gain entry into a peer group, or simply relieve stress. There are many documented consequences of early experimentation with alcohol, tobacco, and other drugs, such as becoming heavier smokers, lower academic achievement, dropping out of school, and early sexual behavior.

Depression and Suicide

A national survey of 9th- through 12th-grade students found that 21.4% of boys and 41.1% of girls reported feeling sad or hopeless (Kann et al., 2018) due to real or perceived stress (Fig. 15.9 and Box 15.4). Nearly 17.2% of high school students reported seriously considering suicide during the past year, with female students being more likely than male students to consider a suicide attempt (Kann et al., 2018).

A brief psychologic screening is necessary during a routine health visit. Screening for depression or suicidal risk should be done with adolescents who note declining school grades; chronic melancholy; family dysfunction; alcohol or other drug use; gay, lesbian, or bisexual orientation; a history of abuse; or previous suicide attempts. Immediate referral for an acute intervention with a psychiatrist or other mental health professional is indicated for any suicidal patient.

School and Learning Problems

Among in-school adolescents, a low grade point average has been associated with higher levels of emotional distress; cigarette, alcohol, and marijuana use; and earlier onset of sexual activity. School problems and dropping out of school can be markers for difficulties, such as learning disabilities, language barriers, family problems, lack of supportive relationships at school, and employment needs. In contemporary American society, education is critical to economic self-sufficiency.

Questions about recent grades, school absences, suspensions, and any history of repeating a grade in school can be used to screen for school-related problems. Specific management plans for youth who note school problems should be coordinated with school personnel and with the adolescent's parents or caregivers if possible.

Hypertension

As adolescents experience sexual maturation, along with increases in height and weight, blood pressure increases from the onset of adolescence and continues to rise until the end of pubertal growth. This trend is especially apparent among males. Approximately 1% of adolescents have sustained hypertension, which is defined as a blood pressure greater than the 95th percentile of standards. The detection of hypertension during adolescence is important because hypertension is one of the major preventable risk factors for adult cardiovascular disease. With increasing levels of obesity, there have been reports of increasing incidence of hypertension among adolescents (Cheung, Bell, Samuela, et al., 2017). Screening for hypertension and associated risk factors should take place annually beginning at 3 years old. Specific guidelines for monitoring and treatment of hypertension in adolescents are found in the National Heart, Lung, and Blood Institute's (2016) Summary Report (see also Chapter 23).

Hyperlipidemia

Along with hypertension, smoking, and obesity, elevated serum cholesterol and triglyceride levels are major risk factors for the development of adult cardiovascular disease. The National Heart, Lung, and Blood Institute (2016) recently issued a recommendation for universal lipid (nonfasting or fasting) screening of all children and adolescents between 9 and 11 years old and again between 17 and 21 years old. Drug therapy to lower low-density lipoprotein (LDL) cholesterol levels is recommended for children and adolescents age 10 years and older whose LDL remains elevated after 6 months to 1 year on a restricted-fat diet, lifestyle modification (exercise), and weight management (National Heart, Lung, and Blood Institute, 2016). Additional information and practice guidelines for monitoring cholesterol levels and initiation of medication to lower LDL cholesterol levels, as well as specific dietary modifications, are found in the 2016 National Heart, Lung, and Blood Institute's Summary Report at http://www.nhlbi.nih.gov/health-pro/guidelines/current/cardiovascular-health-pediatric-guidelines/summary.

Immunizations

An immunization update is an important part of adolescent preventive care. Obtaining a record of the teenager's prior immunizations is important. The Tdap (tetanus, diphtheria, acellular pertussis) vaccine is recommended for adolescents 11 to 18 years old who have not received a tetanus-diphtheria booster (Td) or Tdap dose and have completed the childhood diphtheria, tetanus, and acellular pertussis (DTaP/DTP) series. When Tdap is used as a booster dose, it may be administered at any time earlier than the previous 5-year interval to provide adequate pertussis immunity (regardless of interval from the last Td dose) (Centers for Disease Control and Prevention, 2019). Meningococcal vaccine (Menactra or Menveo) should be given to adolescents 11 to 12 years old with a booster dose at 16 years old. If not previously vaccinated, they should receive one dose at 13 through 18 years old (Centers for Disease Control and Prevention, 2019) (see also Chapter 6, Immunizations).

Vaccination against HPV is recommended to prevent HPV infections and HPV-associated diseases, including cancers. Routine vaccination at age 11 or 12 years has been recommended by the Advisory Committee on Immunization Practices since 2006 for females and since 2011 for males. New recommendations involve the use of a two-dose schedule for girls and boys who initiate the vaccination series at ages 9 through 14 years. For persons initiating vaccination on or after their 15th birthday, the recommended immunization schedule is three doses of HPV vaccine (Centers for Disease Control and Prevention, 2019). Each of the HPV vaccines is administered in a two- or three-dose series; it is important to follow the recommended dose intervals for optimal effectiveness.

All adolescents who have not previously received three doses of hepatitis B vaccine should be vaccinated against hepatitis B virus. The hepatitis A vaccine should be given to adolescents who live in areas where vaccination programs target older children or who are at increased risk for infection or for whom immunity against hepatitis A is desired (Centers for Disease Control and Prevention, 2019). Annual influenza vaccination with either the live attenuated influenza vaccine or the trivalent influenza vaccine is recommended for all children and adolescents (see Chapter 6). All adolescents should also be assessed for previous history of varicella infection or vaccination. Vaccination with the varicella vaccine is recommended for those with no previous history; for those with no previous infection or history, the varicella vaccine may be given in two doses 4 or more weeks apart to adolescents age 13 years and older (Centers for Disease Control and Prevention, 2019). Adolescents should receive a tuberculin skin test if they have been exposed to active tuberculosis (TB), have lived in a homeless shelter, have been incarcerated, have lived in or come from an area with a high prevalence of TB, or currently work in a health care setting.

Body Art

Body art (piercing and tattooing) is an aspect of adolescent identity formation. The skin has become the latest source of parent-adolescent conflict. Adolescents often seek body art as an expression of their personal identity and style. Tattoos may mark significant life events, such as new relationships, births, and deaths. Piercing the ear, nose, nipple, eyebrow, navel, penis, or tongue may sometimes create a health problem. It is a nurse's responsibility to caution girls and boys against having piercing performed by friends, parents, or themselves. Although in most cases piercings have few (if any) serious side effects, there is always a risk of complications such as infection, cyst or keloid formation, bleeding, dermatitis, or metal allergy. Using the same unsterilized needle to pierce body parts of multiple teenagers presents the same risk of HIV, hepatitis C virus, and hepatitis B virus transmission as occurs with other needle-sharing activities.

A qualified operator using proper sterile technique should perform the procedure. This is especially important if an adolescent has a

history of diabetes, allergies, or skin disorders. Adolescents should be informed about the approximate time for healing after body piercing and the care of the pierced area during and after healing. Some body sites need extra precautions. For example, cartilage (ear, nose) has a poor blood supply and heals slowly and scars easily; nipple piercing puts adolescents at risk for breast abscesses. Finally, migration of the piercing is common with naval and other flat skin surface piercing. Piercing guns should not be used for piercing anything other than the earlobe, because guns place the piercing too deeply.

The presence of body art in the form of tattoos and branding is common among adolescents and young adults. Professionals, as well as amateur artists, administer tattoos. The risk to adolescents receiving tattoos is low. The greatest risk is for the tattoo artist, who comes in contact with the client's blood. Adolescents who are amateur tattoo artists benefit from discussions about Standard Precautions and hepatitis B vaccination. Many states either have no regulations or do not enforce existing regulations of piercing and tattooing facilities. The local health department is a source of information about local regulatory requirements.

Sleep Deprivation and Insomnia

The changing social environment of adolescents can often change their sleep patterns at a time when their growth and development require additional sleep for health. Although adolescents should generally get around 9 hours of sleep each night, early morning school scheduling, extracurricular activities, homework, employment, and desired social time with peers or on the Internet can make it difficult for them to get sufficient sleep. Sleep deprivation can affect physical and mental health and has been associated with higher rates of overweight and obesity, depression, somatic complaints (such as headaches and stomach aches), fatigue, and difficulties with concentration. These physical and psychologic effects of inadequate sleep can also affect school performance and thus contribute to school problems. Health teaching and health promotion should include information to promote sufficient sleep.

Tanning

The quest for an attractive appearance leads many teenagers to excessive sunbathing and artificial means for tanning. However, this practice has serious long-term risks, and adolescents should be educated on the detrimental effects of sunlight on the skin (see Chapter 31, Sunburn). Long-term effects include premature aging of the skin; increased risk of skin cancer; and, in susceptible individuals, phototoxic reactions.

The increasing popularity of artificial tanning has prompted concern from health professionals regarding the use of sunlamps and tanning machines. The long-term effects of tanning machines are similar to those of the sun; dermatologists do not recommend tanning by this means. Those who insist on using tanning equipment should be warned that goggles must be worn in tanning booths to prevent serious corneal burning. Education on the use of sunscreens, including hypoallergenic products, with a sun protection factor (SPF) of at least 15 and a nonalcohol base without lanolin, parabens, or fragrance is important. Broad-spectrum sunscreens that protect against both ultraviolet A and ultraviolet B (UVA and UVB) are the most effective. Self-tanning creams safely stimulate the appearance of a tan; however, teens using these products should be cautioned that with sun exposure, protection is still required. Targeting health education messages to adolescents and incorporating educational components relating to sun protection behaviors in school health curricula and in health care visits will increase adolescents' knowledge and awareness.

Nursing Care Management

With continued increases in the numbers of adolescents in the United States and rising rates of health-related problems of youth, there is an unprecedented need for adolescent health promotion. Nursing professionals can make significant contributions to health promotion among adolescents and their families. Because nurses understand the biologic, cognitive, psychosocial, and social transitions of adolescence and their impact of health behavior, they can address adolescents' developmental and health needs. Working with colleagues from other disciplines, community members, parents, and adolescents themselves, nurses must become part of a comprehensive approach that delivers consistent messages across clinical, school, and community-based settings. Nurses should be at the forefront of developing and disseminating culturally appropriate health promotion interventions.

Both adolescents and their parents are often confused and perplexed about the changes and behavior of this stage of development. Parents need support and guidance to help them through this trying time. They need to understand the changes taking place and to accept the expected behaviors that accompany the process of detachment. Parents may need help to "let go" and to promote the changed relationship from one of dependence to one of mutuality. Suggestions for anticipatory guidance of parents of adolescents are listed in the Family-Centered Care box.

FAMILY-CENTERED CARE

Guidance During Adolescence

Encourage parents to:

- Accept adolescent as a unique individual.
- Respect adolescent's ideas, likes and dislikes, and wishes.
- Be involved with school functions and attend adolescent's performances, whether it is a sporting event or school play.
- Listen and try to be open to teenager's views even when they disagree with parental views.
- Avoid criticism about no-win topics.
- Provide opportunity for choosing options and accept natural consequences of these choices.
- Allow young persons to learn by doing, even when choices and methods differ from those of adults.
- Provide adolescent with clear, reasonable limits.
- Clarify house rules and consequences for breaking them. Let society's rules and consequences teach responsibility outside the home.
- Allow increasing independence within limitations of safety and well-being.
- Respect adolescent's privacy.
- Try to share adolescent's feelings of joy or sorrow.
- Respond to feelings as well as words.
- Be available to answer questions, give information, and provide companionship.
- Try to make communication clear.
- Avoid comparisons with siblings.
- Assist adolescent in selecting appropriate career goals and preparing for adult roles.
- Welcome adolescent's friends into the home and treat them with respect.
- Provide unconditional love and acceptance.
- Be willing to apologize when mistaken.

Be aware that adolescents:

- Are subject to turbulent, unpredictable behavior.
- Are struggling for independence.
- Are extremely sensitive to feelings and behavior that affect them.
- May receive a different message from what was sent.
- Consider friends extremely important.
- Have a strong need to belong.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A 14-year-old boy is being seen in the clinic because of concerns that he is not maturing at the same rate as other boys his age. On examination, he has enlargement of the testes and scrotal changes are observed. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**
The first pubescent change in boys is _____1_____. Temporary_____2_____ enlargement and tenderness are common and can commonly occur of boys.

Options for 1	Options for 2
facial hair	muscle
height	breast
testicular enlargement	penile
ejaculation	testicular
axillary hair	larynx
voice changes	neck

2. A 16-year-old boy is being seen in the emergency department following a car accident while he was driving. He is not severely injured but is being observed for a head concussion. His mother arrives and is extremely concerned because as she states, "he is such a risk taker and never seems to consider what might happen to him." Which of the following statements describe the most common source of unintentional injury and death in young people and would be shared with the mother? **Select all that apply.**
   - **A.** "The leading cause of death in teenagers is suicide."
   - **B.** "Teenagers can be risk takers because of new feelings of strength and confidence."
   - **C.** "Motor vehicle crashes are a concern in that they are the greatest cause of unintentional injuries in young people."
   - **D.** "Teenagers should avoid distractions while driving including cell phone talking and texting."
   - **E.** "Teaching teenagers at this age about safe driving does little to improve their driving habits."
   - **F.** "Giving your teenager an opportunity to talk about the accident without judging his actions is important."

3. A nurse is interviewing a 16-year-old female who is here for a history and physical examination required for all cheerleaders. Which of the following statements would help the nurse **most effectively** communicate with this teenager? **Select all that apply.**
   - **A.** Ask open-ended questions
   - **B.** Ensure confidentiality and privacy
   - **C.** Maintain objectivity and avoid judgment
   - **D.** Begin with sensitive issues then proceed with less sensitive topic
   - **E.** Assume you understand the adolescent by including your own experiences
   - **F.** Interview the adolescent with the parents to ensure accuracy

4. A 12-year-old adolescent male who has completed all recommended routine childhood vaccinations is being seen for a well child examination before school. He has not received any of the immunizations recommended as part of adolescent preventive care. From the list below, which immunizations would be given today? **Select all that apply.**
   - **A.** DTaP vaccine
   - **B.** Tdap vaccine
   - **C.** Measles vaccine
   - **D.** Meningococcal vaccine
   - **E.** Pneumococcal vaccine
   - **F.** HPV vaccine
   - **G.** Hepatitis B vaccine

HEALTH PROBLEMS OF SCHOOL-AGE CHILDREN

PROBLEMS RELATED TO ELIMINATION

Enuresis

The *Diagnostic and Statistical Manual of Mental Disorders,* Fifth edition (DSM-5; (American Psychiatric Association, 2013) separates elimination disorders into enuresis and encopresis. Enuresis is defined as repeated urination into bed or clothing at least twice a week for a period of at least 3 months that is not due directly to a physiologic condition or substance and occurs in an individual who is at least 5 years of age (American Psychiatric Association, 2013).

Enuresis can happen during the day or at night. It can be a frustrating condition for the caregiver and child. Enuresis is classified into "monosymptomatic" and "nonmonosymptomatic" types, with the former referring to bedwetting plus no other symptoms and the latter referring to bedwetting plus other urinary tract symptoms such as daytime incontinence, infections, or holding maneuvers (Fagundes, Lebl, Soster, et al., 2016). Medical evaluation is recommended when inappropriate voiding of urine occurs at least once a month for a minimum of 3 consecutive months and the chronologic or developmental age of the child is at least 5 years old (Caldwell, Lim, & Nankivell, 2018). In addition, the urinary incontinence must not be related to the direct physiologic effects of a medication (e.g., diuretics) or a general medical condition (e.g., diabetes mellitus or diabetes insipidus, spina bifida, seizure disorder, constipation, sexual abuse).

Enuresis is more common in boys (Fagundes et al., 2016); nocturnal bedwetting usually ceases between 6 and 8 years old. Enuresis can also be defined as **primary** (bedwetting in children who have never been dry for extended periods) or **secondary** (the onset of wetting after a period of established urinary continence).

During the initial phases of evaluation, a routine physical examination is performed to rule out physical causes related to enuresis. These include structural disorders of the urinary tract; urinary tract infection; neurologic deficits; disorders that increase the normal output of urine, such as diabetes; and disorders that impair the concentrating ability of the kidneys, such as chronic renal failure. In addition, the family may be instructed to keep a voiding diary to estimate bladder capacity and urine output. In other cases, enuresis is influenced by psychologic factors. If psychologic difficulties are evident, a routine psychiatric evaluation is warranted.

A detailed history of voiding and bowel habits is obtained, including information about the toilet training process. An important feature of assessment is a baseline count of enuretic incidents and the time of day when each occurs. Despite parental reports that these children sleep more soundly than other children, the depth of sleep has not been identified as the cause of nocturnal enuresis, although defective sleep arousal may contribute to the problem (Elder, 2020). Obstructive sleep apnea (OSA) and nocturnal enuresis (NE) are common clinical problems in children. OSA and NE are thought to be interrelated, but the exact pathophysiologic mechanisms are not yet clear. Nocturnal enuresis has a strong familial tendency in more than 90% of first- and second-degree relatives (Fagundes et al., 2016). Enuresis can persist into adulthood, with prevalence rates of 1% to 3% (American Psychiatric Association, 2013).

The physical examination may be followed by diagnostic evaluation of functional bladder capacity. Normal bladder capacity (in ounces) is calculated as the child's age plus 2 (up to 14 years old); therefore normal bladder capacity for a 6-year-old is 8 ounces (237 ml). A bladder volume of 10 to 12 ounces (300 to 350 ml) is sufficient to hold one night's urine.

Enuresis has been treated in several ways. The first steps of therapy for primary monosymptomatic enuresis include education, behavior modification, and reassurance. No single method has achieved universal endorsement, and more than one technique is often used by families coping with enuresis. Therapeutic techniques used to manage nocturnal enuresis include medications; complementary and alternative medicine techniques, such as hypnotherapy; restriction or elimination of fluids after the evening meal; avoidance of caffeinated and sugar-containing beverages after 4 PM; avoidance of high-protein foods and salt; purposeful interruption of sleep to void; and motivational therapy. Parents should be educated that punishment is not an acceptable treatment for enuresis. Devices designed to establish a conditioned reflex response to waken the child at the initiation of voiding, such as bedwetting alarms, are the first-line treatment for children with nocturnal enuresis (Walle, Rittig, & Tekgul, 2017). The mechanism

of alarm therapy is not well understood, but successful resolution of enuresis is thought to be due to changes in sleep arousal associated with voiding. Poor compliance and insufficient duration of therapy are common with alarm therapy (Caldwell et al., 2018).

Drug therapy can be prescribed to treat enuresis. The selection of medication depends on the interpretation of the cause. Desmopressin acetate (DDAVP), an analog of vasopressin, is commonly used to treat nocturnal enuresis. DDAVP works by increasing water reabsorption, thus reducing urine production to a volume less than functional bladder capacity. The medication is available in an oral preparation and is generally well tolerated but may cause dry mouth, headache, or nausea. An advantage of using desmopressin is that a patient will have an immediate response, whereas alarm therapy may take up to 2 weeks to be effective. The drug imipramine (Tofranil) and anticholinergics are not used routinely in primary care to treat enuresis due to their cardiac side effects, including cardiac arrhythmias, hypotension, and hepatotoxicity. Drugs are considered second-line management for enuresis, and parents should be cautioned not to think that these agents will cure the condition; parents are also advised of the drugs' side effects (Elder, 2020). Researchers continue to study interventions for resistant cases of enuresis (Caldwell et al., 2018).

Nursing Care Management

No matter what techniques are used, the nurse can support both children and parents who are coping with the problem of enuresis, the treatment plan, and the difficulties they may encounter in the process. Essential to the success of any method is the supportive management of parents and their children. Both need encouragement and patience. The problem is discussed with both the parent and the child because all treatments involve and require the child's active participation. In some treatment interventions, the child is in charge of the intervention; therefore parents must learn to support the child rather than intervene themselves. Parents should also be taught to observe for side effects of any medications used. Parents should encourage the child to maintain a regular bowel evacuation regimen; constipation can contribute to nocturnal enuresis (Elder, 2020). A calendar with wet and dry nights may be helpful to motivate the child to stay dry and maintain a positive perspective on the problem.

Many parents believe that enuresis is caused by an emotional disturbance and fear that they have somehow produced the situation through improper childrearing practices. They need reassurance that bedwetting does not represent willful misbehavior. Parents need to understand that punishment such as scolding, shaming, and threatening is contraindicated because of its negative emotional impact and limited success in reducing the behavior. Children need to believe that they are helping themselves, and they need to sustain feelings of confidence and hope. Encourage parents to be patient, to be understanding, and to communicate love and support to the child.

Communication with children is directed toward eliminating the emotional impact of the problem, relieving feelings of shame and guilt and the burden of parental disapproval, building self-confidence, and motivating children toward independent control. More important, the nurse can provide consistent support and encouragement to help children through the inconsistent and unpredictable treatment process. Children need to believe that they are helping themselves and to maintain feelings of confidence and hope.

Encopresis

Encopresis is defined as repeated bowel movements into bed or clothing at least one time per month for a period of at least 3 months, is not due directly to a physiologic condition or substance, and occurs in an individual who is at least 4 years of age (American Psychiatric Association, 2013).

The fecal incontinence must not be caused by any physiologic effect, such as a laxative, or a general medical condition. The consistency of the stool may vary from normal to liquid, with a more liquid stool seen in individuals who have overflow incontinence secondary to fecal retention. There are many possible causes of constipation, including behavioral reasons and medical or physiologic reasons. Subtypes of encopresis, including encopresis with constipation and overflow incontinence (which requires the passage of stool less than three times per week) and encopresis without constipation and overflow incontinence (where there is no evidence on physical examination or by history of constipation and soiling is no more than intermittent), continue to be used in diagnosing the condition (American Psychiatric Association, 2013). **Primary encopresis** is identified by 4 years of age when a child has not achieved fecal continence. **Secondary encopresis** is fecal incontinence occurring in a child older than 4 years of age after a period of established fecal continence. One of the most common causes of encopresis is constipation, which may be precipitated by environmental change, such as having a new sibling, moving to a new house, changing schools, or even having to use new or unfamiliar toilet facilities. Chronic, severe constipation has a tendency to impair the usual movement and contractions of the colon, which can lead to fecal obstruction. Abnormalities in the digestive tract (e.g., Hirschsprung disease, anorectal lesions, malformations, rectal prolapse) and medical conditions (such as hypothyroidism, hypokalemia, hypercalcemia, lead intoxication, myelomeningocele, cerebral palsy, muscular dystrophy, and irritable bowel syndrome [IBS]) are also associated with constipation, which can lead to encopresis. Voluntary retention of stool may also follow an incident of painful defecation (e.g., in a child with anal fissures). Involuntary retention may be produced by emotional problems caused by the encopresis, which sets up a fear–pain cycle and results in learned abnormal defecation patterns. **Psychogenic encopresis**, in which the soiling is caused by emotional problems, is often related to a disturbed mother-child relationship.

Normally, children and adolescents have one or two soft-formed stools per day. Children with soiling problems tend to form large-bore stools, which are painful to excrete. Therefore they tend to avoid defecation and withhold stooling. Stool held in the rectum and sigmoid colon loses water and progressively hardens, which causes successively more painful bowel movements and a stretched rectal vault. Over time, the child will lose the urge to defecate on his or her own. A pain–retention–pain cycle is established. Many children have diarrhea or loose leakage in their clothing and pass small amounts of hard stool, which suggests leakage around an impaction.

Children may experience exacerbations with transitions in the school setting. Some reasons for developing retentive tendencies at this time are fear of using school bathrooms, a busy schedule, and the interruption of an established time schedule for bowel evacuation. Children may also react to stress with bowel dysfunction. Children with encopresis have a significantly greater incidence of anxiety and depressive symptoms, attention problems, social problems, disruptive behavior, lower academic performance, and family environments characterized by less expression and poor organization (Olaru, Diaconescu, Trandafir, et al., 2016).

Therapeutic management consists of ruling out a structural issue like congenital megacolon. To determine the cause, a detailed history, including risk factors (negative toilet training, child abuse or neglect, fear of bathrooms), comorbid conditions (such as attention deficit disorder, cognitive delays, oppositional disorders), and associated symptoms of bowel movements (retention, overflow soiling, incontinence), is obtained (Olaru et al., 2016). Next, a thorough physical examination,

including a rectal examination, is completed. Abdominal radiography may be done to determine the severity of impaction. Once encopresis is diagnosed, standard therapy involves laxatives, enemas, suppositories, and sometimes manual removal of impacted feces.

Many children require an extensive and invasive bowel cleansing to remove the bowel impaction before starting treatment (Koppen, Vriesman, Saps, et al., 2018). Fecal impaction is relieved by lubricants (such as mineral oil), osmotic laxatives (such as lactulose, sorbitol, or polyethylene glycol [PEG or MiraLax]), probiotics, and magnesium hydroxide (Koppen et al., 2018). Customary dosages are usually insufficient to produce a therapeutic response. Mineral oil should be avoided in children who have dysphagia or vomiting to prevent aspiration.

Children without bowel impaction can start treatment immediately. Dietary modifications, lubricants, and behavior therapy that encourage the child to establish normal defecation are used. Dietary changes, including consumption of increased amounts of high-fiber foods such as fruits, vegetables, and cereals and increased hydration with water, are encouraged. Stool softeners and laxatives are used until stools become soft. Behavior therapy, such as maintaining regular bathroom routines, increasing exercise, and having the child take on more responsibility for the bowel program, is a vital part of the treatment plan (Koppen et al., 2018). Psychotherapeutic intervention with the child and family may become necessary.

Nursing Care Management

A thorough history of the soiling is essential, including when soiling began, how often it occurs and under what circumstances, and whether the child uses the toilet successfully at all. Because the parents and child are reluctant to volunteer information, direct questioning about the soiling is more successful.

Education on the physiology of normal defecation, toilet training as a developmental process, and the treatment outlined for the family is a prerequisite to a successful outcome. Bowel retraining with mineral oil, a high-fiber diet, and a regular toileting routine is essential in treating encopresis or chronic constipation. The toileting routine should consist of the child sitting on the toilet 10 to 15 minutes after meals for intervals of 10 minutes and placing a footstool below the feet to relax the abdomen and make the child more comfortable. Positive reinforcement such as giving stickers, praising the child, and awarding special activities may encourage the child to participate in the bowel regimen.

Family counseling is directed toward reassurance that most problems resolve successfully, although the child may have relapses during periods of stress, such as vacations or illness. If encopresis persists beyond occasional relapses, the condition must be reevaluated. Behavior modification techniques are explained, and the family is assisted with a plan suited to the particular situation.

SCHOOL-AGE DISORDERS WITH BEHAVIORAL COMPONENTS

Attention-Deficit/Hyperactivity Disorder and Learning Disability

Attention-deficit/hyperactivity disorder (ADHD) refers to developmentally inappropriate degrees of inattention, impulsiveness, and hyperactivity (American Psychological Association, 2013). Early identification of affected children is important because the characteristics of ADHD significantly interfere with the normal course of emotional and psychologic development. The behavior of children with ADHD evokes negative responses from others, and repeated exposure to negative feedback adversely affects self-concept. Children with ADHD are at greater risk for conduct disorders, oppositional defiant disorders, depression, anxiety disorders, and developmental disorders (such as speech and language delays and learning disabilities) than are children without ADHD (American Academy of Pediatrics, 2011).

Clinical Manifestations

The behaviors exhibited by the child with ADHD are not unusual aspects of child behavior. The difference lies in the quality of motor activity and developmentally inappropriate inattention, impulsivity, and hyperactivity that the child displays. The manifestations may be numerous or few, may be mild or severe, and vary with the child's developmental level; about half of diagnoses are made by a primary care provider (Canady, 2015). Mild manifestations of the symptoms are apparent in at least two settings, usually educational and family environments. Each child with ADHD is different from all other children with ADHD (American Psychiatric Association, 2013). The American Academy of Pediatrics (2011) recommends that diagnosis incorporate both the use of standardized rating scales based on criteria from the DSM-5 and information from multiple sources such as parents, teachers, and older family members. Current DSM-5 diagnostic criteria include at least six designated symptoms of inattention or hyperactivity-impulsivity (lowered to five symptoms in adolescents over age 17 years) appearing before 12 years of age, with symptoms present for at least 6 months, occurring in more than one setting, and of a degree that impairs functioning or normal development (American Psychological Association, 2013).

Most behavioral manifestations are apparent at an early age, but the associated learning disabilities may not become evident until the child enters school. A major clinical manifestation is distractibility. The stimuli may come from external or internal sources. Children frequently demonstrate immaturity relative to chronologic age. Selective attention in which the child has difficulty attending to "nonpreferred" tasks, such as completing chores or finishing homework, is often seen. The child may not consider the consequences of behavior, may take excessive physical risks (often beginning early in life), and may demonstrate inappropriate social skills.

People with ADHD show a persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development. Based on the types of symptoms, different kinds (presentations) of ADHD can occur:

- *Inattentive presentation:* If enough symptoms of inattention but not hyperactivity-impulsivity were present in the past 6 months
- *Hyperactive-impulsive presentation:* If enough symptoms of hyperactivity-impulsivity but not inattention were present in the past 6 months

Diagnostic Evaluation

It is important to emphasize the need for a complete and thorough multidisciplinary evaluation of the child, incorporating the efforts of the primary pediatric health care provider and the family as well as possible support from a psychologist, developmental pediatrician, neurologist, pediatric nurses, classroom teachers, and administrators. The clinicians and professionals must first determine whether the child's behavior is age appropriate or truly problematic. The American Academy of Pediatrics (2011) recommends that children diagnosed with ADHD be assessed for comorbidities of anxiety, depression, oppositional defiant disorder, conduct disorders, language and learning disorders, tics, and sleep apnea.

Prior to diagnosis a complete medical and developmental history is obtained. Descriptions of the child's behavior in the home, school, and social situations are obtained from as many observers of the child as possible, especially the parents and teachers involved in the child's

care. A physical examination, including vision and hearing screening and a detailed neurologic evaluation, is completed. Psychologic testing, especially projective tests, is used to identify visual-perceptual difficulties, problems with spatial organization, and other phenomena that suggest cortical or diencephalic involvement, and it helps to identify the child's intelligence and achievement levels.

Behavioral checklists and adaptive scales should be completed by the child's caregivers and educators and scored by the primary care provider. These assessment tools are helpful in measuring social adaptive functioning in children with ADHD as well as providing benchmarks for evaluation of improved or worsening behavioral changes once therapy has begun. Psychiatric disorders, medical problems, and traumatic experiences are ruled out, including lead poisoning, seizures, partial hearing loss, psychosis, and witnessing of sexual activity or violence.

Therapeutic Management

Treatment of ADHD depends on the child's age and severity of symptoms. Evidence supports behavioral therapy as the first-line treatment, but other approaches include family education and counseling, medication, proper classroom placement, environmental manipulation, and psychotherapy for the child. According to McClain and Burks (2015), just over 80% of youth with ADHD receive ongoing treatment.

Behavioral Therapy

Behavioral therapy focuses on the prevention of undesired behavior. Families are helped to identify new appropriate contingencies and reward systems to meet the child's developing needs through different techniques and strategies. Behavior therapy requires both time and effort, but it can lead to improved functioning at home, in school, and in social situations (Centers for Disease Control and Prevention, 2017). Families may also receive instruction in effective parenting skills, such as delivering positive reinforcement, rewarding small increments of desired behaviors, and providing age-appropriate consequences (e.g., time-out, response cost). Additional interventions include skill building, social skills training, and intensive summer-camp treatment programs. Through collaborative teamwork parents learn techniques to help the child become more successful at home and in school.

Pharmacologic Therapy

The choice of medication is determined by age. For children (age 5 years and over) and young people, the drug of first choice is methylphenidate (either long acting or immediate release). If symptoms and impairment are not sufficiently reduced after methylphenidate at an adequate dose, a switch to lisdexamfetamine should be considered (Frampton, 2018).

Children are given a small dosage initially, and the dosage is gradually increased until the desired response is achieved. Children who receive stimulants should be monitored carefully for side effects of the medication: appetite loss, abdominal pain, headaches, sleep disturbances, and growth velocity. Stimulants should be avoided in children who have a history of ticlike behaviors, a family history of Tourette syndrome (TS), or ADHD combined with TS, because these medications may exaggerate tics.

Other medications, including tricyclic antidepressants and extended-release clonidine, may be used as adjunct therapy for ADHD, primarily for children with coexisting conditions, such as sleep disturbances (American Academy of Pediatrics, 2011). The use of stimulants requires special consideration. They are controlled drugs and so prescribing and storage must meet specific requirements. Modified-release, once-daily preparations offer convenience and better adherence. They reduce stigma because they can be taken outside school. Modified-release formulas also eliminate the risk of misuse and diversion. Misuse includes cognitive enhancement in adolescents and appetite suppression. It is important to remember that these medications are not prescribed based on the child's weight (except for atomoxetine) but on resolution of the symptoms; therefore it is important to follow the child closely and evaluate for therapeutic effects as well as potential side effects. Regularly scheduled reevaluation of the child is essential with all of these medications to determine medication effectiveness, detect and evaluate any side effects, monitor development and health status (especially growth and blood pressure), and assess family interaction. See Table 16.1 for a description of the Pediatric Quality Indicator for follow-up of children taking ADHD medications (see also Critical Thinking Case Study box).

TABLE 16.1 Pediatric Quality Indicator[a]

Follow-Up Care for Children Prescribed ADHD Medications	
Measure	Children 6-12 years of age who were given a prescription of ADHD medication had at least two follow-up visits within 270 days, including one visit within 30 days after starting the medication.
Numerator	Number of children who had at least one face-to-face visit with a practitioner with prescribing authority within 30 days after starting the medication during the measurement time.
Denominator	Number of children who were dispensed an ADHD medication during the intake period and who had a visit during the measurement period.

ADHD, Attention-deficit/hyperactivity disorder.

CRITICAL THINKING CASE STUDY

Attention-Deficit/Hyperactivity Disorder (ADHD)

Johnnie, an 8-year-old third-grader, was recently diagnosed with ADHD. He has been taking the drug methylphenidate (Ritalin) for about 1 month. In the short time that Johnnie has been taking this medication, his math teacher has noticed an improvement in his performance in math class. He is receiving a grade of B instead of his previous grades of D on most math quizzes. The math teacher has also noted that Johnnie is socializing more with his classmates and that he now has a "best friend" in math class. Johnnie usually receives his methylphenidate from the school nurse before lunch. Yesterday Johnnie's mother told the school nurse that Johnnie has not eaten his lunch for the past week and that he is not hungry.

Initial Assessment. How would you describe Johnnie's response to ADHD medication?

Clinical Reasoning. What evidence is found in the case study that supports the use of medication for ADHD in this child?

Teaching Points

- Children on ADHD medication must be monitored closely for side effects.
- Lack of appetite is a common symptom related to ADHD medication.

Critical Thinking Answers

Initial Assessment. The assessment shows that Johnnie has had a positive response to ADHD medication. He is performing better in class and socializing more with others.

Clinical Reasoning. ADHD causes symptoms of inattention that leads to a variety of other behaviors. Children often have trouble with social skills. The case study indicates that Johnnie is more attentive at school and making friends.

Multimodal treatment. The results of several studies suggest that multimodal treatment involving the use of pharmacotherapy and behavioral intervention as well as close follow-up and feedback from school personnel is more effective than intensive behavioral treatment alone (Ahmann, 2017). ADHD coaching has been increasingly identified as a useful, important aspect of multimodal treatment for individuals of all ages with ADHD (Roy & Hectman, 2016). According to the Professional Association for ADHD Coaches, this approach empowers individuals to manage their attention, hyperactivity, and impulsivity by developing self-awareness and strategies.

Environmental manipulation. Encourage families to learn how to modify the environment to allow the child to be more successful. Consistency is especially important for children with ADHD. Consistency between families and teachers in terms of reinforcing the same goals is essential. Fostering improved organizational skills requires a more highly structured environment than most children need. Children should be encouraged to make more appropriate choices and to take responsibility for their actions.

Other helpful interventions include teaching parents how to make organizational charts (e.g., listing all activities that must be performed before leaving for school) and decrease distractions in the environment while the child is completing homework (e.g., turning off the television, having a consistent study area equipped with needed supplies) and helping parents to understand ways to model positive behaviors and problem solving. The focus is on strategies to help the child succeed and cope with deficits while emphasizing strengths.

Appropriate classroom placement. Children with ADHD need an orderly, predictable, and consistent classroom environment with clear and consistent rules. Homework and classroom assignments may need to be reduced, and more time may need to be allotted for tests to allow the child to complete them. Verbal instructions should be accompanied by visual references, such as written instructions on the blackboard. Schedules may need to be arranged so that academic subjects are taught in the morning when the child is experiencing the effects of the morning dose of medication. Low-interest and high-interest classroom activities should be intermingled to maintain the child's attention and interest. Regular and frequent breaks in activity are helpful because sitting in one place for an extended time may be difficult. Computers are helpful for children who have difficulty with written assignments and fine motor skills.

If learning disabilities exist, special training activities may be accomplished. These include self-contained classes limited to six to eight children, special resource rooms with equipment and teaching teams, mobile consultants who move from room to room to provide assistance to teachers and children, and first-grade programs in which high-risk children receive special attention to prevent or reduce the need for services as they progress. The purpose of programs for children with learning disabilities is to assist them toward more successful achievement, personal adjustment, and retention in the regular classroom.

Prognosis. With appropriate intervention, ADHD is relatively stable through early adolescence for most children. Some children experience decreased symptoms during late adolescence and adulthood, but a significant number of these children carry their symptoms into adulthood. The goal for children with ADHD is to help them identify their areas of weakness and learn to compensate for them.

Nursing Care Management

Nurses, especially school nurses, are active participants in all aspects of management of children with ADHD. Nurses in the community work with families and school personnel on a long-term basis to help plan and implement therapeutic regimens and to evaluate the effectiveness of therapy. They coordinate services and serve as a liaison between health and education professionals directly involved in the child's therapy program. School nurses understand the child's special needs and work with teachers (see Family-Centered Care box). Nurses in any setting (community, school, hospital, practitioner's office) provide support and guidance to children and families during the difficult period of the child's growing up with a disabling condition.

FAMILY-CENTERED CARE

A Child's Perception of Taking Ritalin at School

I feel embarrassed by having to leave class early to go take my medication. The other kids always ask where I'm going and why. It would be better if we could leave class at the same time as everyone else, go take the medication, and then just be a little late to the next class. Students don't ask why people are late for class, only why they leave early. It also bothers me when kids tell other kids, "Go take a pill" and other mean things just because someone is acting up.

What could nurses and teachers do to help? Most kids do not understand why other kids have to take medication. I think it would help if a nurse or teacher talked with the other kids and explained why some children take the medication and how ADHD affects people. That way there would be more understanding among all the kids.

—Marissa White, age 16 years

Management begins with an explanation to the parents and the child of the diagnosis, including the nature of the problem and the practitioner's concept of the underlying central nervous system (CNS) basis for the disorder. Parents need to be informed of the possible side effects of medications. If decreased appetite is a concern, giving the psychostimulants with or after meals rather than before, encouraging consumption of nutritious snacks in the evening when the effects of the medication are decreasing, and serving frequent small meals with healthy "on-the-go" snacks are helpful interventions. Sleeplessness is reduced by administering medication early in the day.

Children taking tricyclic antidepressants display a dramatic increase in the incidence of dental caries. The marked anticholinergic action of the drugs increases saliva viscosity and produces a dry mouth. Emphasis on rigorous dental hygiene, conscientious home fluoride treatments, regular visits to the dentist, limited intake of refined carbohydrates, and use of artificial saliva is an important nursing function. The child should drink plenty of fluids and be well hydrated.

Parents often express concern that their children will become addicted to the psychostimulants or antidepressant drugs. Both types of drugs have the potential for abuse, and all children taking these drugs should be monitored closely for psychologic dependence, tolerance, depression, and other adverse behavior changes or idiosyncratic effects. Most children with ADHD are not interested in abusing their drugs because the effect of the drugs in these children is opposite that produced in normal individuals. However, caution parents to keep these drugs safely stored away from young children who may inadvertently ingest them and from adolescents who may abuse them.

Parents need information about the prognosis and an understanding of the treatment plan. The greater their understanding of the disorder and its effects, the more likely they will be to carry out the recommended program of therapy. It is important that they understand that the therapy is not necessarily a panacea and that it will extend over a long period. This has particular significance for changes they need to make in environmental management. Reading material to help the child and family can be obtained from a variety of sources.

Posttraumatic Stress Disorder

Characteristic symptoms of posttraumatic stress disorder (PTSD) occur after exposure to an extremely traumatic experience or catastrophic event. The traumatic experience is typically life threatening to self or a significant other and may involve witnessing mutilation or death, experiencing or witnessing a serious injury, or physical coercion. An accident, assault, or victimization; a natural disaster (e.g., earthquake, flood); sexual abuse; or witnessing a suicide, homicide, beating, or shooting can lead to PTSD. It is important to note that PTSD is not limited to children who have lived in "war-torn" countries. Events such as automobile, school, or recreational accidents and bullying have also been identified as causes of PTSD.

The characteristic symptoms are persistent reexperiencing of the traumatic event, persistent avoidance of stimuli associated with the trauma, numbing of general responsiveness, and persistent symptoms of increased arousal. The response to the event takes place in three stages. The initial response involves intense arousal, which usually lasts for a few minutes to 1 or 2 hours. The stress hormones are at maximum level as the individual prepares for "fight or flight." A prolonged arousal phase may indicate psychosis.

The second phase, which lasts approximately 2 weeks, is one in which defense mechanisms are mobilized. It is a period of calm in which the event appears to have produced no impression. The victim feels numb, and stress hormone secretion is absent. Defense mechanisms are less adaptive to specific situations and may not be what the situation demands. Denial that anything is wrong is a frequently observed defense mechanism. Without professional support the victim may develop severe depression, aggression, or psychosis (Meiser-Stedman & McKinnon, et al., 2017).

The third phase is one of coping and consciously directed inquiry, which normally extends over 2 to 3 months. The victims want to know what happened and appear to be getting worse when actually they are getting better. Numerous psychologic symptoms, such as depression, repetitive phenomena, phobic symptoms, anxiety, and conversion reactions, may be apparent. Children frequently display repetitive actions. They play out the situation over and over in an attempt to come to terms with their fear. Flashbacks are common. This phase can be self-perpetuating, and a prolonged reaction can develop into an obsession with the traumatic event. Some traumatic effects remain indefinitely.

Nursing Care Management

Children need to deal with any traumatic event; much hinges on the intensity of the event and their reactions to it. Children's reactions depend heavily on their social environment and the way in which their caretaking adults react to the event. In the second phase of PTSD, the appropriateness of the defense mechanism must be assessed, and children must be assisted in coping with their emotions.

Coping is a learned response, and children in the third phase can be helped to use their coping strategies to deal with their fears. Children usually are willing to accept reasoning. Those who are assisted in their catharsis and allowed expression will survive without serious lasting effects. Encourage them to play out the stress and discuss their feelings about the event.

Children need professional help if any of the phases of PTSD are prolonged. Boys tend to have a prolonged defense phase more often than girls. Occasionally the precipitating event will go unrecognized (bullying and psychologic abuse are most common in school-age children), and the affected child will engage in what is considered to be unusual behavior. Children exhibiting any sudden change in behavior need to be assessed for exposure to a traumatic event. When the change in behavior is traced to a traumatic event, treatment should be implemented immediately to prevent or reduce the long-term emotional and psychologic effects of PTSD (Hagan, Gentry, Ippen, et al., 2017).

School Phobia

Children, other than beginning students, who resist going to school or who demonstrate extreme reluctance to attend school for a sustained period as a result of severe anxiety or fear of school-related experiences are said to have school phobia. The terms *school refusal* and *school avoidance* are also used to describe this behavior. School phobia occurs in children of all ages, but it is more common in children 10 years of age and older. School avoidance behaviors occur in both boys and girls and in children from all socioeconomic levels.

Anxiety that verges on panic is a constant manifestation, and children can develop symptoms as a protective mechanism to avoid facing the situation that distresses them. Physical symptoms are prominent and may affect any part of the body; anorexia, nausea, vomiting, diarrhea, dizziness, headache, leg pains, and abdominal pains are most common. Children may even develop a low-grade fever. A striking feature of school phobia is the prompt subsiding of symptoms when it is evident that the child can remain at home. Another significant observation is absence of symptoms on weekends and holidays unless they are related to other places, such as Sunday school or parties. Occasional mild reluctance to attend school is common among school-age children, but if the fear continues for longer than a few days, it must be considered a serious problem.

The onset is usually sudden and precipitated by a school-related incident. By taking a careful history, nurses can find out whether a poor attendance record is caused by trivial reasons.

Nursing Care Management

Treatment for school phobia depends on the cause. The primary goal is school attendance. The longer a child is permitted to stay out of school, the more difficult it is for the child to reenter. Parents must be convinced gently but firmly that immediate return is essential and that it is their responsibility to insist on school attendance.

A school reentry protocol may be necessary for the child with severe symptoms. In reentry programs, the child role-plays routines involved in getting ready for school and activities that occur at school. Relaxation techniques are also used. The child usually goes to school initially for a half-day and then progresses to a full day. Often the school nurse can provide support to the parents and teacher during the reentry process. If the problem persists, professional help is recommended.

Conversion Reaction

Conversion reaction, also known as hysteria, hysterical conversion reaction, and childhood hysteria, is a psychophysiologic disorder with a sudden onset that usually can be traced to a precipitating environmental event. The disorder is observed with equal frequency in both sexes in childhood, but affected girls outnumber affected boys during adolescence. The manifestations involve primarily the voluntary musculature and special senses and include abdominal pain, fainting, pseudoseizures, paralysis, headaches, and visual field restriction. Once considered rare in childhood, the disorder occurs more frequently than has generally been acknowledged. The most commonly observed symptom is seizure activity, which can be differentiated from symptoms of neurogenic origin by formal tests, the most useful of which is the finding of a normal electroencephalogram.

Many children with conversion reaction have experienced a major family crisis, such as loss of a parent or other significant person through death, divorce, or moving, before the onset of symptoms. The families of children with conversion reaction characteristically display problems in communication and depression or hypochondriasis in a parent.

BOX 16.1 Characteristics of Children With Depression

Behavior

Predominantly sad facial expression with absence or diminished range of affective response
Solitary play or work; tendency to be alone; disinterest in play
Withdrawal from previously enjoyed activities and relationships
Lowered grades in school; lack of interest in doing homework or achieving in school
Diminished motor activity; tiredness
Tearfulness or crying
Dependent and clinging or aggressive and disruptive behavior

Internal States

Utterance of statements reflecting lowered self-esteem, sense of hopelessness, or guilt
Suicidal ideations

Physiologic Manifestations

Constipation
Nonspecific complaints of not feeling well
Change in appetite resulting in weight loss or gain
Alterations in sleeping pattern, sleeplessness, or hypersomnia

Educating the child and family on the cause of emotional stresses or feelings and alternative approaches to coping with stress may alleviate the child's symptoms. If deep personality problems are evident, psychiatric consultation is indicated. Nursing care is similar to that for the child with recurrent abdominal pain.

Childhood Depression

Childhood depression has been shown to lead to an increased risk of poor academic performance, impaired social functioning, suicidal behavior, homicidal ideation, and alcohol or substance abuse. It is also associated with an increased risk of recurrent depressive episodes. Unfortunately, a large proportion of depression in children and adolescents is underdiagnosed and undertreated. Depression in childhood is often difficult to detect because children may be unable to express their feelings and tend to act out their problems and concerns rather than identify them verbally. Children who cannot verbalize their feelings may exhibit irritability, which may manifest as frustration, temper tantrums, and behavioral problems. Other symptoms indicative of depression in children include increased rejection sensitivity.

Adult caregivers, health care professionals, and educators may not recognize early warning signs of depression in children or may delay referral and treatment, believing that symptoms of depression are "just a stage of development" and will resolve with maturation. Authorities agree that childhood depression exists, but the manifestations often differ from those in depressed adults. Depressed children often exhibit a distinctive style of thinking characterized by low self-esteem, hopelessness, poor social engagement with peers, and a tendency to explain negative events in terms of personal shortcomings (Box 16.1).

Some states of depression are temporary, such as acute depression precipitated by a traumatic event. The causative event might include a period of hospitalization; loss of a parent through death or divorce; or loss of a significant relationship with something (a pet), someone (a friend or family member), or a place (move from a familiar home, neighborhood, or city). The easily identified manifestations include a sad face; tearfulness; irritability; and withdrawal from previously enjoyed activities and relationships. The child tends to spend more time in solitary activities, and schoolwork is impaired. Sleeplessness or hypersomnia, changes in appetite or weight (either increased or decreased), constipation, tiredness, and nonspecific complaints of not feeling well are common reactions.

More serious and less common are depressive responses to more chronic stress and loss. These are frequently observed in children with chronic illness or disability. The manifestations are similar to those seen in acute reactions. Major depressive disorders in childhood have a number of similarities with several other psychologic disorders.

Considering the fact that depression symptoms may be attributed to various physical illnesses, a through physical examination must be carried out in all children and adolescents presenting with depressive features. It is difficult to identify depression in the presence of a medical disorder, especially when the medical disorder is associated with change in appetite, sleep disruption, somatic symptoms, and fatigue.

Therapeutic Management

Depressed children are managed by a health team that is specially trained in the care of children with mental disorders. Treatment is highly individualized and undertaken in the least restrictive environment. Suicidal children are admitted to the hospital for protection if the family is unable to provide constant monitoring. Hospitalization may also be advised for children with associated disruptive behavior, such as fighting with peers or family. Most therapeutic regimens focus on various combinations of counseling, psychotherapy, family therapy, cognitive therapy, education (teaching social and life skills that facilitate coping), environmental improvement, and pharmacotherapy.

For mild-to-moderate depression, psychotherapy is considered to be the preferred initial modality of treatment. Cognitive-behavioral therapy (CBT) is preferred in children and adolescents with cognitive distortions and comorbid anxiety disorders (Weersing, Jeffreys, Do, et al., 2017). Antidepressants are usually considered in the presence of moderate depression for which psychotherapy is not feasible, severe depression with or without psychotic symptoms, and depression that fails to respond to an adequate trial of psychotherapy.

Pharmacotherapy may involve tricyclic antidepressants or selective serotonin reuptake inhibitors (SSRIs); fluoxetine should be considered the first choice in children ages 8 years and older.

Escitalopram or sertraline can also be considered in treatment. There have been reports that antidepressant medications may cause increased suicidal thinking and behaviors in pediatric patients. This prompted the US Food and Drug Administration to require black box drug labeling detailing potential suicide-related risks for pediatric patients. Parents and significant others involved in the care of patients should also be informed of the possible role of SSRIs in suicidality. The decision to start an antidepressant or specific psychotherapy should be made jointly by the clinician and adequately informed parents (guardians) with agreement from the child.

Nursing Care Management

One care of the most important aspects of assessment of children and adolescents with depression includes the assessment of suicide risk. Care providers should not underestimate the risk of suicidal behavior in children and adolescents. Caregivers should ask about the presence of suicidal ideation, specific plans for self-injury, and any history of actual self-harm or overt threats or gestures.

Nurses should be aware that depression is a problem that can be easily overlooked in children and one that can interrupt normal growth and development. Recognizing depression and making appropriate referrals are important nursing functions. Identification of a depressed child requires a careful history (health, growth and development, social and family health); interviews with the child; and

TABLE 16.2 Pediatric Quality Indicator[a]

Screening for Depression and Follow-Up Plan	
Measure	Patients 12 years of age and older screened for depression on the date of the encounter using an age-appropriate standardized depression screening tool AND, if positive, a follow-up plan is documented on the date of the positive screen
Numerator	Patients screened for depression on the date of the encounter using an age-appropriate standardized tool AND, if positive, a follow-up plan is documented on the date of the positive screen
Denominator	All patients ages 12 years and older before the beginning of the measurement period with at least one eligible encounter during the measurement period

[a]Endorsed by the National Quality Forum NQF #0418 and 2019 Core Set of Children's Health Care Quality Measures for Medicaid and CHIP. https://www.medicaid.gov/federal-policy-guidance/downloads/cib112018.pdf.

observations by the nurse, parents, and teachers. If antidepressants are prescribed, the child and family need to know that antidepressants must be at a therapeutic level for 2 to 4 weeks to achieve a beneficial effect. The child and family also need to monitor the child for side effects of the specific drug prescribed and any interactions with other drugs. Hospitalization is usually indicated when a child or adolescent poses a serious threat of harm to self or others. See Table 16.2 for the Pediatric Quality Indicator for screening and follow-up in children and adolescents being treated for depression.

Anxiety

Considerable advances have been made in the assessment and treatment of pediatric anxiety disorders. However, children are often unrecognized and never receive suitable treatment recognition. Although they are common among children and adolescents, many parents and health care providers do not realize that anxiety disorders in youth predict anxiety disorders in adulthood. Symptoms include excessive anxiety, unrealistic worries, and fearfulness not related to a specific object or situation. The adolescent finds it difficult to control worry, with comorbid symptoms of restlessness or feeling keyed up or on edge, being easily fatigued, difficulty concentrating or the mind going blank, irritability, muscle tension, and sleep disturbance. Developing and implementing effective early interventions therefore has been a priority for clinical research over the last decades. CBT has robust empirical support for the treatment of youth anxiety disorders. Generic CBT programs for youth anxiety generally involve 10 to 16 therapy sessions, with change of dysfunctional thoughts and gradual exposure to feared situations as core elements (Heiervang, Villabø, & Wergeland, 2018).

Childhood Schizophrenia

Childhood schizophrenia refers to severe deviations in ego functioning and is generally reserved for psychotic disorders that appear in children younger than 15 years old. Childhood schizophrenia is a very rare illness among children in the general population; only about 2 in every 1000 with mental illness have childhood schizophrenia.

Childhood schizophrenia is characterized by symptoms that last at least 6 months and that seriously interfere with the child's functioning in school, at home, or in other social situations. The basic core disturbance is a lack of contact with reality and the subsequent development by the child of a world of his or her own. Young schizophrenic children can and do experience psychosis, which often is preceded by behavioral problems, developmental lags in fine motor and sensory functions, as well as persistence of primitive reflexes. There may be language and motor delays well before the development of actual psychosis. The DSM-5 points out the poorer prognosis for early-onset schizophrenia. The earlier age of onset has been correlated with high social disability. There are now clear distinctions between childhood schizophrenia, autistic disorder, and pervasive developmental disorders (PDDs). In autistic disorder, onset is before age 3 years and, in contrast to childhood schizophrenia, mental retardation is common. The PDDs each have criteria that differ from childhood schizophrenia and are not usually accompanied by psychosis. The longer psychosis continues to be untreated, the worse the eventual long-term prognosis becomes, so early intervention is important. The treatment for childhood schizophrenia needs to be multimodal and possibly include pharmacotherapeutics, family interventions, cognitive therapy, and environmental interventions.

Treatment involves management of symptoms, prevention of relapse, and social and occupational rehabilitation of the young person. Antipsychotic drugs that may be used include haloperidol, clozapine, chlorpromazine, and risperidone. Antipsychotic drugs are used with caution in children because of the risk of extrapyramidal symptoms of acute dyskinesias and dystonic reactions, tardive dyskinesia, parkinsonism, akinesia, akathisia, and neuroleptic malignant syndrome. Extrapyramidal symptoms are caused by dopamine blockade or depletion in the basal ganglia; this lack of dopamine often mimics idiopathic pathologies of the extrapyramidal system.

Family interventions and family therapy often result in improvements in psychotic symptoms, thought disorders, and social functioning among children with schizophrenia. Children may be managed in both inpatient and outpatient settings.

Nursing Care Management

Nursing care of psychotic children is a highly specialized area. However, nurses should be alert to the possibility that schizophrenia can occur in children and refer children who consistently demonstrate abnormal behavior for evaluation. In addition, nurses need to teach family members of children taking antipsychotic drugs to observe for possible side effects. When the child's reality is distorted due to misperceptions of the environment, the nurse must continually clarify these perceptions and correct them. Parents and guardians of children with schizophrenia typically feel out of control and need help to dispel feelings of helplessness. Parents must be taught that they are an integral part of the treatment plan. Nurses play a key role in the support and psychoeducation of family members of the child with schizophrenia.

HEALTH PROBLEMS OF ADOLESCENTS

ACNE

Acne vulgaris is the most common skin problem treated by physicians during adolescence. Acne stimulates the sebaceous glands of the skin to enlarge, or produce oil, and plug the pores. **Comedogenesis** (formation of comedones) results in a noninflammatory lesion that may be either an open comedone ("blackhead") or a closed comedone ("whitehead") (Fig.16.1).

More than half of the adolescent population will experience acne by the end of the teenage years. Although the disorder can appear before 10 years old, the peak incidence occurs in middle to late adolescence (16 to 17 years old in girls and 17 to 18 years old in boys). It is more common in boys than in girls. After this age period, the disease usually decreases in severity, but it may persist into adulthood. Although the disease is self-limiting and is not life threatening, it has

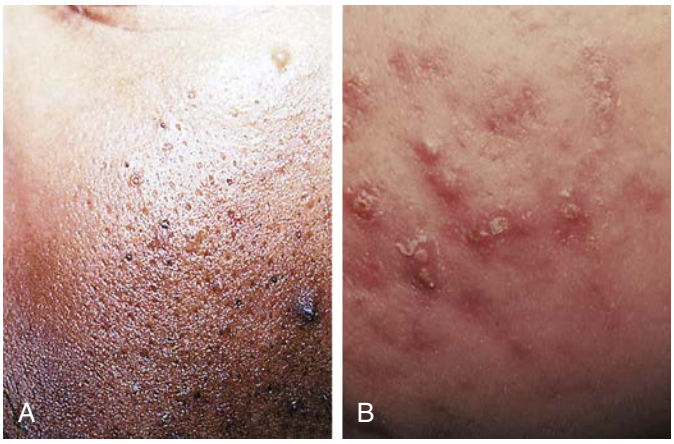

Fig. 16.1 Acne vulgaris. **A,** Acne vulgaris. **B,** Comedones with a few inflammatory pustules. (From Zitelli, B. J., McIntire, S. C., & Nowalk, A. J. [2012]. Zitelli and Davis' atlas of pediatric physical diagnosis [6th ed.]. St Louis, MO: Elsevier.)

great significance to affected adolescents. Health professionals should not underestimate the impact that acne has on teens.

Numerous factors affect the development and course of acne. Its distribution in families and a high degree of concordance in identical twins suggest hereditary factors. Premenstrual flare-ups of acne occur in nearly 70% of adolescent girls, suggesting a hormonal cause. Studies do not indicate a clear association between stress and acne, but adolescents commonly cite stress as a cause for acne outbreaks. Cosmetics containing lanolin, petrolatum, vegetable oils, lauryl alcohol, butyl stearate, and oleic acid can increase comedone production. Exposure to oils in cooking grease can be a precursor in adolescents working in fast-food restaurants. The link between dietary intake and the development or worsening of acne lesions has been a topic of much discussion. There is evidence that there may be an association with the intake of dairy products and high glycemic index foods that may potentiate hormonal and inflammatory factors that contribute to acne severity (Cerman, Aktas, & Altunay, 2016). In patients with features of metabolic syndrome, a low-glycemic diet can be recommended to improve both acne and other metabolic parameters.

Pathophysiology

Acne is a multifactorial inflammatory disease affecting the pilosebaceous follicles of the skin. Four major factors are identified in the pathogenesis of acne: increased sebaceous gland activity, follicular hyperkeratinization, proliferation of *Cutibacterium acnes* (previously *Propionibacterium acnes*), and inflammation (Li, He, & Chen, 2017). Genetic background and environmental factors modulate these factors, driving the flare-ups of acne.

Acne can be categorized as comedonal, inflammatory, or both and can be classified as mild, moderate, or severe based on the number and type of comedones and the extent of affected skin (Eichenfield, Krakowski, Piggott, et al., 2013).

Therapeutic Management

Successful management of acne depends on a cooperative effort between the care provider, adolescent, and parents. Unlike many dermatologic conditions, acne lesions resolve slowly, and improvement may not be apparent for at least 6 weeks. Individual comedones can take several weeks to months to resolve, and papules and pustules usually resolve in about 1 week. The multifactorial causes of acne require a combined approach for successful treatment. Treatment consists of general measures of care and specific treatments determined by the type of lesions involved.

Medications

Treatment success depends on commitment from the adolescent. Before prescribing treatment, the practitioner should determine the adolescent's level of comfort and readiness to begin treatment. The adolescent should be reminded that clinical improvement may take weeks to months. Early intervention, most often with topical medications, may prevent the development of more severe acne.

Tretinoin (Retin-A). Topical retinoids are vitamin A derivatives that normalize keratinization, decrease microcomedone formation, and reduce inflammation. They are strongly recommended for use in all types of acne, as they not only treat active lesions, but also work to prevent recurrences and help with scarring. The US Food and Drug Administration approved adapalene (Differin) 0.1% gel as the first retinoid for sale over the counter (OTC). Now it is possible to have a complete and effective acne regimen, with a retinoid and benzoyl peroxide, available without a prescription (Leyden, Stein-Gold, & Weiss, 2017).

Tretinoin is available as a cream, gel, or liquid. This drug can be extremely irritating to the skin and requires careful patient education for optimal usage. The patient should be instructed to begin with a pea-size dot of medication, which is divided into the three main areas of the face and then gently rubbed into each area. The medication should not be applied for at least 20 to 30 minutes after washing to decrease the burning sensation. The avoidance of the sun and the daily use of sunscreen must be emphasized because sun exposure can result in severe sunburn. Adolescents should be advised to apply the medication at night and to use a sunscreen with a sun protection factor (SPF) of at least 15 in the daytime.

Topical benzoyl peroxide. Benzoyl peroxide is an antibacterial agent that is broadly antimicrobial and inhibits the formation of comedones. Benzoyl peroxide is commonly available as OTC acne washes, gels, foams, or creams in concentrations ranging from 2.5% to 10%. The addition of benzoyl peroxide to acne regimens with other antibiotic therapy enhances results and reduces bacterial resistance.

Benzoyl peroxide is effective against both inflammatory and noninflammatory acne and is an effective first-line agent. Benzoyl peroxide and salicylic acid are the most effective acne treatment kits available OTC. The patient should be informed that the medication may have a bleaching effect on sheets, bedclothes, and towels. The adolescent can be reassured that skin bleaching will not occur. Accommodation to the medication can be gained with a gradual increase in the strength and frequency of application. The current acne guidelines recommend the use of benzoyl peroxide as monotherapy for mild acne or in any combination with topical or topical and oral treatment for mild to severe acne.

When inflammatory lesions accompany the comedones, a **topical antibacterial agent** may be prescribed. These agents are used to prevent new lesions and to treat preexisting acne. Clindamycin, erythromycin-metronidazole, and azelaic acid are currently available for topical antibacterial therapy. Side effects of these medications include erythema, dryness, and burning; using the medications every other day will decrease the adverse effects. A 5% dapsone gel is approved for the treatment of inflammatory acne lesions for children over 12 years of age and is reported to be effective when used in combination with a topical retinoid, such as adapalene or tazarotene. Topical antimicrobials combined with benzoyl peroxide are more effective than either product alone. Retinoids in combination with antimicrobials also improve the penetration of these topical agents and are the only means to address three of the pathogenic causes of acne: keratinization, *C. acnes,* and inflammation.

Systemic antibiotic therapy is initiated when moderate to severe acne does not respond to topical treatments. Recommendations from the American Academy of Dermotology's acne guidelines, as well as other acne guidelines from around the world, emphasize a major change in the role of oral antibiotics in the management of acne. The use of antibiotics is being limited. Systemic antibiotics should be used for the acute management of acne but then discontinued at 3 to 4 months, with the goal of maintaining improvement with a topical retinoid and antimicrobial agent.

Systemic antibiotics are relatively free of side effects, with the exception of occasional gastrointestinal upset, photosensitivity, or vaginal candidiasis. The tetracyclines, doxycycline and minocycline, are preferred over other antibiotics for the treatment of acne in patients older than 8 years of age. With the increase in antibiotic stewardship, patients should be treated systemically for the shortest amount of time possible.

Hormonal. Hormonal treatment is the mainstay systemic treatment in female acne with a significant endocrinologic involvement. Combined oral contraceptives (COCs) are effectively and safely used in combination with other topical and oral antibiotic or hormonal treatment. COCs reduce the endogenous androgen production and decrease the bioavailability of the woman's circulating androgens. COCs containing levonorgestrel, norethindrone, norgestimate, drospirenone, or dienogest decrease acne in women (Powell, 2017).

Isotretinoin, 13-cis-retinoic acid (Accutane), is the only agent available that affects factors involved in the development of acne. Patients who have very severe acne, scarring acne, or significant acne that has not responded to therapy within 3 to 4 months can be prescribed isotretinoin treatment. Pediatric providers typically do not prescribe isotretinoin, but all medical providers of patients who are on it should be familiar with its side effects. These side effects include dry skin and mucous membranes, nasal irritation, dry eyes, decreased night vision, photosensitivity, arthralgia, headaches, mood changes, aggressive or violent behaviors, depression, and suicidal ideation. Many studies, particularly those done prospectively, question the risk of depression or suicide with isotretinoin treatment (Šimić, Babić, & Gunarić, 2017). Given the high risk of depression and suicide in the adolescent and young adult populations, it is judicious for all health care providers to screen patients accordingly, and if depressive or other mood changes develop, isotretinoin use should be discontinued. All systemic retinoids are teratogenic, and the prescription of isotretinoin is strongly regulated by a government prescription program, iPLEDGE, which mandates strict patient counseling and pregnancy testing for all female patients (Henry, Dormuth, Winquist, et al., 2016). The most significant side effects of this drug are the teratogenic effects. Isotretinoin is absolutely contraindicated in pregnant women. Sexually active young women must use an effective contraceptive method during treatment and for 1 month after treatment.

Patients receiving isotretinoin should also be monitored for elevated cholesterol and triglyceride levels. Significant elevation may require discontinuation of the medication.

Health care providers should provide the adolescent with an overall explanation of the disease process, emphasizing the patient's involvement. Improvement of the adolescent's overall health status is part of the general management. Adequate rest, moderate exercise, a well-balanced diet, reduction of emotional stress, and elimination of any foci of infection are all part of general health promotion.

Cleansing

Acne is not caused by dirt or oil on the surface of the skin. Gentle cleansing with a mild cleanser once or twice daily is usually sufficient. Antibacterial soaps are ineffective and may be drying when used in combination with topical acne medications. For some adolescents, hygiene of the hair and scalp appears to be related to the clinical activity of acne. Acne on the forehead may improve with brushing the hair away from the forehead and more frequent shampooing

Nursing Care Management

Because acne is so common and its appearance may seem so mild, the health care provider may underestimate the relative importance of the disease to the adolescent. The nurse should assess the individual adolescent's level of distress, current management, and perceived success of any regimen before initiating a referral. If adolescents do not perceive the acne to be a problem, they may lack motivation to follow the treatment plan.

The nurse can provide ongoing support for the adolescent when a treatment plan is initiated. The family is also encouraged to support the adolescent in his or her efforts. Discuss the use of medications and basic skin care information in detail with the adolescent. Written instructions to accompany the verbal discussion are helpful. Information to dispel myths about the use of abrasive cleansing products can prevent unnecessary costs and trauma to the skin. Adolescents also need education about the factors that aggravate acne and damage the skin, such as too vigorous scrubbing. Picking, squeezing, and manual expression with fingernails break down the ductal walls of lesions and cause the acne to worsen. Mechanical irritation, such as vinyl helmet straps that rub areas predisposed to acne, can also cause the development of lesions.

HEALTH CONDITIONS OF THE MALE REPRODUCTIVE SYSTEM

Because of the physical, mental, and social changes that occur in boys around puberty and into adolescence, and because boys are more likely to initiate sexual behavior, it's important for health care providers to discuss sexual and reproductive health care with their male patients. In younger children, the genital exam provides an opportunity for the health care provider to discuss "safe touch" issues with the child, allowing the parent to reinforce the message. In addition, in preadolescents and adolescents, discussion about testicular self-exam should also be done during the genital exam. Although testicular cancer is rare in teenage boys overall, it is the most common cancer in males between the ages of 15 and 35.

Many obvious anomalies, such as hypospadias, hydrocele, and cryptorchidism, are identified, with corrective measures instituted during infancy or early childhood. Uncircumcised males may encounter problems related to a tight foreskin that cannot be retracted (phimosis) and are at a higher risk for infections, such as balanitis and prostatitis.

Adolescent boys are also self-conscious about their changing bodies and need preparation for a genital examination. The most successful approach is to assume a matter-of-fact attitude toward the examination, explain precisely what will take place, and maintain a continuous commentary about what is being done and the findings at each phase of the examination.

Varicocele

A varicocele is a pathologic enlargement of the testicular veins that is associated with impaired spermatogenesis and infertility. In fact, varicocele is the most common correctable cause of male infertility (Masterson, Ramasamy, & Hotaling, 2017)

Varicoceles are diagnosed by physical examination and are graded I to III. Grade I varicocele is palpable only during the Valsalva maneuver. grade II varicocele is palpable in the standing position. and grade

III varicocele is visible without palpation. Varicoceles are treated with either surgery or embolization. Varicocelectomy is indicated in adolescents when there is growth arrest of the affected testicle or when there is pain associated with the varicocele.

Epididymitis

Epididymitis is an inflammatory response of the epididymis, whereas epididymo-orchitis refers to inflammation of both the epididymis and the testes. Epididymitis may be caused by infectious and noninfectious processes. The etiology of bacterial epididymitis is dependent on age, sexual practices, and the presence of urinary tract abnormalities.

In males younger than 35 years of age, epididymo-orchitis is often associated with sexually transmitted organisms such as *Chlamydia trachomatis* or *Neisseria gonorrhoeae,* whereas in males over 35 years of age, it is often caused by non–sexually transmitted enteric organisms, such as *Escherichia coli* and *Proteus*. The term *men who have sex with men* (MSM) describes a heterogeneous group of men who have varied behaviors, identities, and health care needs. Some MSM are at high risk for human immunodeficiency virus (HIV) infection and other viral and bacterial sexually transmitted infections (STIs) because MSM may practice anal sex and the rectal mucosa is uniquely susceptible to certain STI pathogens.

Clinical presentation is slow and insidious with unilateral scrotal pain, redness, and swelling. Associated symptoms include urethral discharge, dysuria, fever, and pyuria. Treatment consists of analgesics, scrotal support, bed rest, and appropriate antibiotic therapy.

Testicular Torsion

Nurses must be aware of the presentation, timing, and evaluation of testicular torsion because they may triage the pediatric patient with a painful scrotum or be involved in the evaluation in the emergency department or clinic. Pediatric testicular torsion is a surgical emergency that requires a thorough history and physical examination and is, at the outset, a clinical diagnosis. Testicular torsion can occur neonatally, peripubertally, or as an adult. In the pediatric population, approximately 90% of cases occur peripubertally. In a neonate, 70% of torsion occurs prior to birth. Neonatal testicular torsion often presents as a hard mass found on routine examination. Surgical management typically involves orchiectomy with a contralateral orchiopexy. The only known risk factor for peripubertal and adult torsion is the bell clapper deformity, which leaves the testis free to swing and rotate within the tunica vaginalis of the scrotum much like the gong (clapper) inside a bell, predisposing the patient to intravaginal testicular torsion. Peripubertal and adult testicular torsion classically presents with acute-onset severe scrotal pain, nausea and vomiting, a high and horizontal testicular lie, and an absent cremasteric reflex (Hazeltine, Panza, & Ellsworth, 2017, 2018).

In severe torsion, the organ can become swollen and painful; the scrotum becomes red, warm, and edematous and appears to be immobile or fixed as a result of spasm of the cremasteric fibers.

In the pediatric population, testicular torsion has an annual incidence of 3.8 per 100,000 pediatric patients, with the peak incidence occurring between ages 12 and 16 years (Riccabona, Darge, Lobo, et al., 2015). Approximately 10% of testicular torsions occur in neonates; of these, 70% are believed to occur in utero (prenatal torsion), with the remaining 30% occurring within the first 30 days of life (postnatal torsion) (Basta, Courtier, Phelps, et al., 2015).

A prompt diagnosis and definitive surgical management are essential in males of any age to preserve the affected testicle. In patients with a high clinical suspicion, emergent surgical management is warranted.

Gynecomastia

Some degree of bilateral or unilateral breast enlargement occurs frequently in boys during puberty. Approximately half of adolescent boys have transient gynecomastia, usually lasting less than 1 year, which subsides spontaneously with achievement of male development. A careful assessment of the pubertal stage at the onset of gynecomastia; medication history, including anabolic steroids; and the exclusion of renal, liver, thyroid, and endocrine disorders or dysfunction allow the examiner to reassure the adolescent that the changes are pubertal gynecomastia and that no further assessment is indicated. Gynecomastia may also be drug induced; calcium channel blockers, cancer chemotherapeutic agents, histamine$_2$-receptor antagonists, and oral ketoconazole medications have all been shown to cause the condition.

For all adolescents presenting with gynecomastia, a detailed history and physical examination should be performed with the goal of differentiating true pubertal gynecomastia from other causes of breast enlargement. Pertinent information to obtain from the history includes duration of symptoms, presence of nipple discharge or overlying skin changes, reports of below-normal prenatal (less commonly pubertal) androgen effects, and testicular swelling or masses. A careful genitourinary examination is also of particular importance. Attention should be paid to Tanner staging, testicular volume, and masses or irregularities along the testes. Examination for a varicocele should also be undertaken, as recent evidence has shown that gynecomastia is more common in 12- to 14-year-old boys with varicocele than without varicocele.

If gynecomastia persists or is extensive enough to cause embarrassment, plastic surgery is indicated for cosmetic and psychologic considerations. Administration of testosterone has no effect on breast development or regression and may aggravate the condition.

Nursing Care Management

Management usually consists of assurance to the adolescent and his parents that the situation is benign and temporary. However, all adolescents with gynecomastia should receive a careful medical evaluation to rule out pathologic causes. The adolescent may benefit from the knowledge that this condition occurs in more than 50% of all adolescent boys.

HEALTH CONDITIONS OF THE FEMALE REPRODUCTIVE SYSTEM

Amenorrhea

Menarche, or the first menstrual period, occurs relatively late in female pubertal development. Although girls vary in the onset and rate of progression of pubertal development, the sequence and tempo should be the same. When an adolescent is seen with a complaint of absence of menses, a careful history of the timing of her pubertal development will help determine if there is a need for further evaluation or if reassurance is all that is necessary. Amenorrhea can be classified as either primary or secondary depending on the presence (secondary) or absence (primary) of previous menses. Primary amenorrhea is defined as the absence of menses by age 14 years in the absence of secondary sexual characteristics or the absence of menses by age 16 years in the presence of normal secondary sexual characteristics (Austin & Mahmood, 2018).

Irregular menstrual cycles are common within the first year after menarche because these early cycles may be anovulatory, resulting in regular, irregular, or absent bleeding. Girls with a later onset of menarche take longer to establish regular ovulatory cycles. Primary amenorrhea is rare, with less than 5% of adolescent girls presenting to gynecologic services.

It is essential to take a thorough history, particularly focusing on any red-flag symptoms (underweight/eating disorder, raised body mass index [BMI], acne, hirsutism, polycystic ovarian syndrome, short stature, wide-spaced nipples, Turner syndrome) or family history of delayed puberty. An examination should always include height, weight, and an assessment of secondary sexual characteristics (breast development, pubic and axillary hair growth).

Pregnancy is the most common cause of secondary amenorrhea and should be ruled out in both types of amenorrhea even if the adolescent denies sexual activity. Other factors that disturb the hypothalamic–pituitary–gonadal axis and cause amenorrhea include physical or emotional stress; hyperthyroidism or hypothyroidism; polycystic ovary syndrome; sudden and severe weight loss; strenuous exercise; eating disorders; and use of extrinsic pharmacologic agents, especially phenothiazines, contraceptive steroids, and heroin.

Nursing Care Management

When amenorrhea is caused by hypothalamic disturbances, the nurse is an ideal health professional to assist the adolescent because many causes are potentially reversible (e.g., stress, weight loss for nonorganic reasons). Counseling and education are primary interventions and appropriate nursing roles.

Dysmenorrhea

Dysmenorrhea, pain during or shortly before menstruation, is one of the most common gynecologic problems in women of all ages. Approximately 75% of women report some level of discomfort associated with menses, and approximately 15% report severe dysmenorrhea that interferes with work or school (Lentz, 2012). Dysmenorrhea is associated with menarche prior to 12 years of age, nulliparity, heavy menses, pelvic inflammatory disease (PID), BMI greater than 20, smoking, and depression (Roberts, Hodgkiss, DiBenedetto, et al., 2012). Symptoms usually begin with menstruation, although some women may have discomfort several hours before onset of flow. The range and severity of symptoms are different from woman to woman and from cycle to cycle in the same woman. Symptoms of dysmenorrhea may last several hours to several days. Pain is usually located in the suprapubic area or lower abdomen. Women describe the pain as sharp; cramping; or a steady, dull ache.

Dysmenorrhea is differentiated as primary or secondary. Primary dysmenorrhea is a condition associated with ovulatory cycles. Primary dysmenorrhea has a biochemical basis and arises from the release of prostaglandins with menses. The pain begins with the onset of menstruation and lasts 8 to 48 hours (Lentz, 2012). Primary dysmenorrhea usually appears 6 to 12 months after menarche when ovulation is established.

Secondary dysmenorrhea is defined as painful menses associated with a pathologic condition, such as adenomyosis, endometriosis, PID, endometrial polyps, or fibroids. In contrast to primary dysmenorrhea, the pain of secondary dysmenorrhea is often characterized by dull, lower abdominal aching that radiates to the back or thighs and is often associated with feelings of bloating or pelvic fullness. In addition to a history and physical examination, diagnosis may be assisted by ultrasound examination, dilation and curettage (D&C), endometrial biopsy, or laparoscopy. Dysmenorrhea and pelvic pain in adolescent girls should be managed and treated carefully, as this may represent the first sign of a more serious pathology.

Therapeutic Management

Management of dysmenorrhea depends on the severity of the problem and the individual woman's response to various treatments. Heat and exercise minimize cramping by increasing vasodilation and muscle relaxation and minimizing uterine ischemia. Massaging the lower back can reduce pain by relaxing paravertebral muscles and increasing the pelvic blood supply. Soft, rhythmic rubbing of the abdomen (effleurage) is useful because it provides a distraction and alternative focal point. Biofeedback, transcutaneous electrical nerve stimulation (TENS), progressive relaxation, Hatha yoga, acupuncture, and meditation are also used to decrease menstrual discomfort, although evidence is insufficient to determine their effectiveness (Lentz, 2012).

First-line medication treatment for adolescents with dysmenorrhea is the administration of nonsteroidal antiinflammatory drugs (NSAIDs), which block the formation of prostaglandins. Girls should be instructed to begin the medication either at the first sign of symptoms or bleeding or 1 to 2 days before the onset of their menses, and then take it on a regular schedule for 2 to 3 days (Roberts et al., 2012). The medications should be taken with food. If an NSAID such as ibuprofen is not effective, another NSAID should be tried because some women receive relief from different NSAIDs.

Oral contraceptive pills (OCPs) are also effective and a reasonable choice for women who want to use a contraceptive agent. OCPs are effective in relieving symptoms of primary dysmenorrhea for approximately 90% of women, but no single OCP has been shown to be superior to another (Lentz, 2012). However, OCPs may be contraindicated for some women.

Nursing Care Management

All adolescent girls need reassurance that menstruation is a normal function. When nurses are asked for advice on menstrual problems, they have a valuable opportunity to engage in health teaching concerning menstrual physiology; hygiene; and the importance of a well-balanced diet, exercise, and general health maintenance. Health teaching can dispel myths about menstruation and femininity.

A careful history indicates a potential problem and the need for evaluation and referral to an appropriate practitioner, health service, or clinic. The history should include the onset of symptoms; the duration, type of pain, and relationship to menstrual flow; the age at menarche; family history of dysmenorrhea; and sexual history. The nurse should also ask about previous treatments, including dosages of medications. Depending on the results of the history, the physical examination may include a gynecologic examination.

If a gynecologic examination is necessary, the nurse can play a supportive role for the adolescent girl. Whether it is her first experience or not, she is often filled with apprehension. Almost all adolescents are extremely self-conscious about their bodies and the changes taking place. They need continuing support in the form of anticipatory guidance regarding what to expect and suggestions of what to do to relax during the procedure. Most girls favor a semisitting position, which has the additional advantage of allowing eye contact during the procedure. Sometimes a pillow helps the patient feel more comfortable and less vulnerable. The provision of a mirror for the girl to see what is taking place if she so desires helps the examiner explain various aspects of anatomy. When possible, it is important to respect the adolescent's request for a female provider and to have her mother or other supportive person present if she desires.

Premenstrual Syndrome

Approximately 30% to 80% of women experience mood and/or somatic symptoms that occur with their menstrual cycles (Lentz, 2012). Premenstrual syndrome (PMS) is a poorly understood condition that includes one or more of a large number of physical and psychologic symptoms beginning in the luteal phase of the menstrual cycle that occurs to such a degree that lifestyle or work is affected. Symptoms

include fluid retention, behavioral or emotional changes, premenstrual cravings, headache, fatigue, and backache. All age-groups are affected.

Premenstrual dysphoric disorder (PMDD) is a more severe variant of PMS. Approximately 3% to 8% of women are affected and experience marked irritability, dysphoria, mood lability, anxiety, fatigue, appetite changes, and a sense of feeling overwhelmed (Lentz, 2012).

Therapeutic Management

There is little agreement on management of PMS. A careful, detailed history and daily log of symptoms and mood fluctuations spanning several cycles may give direction to a plan of management. Education is an important component of management. Nurses advise women that self-help modalities often result in significant symptom improvement. Diet changes can provide symptom relief for some women. Nurses can suggest that women limit their consumption of refined sugar, salt, alcohol, and caffeinated beverages. Three small to moderate-size meals and three small snacks a day that are rich in complex carbohydrates and fiber have been reported to relieve symptoms (American College of Obstetricians and Gynecologists, 2015). Exercise may also provide symptom relief. Aerobic exercise increases beta-endorphin levels to offset symptoms of depression and elevate mood. Stress reduction techniques may also help with symptom management (American College of Obstetricians and Gynecologists, 2015).

If these strategies do not provide significant symptom relief in 1 to 2 months, medication is often added. Medications used in the treatment of PMS include diuretics, prostaglandin inhibitors (NSAIDs), progesterone, and OCPs; however, no single medication alleviates all PMS symptoms (American College of Obstetricians and Gynecologists, 2015).

Vaginal Infections

Vaginal discharge and itching of the vulva and vagina are among the most common reasons that a woman seeks help from a health care provider. Women complain of vaginal discharge more than any other gynecologic symptoms; however, vaginal discharge resulting from an infection must be distinguished from normal secretions. Physiologic leukorrhea is a normal vaginal secretion occurring at ovulation and just before menses. It is clear to cloudy in appearance; is nonirritating; and has a mild, inoffensive odor. On the other hand, inflammatory leukorrhea is caused by physical (e.g., forgotten tampon), chemical (e.g., bubble baths, douching), or infectious (e.g., *Candida* fungi, *Trichomonas* protozoa parasites, bacteria) agents. It is a glutinous, gray-white discharge with an offensive odor. Diagnosis is confirmed with microscopic evaluation of vaginal secretions, vaginal culture, or rapid testing methods.

Treatment varies depending on the cause. Health teaching is important in the management of vaginal discharge. Adolescent girls need reassurance that increased vaginal mucus can occur at the time of ovulation, before menstruation, or with sexual excitement. Many teenage girls mistake these variations as signs of infection. Girls should be taught to wipe from front to back after toileting and to realize that vaginitis can result from irritation, foreign objects, and sexual activity. Nurses should stress the importance of an evaluation to determine the exact cause.

HEALTH CONDITIONS RELATED TO REPRODUCTION

According to the Youth Risk Behavior Survey (YRBS; Centers for Disease Control and Prevention, 2017), the percentage of students who had ever had sex decreased significantly from 2007 (47.8%) through 2017 (39.5%). A significantly higher percentage of male students (41.4%) than female students (37.7%) had ever had sex. A significantly higher percentage of African American students (45.8%) than white students (38.6%) had ever had sex. There was no significant difference between the percentages of white students and Hispanic students who had ever had sex or between the percentages of African American students and Hispanic students who had ever had sex (Youth Risk Behavior Surveillance, 2017). Many serious health consequences are associated with adolescent sexual activity, including unplanned pregnancy and STIs; additional health problems may arise from an increased number of sexual partners over time and incomplete education on sexual practices in adolescents. Health professionals must understand the issues related to adolescent sexual activity and the psychosocial dynamics that influence them.

Adolescent Pregnancy

According to the Centers for Disease Control and Prevention, in 2017 a total of 194,377 babies were born to women ages 15 to 19 years, for a birth rate of 18.8 per 1000 women in this age-group. This is another record low for US teens and a drop of 7% from 2016. Birth rates fell 10% for women ages 15 to 17 years, and 6% for women ages 18 to 19 years.

The decline is attributed to increased condom and contraception use, as well as a delay in the initiation of sexual activity among adolescents. However, the less familiar an adolescent is with his or her partner, the less likely it is that he or she will use contraception during intercourse. Discontinuation of contraception is common; 30% of women 15 to 19 years old and 47% of women 20 to 24 years old have discontinued at least one method because of dissatisfaction (Pazol, Whiteman, Folger, et al., 2015). Teens who postpone the initiation of sexual intercourse decrease their risk for STIs, including HIV.

In most cases, with early prenatal care, teenage pregnancy is no longer considered to be biologically disadvantageous to the child. However, teenage parenting is still regarded as socially, educationally, psychologically, and economically disadvantageous to both mother and child. Predictors of maternal success include participation in a program for pregnant teens, a social support system, and a sense of control over one's life. With better facilities available for care, the mortality associated with teenage pregnancies is decreasing, but morbidity remains high. Teenage girls and their unborn infants are at greater risk for complications of both pregnancy and delivery. Medical concerns of the adolescent include poor maternal weight gain, anemia, and pregnancy-induced hypertension (Cinar & Menekse, 2017). Rates of eclampsia, puerperal endometritis, infections, and caesarean section were higher among adolescent mothers than among older mothers. The age of the adolescent influences complications; the younger the adolescent, the higher risk of preterm birth.

Labor is often prolonged in younger teenagers, particularly those 12 to 16 years old, because of a fetopelvic incompatibility and the teenager's smaller stature and incomplete growth process. Delivery concerns include premature labor and low-birth-weight infants. Information should be provided regarding the pregnant adolescent's nutritional status and health care needs related to the unborn fetus's condition. Because adolescent nutrition habits may vary, it is important to stress that the mother's overall health status will ultimately influence that of her newborn. Myths such as "you can now eat for two" must be addressed. The diet must provide sufficient nutrients to meet the growth needs of both the prospective mother and the unborn child without the threat of excessive weight gain or fetal malnutrition.

Nursing Care Management

A pregnant teenager needs careful assessment by the nurse to determine the level of social support available to her and her partner. The adolescent needs to make many important decisions and may not have

the life experience to know how to cope with this stress. Whenever possible, guidance from the adults in her life will be invaluable. Information about options to continue the pregnancy and parent the child, continue the pregnancy with adoption, or terminate the pregnancy with abortion should be given in a nonjudgmental manner. If the adolescent chooses to continue the pregnancy, prenatal care should be initiated as soon as possible.

Basic to the implementation of any care program is communication and the establishment of a trusting relationship. Initially the adolescent may appear apathetic and display little interest in discussing her pregnancy. The nurse must make every effort to put the adolescent at ease and avoid undue pressure. Conveying a nonjudgmental and genuine caring acceptance of the adolescent and her goals will assist the nurse in gaining the adolescent's confidence and trust.

Communication takes time and patience. Asking open-ended questions and listening for cues will help identify physical, emotional, social, and cultural influences that might affect the adolescent's progress through the maternity cycle.

The adolescent needs to know what is happening to her, what is expected of her, and how she can help in developing a care plan. Adolescents have their own ideas about the type of help and support they need. Nurses should consult with them and provide them with an opportunity to share their ideas. Adolescent pregnancy affects families, health care professionals, educators, government officials, children, and adolescents. Implementing comprehensive programs that educate adolescents on sexual behavior, contraceptives, and reproductive health may create a positive change in adolescent reproductive health, especially in low- and middle-income communities.

! NURSING ALERT

All pregnant women should take a vitamin and mineral supplement to ensure that the Recommended Dietary Allowance for folic acid (0.4 mg [400 mcg] daily) is met to help prevent neural tube defects. Initiation before pregnancy has been shown to have the most benefit. Consider a multivitamin for all sexually active women.

Contraception

In 2017, 53.8% of high school students (among the 28.7% of students nationwide who were currently sexually active) used a condom the last time they had sexual intercourse. The percentage of students who used a condom decreased significantly from 2007 to 2017 (Centers for Disease Control and Prevention, 2017). The percentage of male students who used a condom the last time they had sex decreased from 68.5% in 2007 to 61.3% in 2017. The percentage of female students who used a condom the last time they had sex decreased from 54.9% in 2007 to 46.9% in 2017. The YRBS found that in 2017, 29.4% of students used effective hormonal birth control the last time they had sex. A significantly higher percentage of female students (34.6%) used effective hormonal birth control than male students reported their partner using (23.9%). Significantly higher percentages of white students (37.4%) and African American students (22.5%) used effective hormonal birth control than did Hispanic students (16.8%). A significantly higher percentage of white students used effective hormonal birth control than did African American students. Family planning services have developed and expanded during recent years, but the need for contraceptive services as part of adolescents' health care remains great. The birth control pill and condom remain the most popular methods for adolescents; 3-month injectable contraception is more popular among lower income adolescents. Adolescents commonly delay seeking contraceptive information; the typical interval from onset of sexual intercourse until the first visit for contraception is 1 year. A pregnancy scare is usually the precipitating event for the contraception appointment. Counseling about contraceptive options should be conducted in a manner that is consistent with the cognitive level of the adolescent. The adolescent should be given accurate information about the risks and benefits of each method before making a choice.

Many teenagers feel ambivalent about their sexual activity and avoid many contraceptives because their use seems too premeditated and implies that sex is planned rather than a spontaneous activity. Most of these girls believe that sex is all right if it is not planned. This may play a role in adolescents delaying contraception, waiting for a relationship that is "close enough." A close relationship would allow adolescents to accept and acknowledge their sexual activity.

Several evidence-based resources are available to medical professionals when performing a contraceptive consult. These include:

- Centers for Disease Control and Prevention (2016) contraception app, https://www.cdc.gov/reproductivehealth/contraception/mmwr/mec/summary.html?CDC_AA_refVal=https%3A%2F%2Fwww.cdc.gov%2Freproductivehealth%2Fcontraception%2Fusmec.htm
- Bedsider (2016) Method Explorer, https://www.bedsider.org/methods

The choice of a safe and effective contraceptive method must be suited to the individual. The choice is based on preference after the adolescent is informed of the benefits and disadvantages. Motivation is necessary for most methods. For example, the pill is effective if used correctly, but the adolescent must remember to take the pill at approximately the same time every day. For many young women, a medroxyprogesterone injection (Depo-Provera) is an ideal choice because it is extremely effective and is administered every 12 weeks; however, side effects such as weight gain and decreased bone mineralization may make it undesirable. Sexually active adolescents need to know that contraceptive devices other than condoms do not prevent STIs. Condom use is still important and must be discussed with all sexually and non–sexually active adolescents.

Confidentiality is a critical issue when discussing contraception with adolescents. Privacy is important to adolescents as they struggle to forge a personal identity and establish social relationships. Adolescents are particularly concerned about the judgments of others. The predominant belief among many health professionals is that parental notification is important but that the "parents' rights" view is not necessarily sensitive to the health needs and basic rights of youth. No evidence substantiates the belief that providing contraceptive guidance contributes to sexual irresponsibility and promiscuity.

Nursing Care Management

Nurses are often involved in providing education about contraception. Such education is ideally combined with ongoing sex education. Although sexual abstinence is a highly desirable form of contraception for teenagers, nurses working with adolescents must recognize that teens feel multiple pressures to engage in sexual intercourse. Postponing sexual involvement requires effective communication and decision-making skills. Adolescents benefit from role-playing refusal skills and opportunities to practice making decisions in a safe environment. Information about safer sex must be provided, and role-playing how to discuss condom use with a partner is helpful to teenagers.

Education on contraception should be provided in both oral and written form. All available methods, including their benefits, disadvantages, and side effects, should be discussed. Concrete, concise language must be used; demonstrations of how to use the contraceptives should

be provided; and adolescents should repeat all instructions in their own words. If teenagers are using OCPs, they should be encouraged to use a daily activity as a reminder or cue to take the pill. A knowledgeable phone triage person should be available for questions and concerns. Parents or other important adults may be included in all discussions, with the adolescent's permission. An organization that provides education and services for adolescents, including both individual and group counseling, is Planned Parenthood Federation of America. It has branches in most cities in the United States.

SEXUALLY TRANSMITTED INFECTIONS

Many young people engage in sexual behaviors that can result in unintended health outcomes, such as unintended pregnancy and STIs, including HIV. In 2016 young people ages 13 to 24 years accounted for an estimated 21% of all new HIV diagnoses in the United States, with most occurring among 20- to 24-year-olds. Half of the nearly 20 million new cases of STIs reported each year are among young people ages 15 to 24 years. Other sexual behaviors, such as condom use and hormonal birth control use, can protect against STIs, including HIV, and unintended pregnancy. Although nearly 210,000 babies were born to teenage girls ages 15 to 19 years in 2016, teenage birth rates are currently at their lowest recorded levels (Centers for Disease Control and Prevention, 2017).

Lack of awareness regarding one's susceptibility to STIs when engaged in unprotected sexual activity, be it oral, anal, or vaginal intercourse, is perhaps one of the greatest dangers adolescents face. Although STIs affect individuals of all ages, they take a particularly heavy toll on young people. The Centers for Disease Control and Prevention estimates that youth ages 15 to 24 years make up just over one-quarter of the sexually active population but account for half of the 20 million new cases of STIs that occur in the United States each year (Centers for Disease Control and Prevention, 2017).

Preventing infection (primary prevention) is the most effective way of reducing the adverse consequences of STIs for adolescents. Despite the high rates of STIs documented in the adolescent population, providers frequently fail to inquire about sexual behaviors, assess STI risks, provide risk reduction counseling, and screen for asymptomatic infections during clinical encounters.

Prompt diagnosis and treatment of current infections (secondary prevention) can prevent personal complications and transmission to others. A critical step in preventing the spread of STIs is including questions about an adolescent's sexual history, sexual risk behaviors, and drug-related risk behaviors in every assessment. When the nurse identifies risk factors, there is an opportunity to provide prevention counseling. Prevention messages should include descriptions of specific actions to prevent contracting or transmitting STIs and should be individualized for each adolescent. To be motivated to take preventive actions, the adolescent must believe that acquiring a disease will be serious and that he or she is at risk for infection. Routine laboratory screening for common STIs is indicated for sexually active adolescents. The following screening recommendations summarize published federal agencies' and medical professional organizations' clinical guidelines for sexually active adolescents (Centers for Disease Control and Prevention, 2017).

Sexually Transmitted Bacterial Infections

C. trachomatis is the most frequently reported infectious disease in the United States, yet most cases remain undiagnosed (Torrone, Papp, Weinstock, et al., 2014). Routine annual screening for *C. trachomatis* is recommended for all sexually active females younger than 25 years of age (LeFevre, 2014). In women, chlamydia infections are difficult to diagnose; the symptoms are nonspecific, and the organism is expensive to culture. These infections are highly destructive, causing PID, increased risk of ectopic pregnancy, and tubal factor infertility. Manifestations, treatment, and nursing considerations of *C. trachomatis* are listed in Table 16.3. See Table 16.4 for the Pediatric Quality Indicator related to chlamydia screening.

Gonorrhea is the oldest communicable disease in the United States, with an estimated 300,000 American men and women contracting gonorrhea each year (Centers for Disease Control and Prevention, 2017). Women are often asymptomatic, therefore the Centers for Disease Control and Prevention recommends screening all women at risk for gonorrhea, including women with previous gonorrhea infection, other STIs, and multiple sex partners with inconsistent condom use and those engaged in commercial sex work and drug use (Centers for Disease Control and Prevention, 2017). Gonococcal infection is concentrated in specific geographic locations and communities. Clinicians should consider the communities they serve and may choose to consult local public health authorities for guidance on identifying groups that are at increased risk. Manifestations, treatment, and nursing considerations of gonorrhea are listed in Table 16.3.

Syphilis is caused by *Treponema pallidum,* a motile spirochete. Transmission occurs by entry through microscopic abrasions in the subcutaneous tissue, kissing, biting, or oral-genital sex. Syphilis is a complex disease that can lead to serious systematic disease and even death when untreated. Manifestations, treatment, and nursing considerations of syphilis are listed in Table 16.3.

Sexually Transmitted Protozoa Infections

Trichomonas vaginalis is a common cause of vaginal infections and is almost always transmitted as an STI. Trichomoniasis is caused by *T. vaginalis,* an anaerobic, one-celled protozoan with characteristic flagella. Manifestations, treatment, and nursing considerations of trichomoniasis are listed in Table 16.3.

Sexually Transmitted Viral Infections

Human papillomavirus (HPV) infection is the most common viral STI seen in ambulatory health care settings. Nearly 80 million Americans are currently infected with some type of HPV. About 14 million Americans, including teens, become infected each year (Centers for Disease Control and Prevention, 2019).

Every year in the United States, HPV causes 33,700 cases of cancer in men and women (Centers for Disease Control and Prevention, 2019). HPV infections can cause cancers of the cervix, vagina, and vulva in women; the penis in men; and the anus and back of the throat, including the base of the tongue and tonsils (oropharynx), in both women and men (Centers for Disease Control and Prevention, 2019).

Herpes simplex virus (HSV) is caused by two different antigen subtypes: HSV type 1 (HSV-1) and HSV type 2 (HSV-2). HSV-1 is commonly associated with gingivostomatitis and oral labial lesions (fever blisters), whereas HSV-2 is transmitted sexually and characterized by genital lesions. During 2015–16, the age-adjusted prevalence of HSV-1 was 48.1% among adolescents and adults ages 14 to 49 years (50.9% for females, 45.2% for males). Prevalence was higher for females than males in most 2-year periods from 1999–2000 to 2015–16. Also during 2015–16, the age-adjusted prevalence of HSV-2 for those ages 14 to 49 years was 12.1% (15.9% for females, 8.2% for males) and was higher for females than males in all 2-year periods (Centers for Disease Control and Prevention, 2019). Adolescents and women between the ages of 15 and 34 years are most likely to become

TABLE 16.3 Selected Sexually Transmitted Infections[a]

Manifestations	Therapy	Nursing Care Management
Gonorrhea *(Neisseria gonorrhoeae)*		
Male: Urethritis (dysuria with profuse yellow discharge, frequency, urgency, nocturia) or pharyngitis *Female:* Cervicitis (postpubertal); may be associated with discharge, dysuria, dyspareunia, vulvovaginitis (prepubertal), or pharyngitis	For uncomplicated urogenital and anorectal gonorrhea: Single intramuscular dose of ceftriaxone *plus* Single oral dose of azithromycin	Instruct patient to abstain from sexual intercourse for 7 days after single-dose treatment. Test and treat for other STIs. Find and treat sexual contacts. Educate young people on facts of the disease and its spread. Encourage use of condoms in sexually active young people.
Chlamydia *(Chlamydia trachomatis)*		
Male: Meatal erythema, tenderness, itching, dysuria, urethral discharge, or no symptoms *Female:* Mucopurulent cervical exudate with erythema, edema, congestion, or no symptoms	Single oral dose of azithromycin *or* 7 days of oral doxycycline administered twice daily If pregnant, azithromycin	Same as above. Rescreen pregnant women 3 wk after treatment. Repeat infection elevates risk for PID.
Syphilis *(Treponema pallidum)*		
Primary stage: Chancre, a hard, painless, red, sharply defined lesion with indurated base, raised border, eroded surface, and scanty yellow discharge; usually located on the penis, vulva, or cervix *Secondary stage:* Systemic influenza-like symptoms; lymphadenopathy; rash; usually appears few weeks to months after healing of chancre	Single intramuscular dose of benzathine penicillin G	Instruct patients to use condoms to avoid spread or infection with other organisms. Identify sexual contacts of infected person. Test women during pregnancy and prior to delivery (VDRL and RPR). Evaluate newborn for presence of disease if mother is untreated.
Herpes Progenitalis (Genital Herpes Simplex Virus)		
Small (usually painful) vesicles on genital area, buttocks, and thighs; itching usually the initial symptom; when vesicles break, shallow, circular, extremely painful lesions remain	No known cure Uncomplicated cases: Acyclovir, famciclovir, or valacyclovir by mouth for 10 days Complicated cases: Acyclovir intravenously May need chronic suppressive therapy for recurrences	Instruct patients to use condoms to avoid spread or infection with other organisms. Infection can be transmitted to infant during birth. Evaluate maternal history and observe infant for signs or symptoms. Cultures may be obtained in newborn.
Trichomoniasis *(Trichomonas vaginalis)*		
Pruritus and edema of external genitalia; foul-smelling, greenish vaginal discharge; sometimes postcoital bleeding May be asymptomatic, especially in men	Single oral dose of metronidazole or tinidazole	Patient should not consume alcohol while taking medication and for at least 48 h after the last dose. Sexual partners should be treated.
Human Papillomavirus		
Warts found on any part of male or female genitalia	Patient applied: Podofilox solution or gel (0.5%) or imiquimod (5%) cream or sinecatechins ointment (15%) Provider applied: Podophyllin resin 10% to 25% in compound tincture of benzoin Freezing with liquid nitrogen (cryotherapy) Trichloroacetic acid or bichloracetic acid 80% to 90% Laser therapy, injectable interferon, or surgical removal	An acceptable alternative is to forgo treatment and await spontaneous resolution. Treatments are usually painful; analgesics may be needed, and steroid cream may provide relief. Vaccine available for prevention (see Chapter 6).

[a]Updated information on specific treatment of STIs may be accessed at http://www.cdc.gov/std/treatment.
PID, Pelvic inflammatory disease; *RPR,* rapid plasma reagin; *STI,* sexually transmitted infection; *VDRL,* Venereal Disease Research Laboratory.

infected with HSV-2, especially if they have multiple partners. Many people are unaware that they are infected and transmit the disease unknowingly.

HIV is a bloodborne pathogen, and transmission of the virus can occur through the perinatal period, sexual intercourse with an infected person, or sharing needles with an infected person. HIV screening should be discussed and offered to all adolescents. Frequency of repeat screenings of those who are at risk for HIV infection should be based on level of risk. HIV is discussed in Chapter 24.

TABLE 16.4 Pediatric Quality Indicator[a]

Chlamydia Screening for Women	
Measure	Assesses the percentage of women 16 to 24 years of age who were identified as sexually active and who had at least one test for chlamydia during the measurement year.
Numerator	At least one chlamydia test during the measurement year as documented through administrative data.
Denominator	Women 16 to 24 years of age.

[a]Endorsed by the National Quality Forum NQF #0033 and 2019 Core Set of Children's Health Care Quality Measures for Medicaid and CHIP. https://www.medicaid.gov/federal-policy-guidance/downloads/cib112018.pdf.
Note: A Healthy People 2020 goal is to reduce the proportion of adolescents and young adults with *Chlamydia trachomatis* infections to 3.0%. In general, females have higher rates of chlamydia, though they also use screening services more often, which may cause misleading statistics. In 2003 the highest age-specific rates of reported chlamydia in women were among 15- to 19-year-olds and 20- to 24-year-olds.

Nursing Care Management

Nursing responsibilities encompass all aspects of STI education, confidentiality, prevention, and treatment. The sex education of young people should include providing information about STIs, including their symptoms and treatment, and dispelling the myths associated with their mode of transmission. Many vulnerable adolescents are uninformed or misinformed about STIs.

Primary prevention efforts for STIs include encouraging abstinence and postponing of sexual involvement, encouraging condom use, and ensuring vaccination for hepatitis A and B and HPV. The Centers for Disease Control and Prevention recommends that all boys and girls get two doses of the HPV vaccine at ages 11 or 12. HPV vaccination can be started at age 9. For the HPV vaccine to be most effective, the series should be given prior to exposure to HPV. HPV vaccine is recommended at ages 11 to 12 to ensure that children are protected long before they are ever exposed to the virus. Children who get the first dose before their 15th birthday only need two doses. Children who get the first dose on or after their 15th birthday need three doses.

Nurses play a role in secondary prevention by helping to identify early cases and referring adolescents for treatment. Nurses can also be involved in tertiary prevention by decreasing the medical and psychologic effects of STIs; conducting support groups for adolescents with HIV, HSV, and HPV infections; and assisting pregnant adolescents in obtaining adequate prenatal screening and treatment of STIs.

Pelvic Inflammatory Disease

PID is an infectious process that most commonly involves the uterine tubes, uterus, and rarely the ovaries and peritoneal surfaces. Multiple organisms have been found to cause PID, and common agents include *N. gonorrhoeae, C. trachomatis,* and a variety of other aerobic and anaerobic bacteria. It is estimated that each year 800,000 women of reproductive age experience an episode of PID, with high rates occurring in adolescents (Trent, 2013). Women younger than 25 years old have a 1 in 8 chance of experiencing PID compared with those older than 25 years of age, whose risk is 1 in 80 (Trent, 2013).

Women who have had PID are at increased risk for ectopic pregnancy, infertility, and chronic pelvic pain. Other problems associated with PID include dyspareunia, pyosalpinx, tubo-ovarian abscess, and pelvic adhesions.

Presenting symptoms in adolescents may be generalized, but pain is a common symptom in all infections. The pain can be dull, cramping, intermittent, persistent, and incapacitating. Women may also report fever, chills, abdominal pain, nausea and vomiting, increased vaginal discharge, urinary tract symptoms, and irregular bleeding. A pelvic examination is indicated for every sexually active woman who complains of lower abdominal pain to evaluate for the possibility of PID.

Prevention is the primary concern of health care professionals. Primary prevention includes education on avoiding contracting STIs; secondary prevention involves preventing a lower genital tract infection from ascending to the upper genital tract. Barrier contraceptive methods, such as condoms, are critical. PID is usually treated with antibiotics to provide empiric, broad-spectrum coverage of likely pathogens. Recommended regimens can be found in the 2015 Sexually Transmitted Diseases Treatment Guidelines (https://www.cdc.gov/std/tg2015/pid.htm).

Treatment for mild to moderate PID may be oral (e.g., ceftriaxone plus doxycycline with or without metronidazole) or parenteral (e.g., cefotetan or cefoxitin plus doxycycline [oral]), and regimens can be administered in inpatient or outpatient settings. Pregnant women should be hospitalized and given parenteral antibiotics. Women should be counseled to comply with therapy and complete all medication, even if symptoms have disappeared. Follow-up after treatment should include endocervical cultures to test for cure.

Sexual Violence

Sexual violence means that someone forces or manipulates someone else into unwanted sexual activity without their consent. Reasons someone might not consent include fear, age, illness, disability, and/or influence of alcohol or other drugs. Anyone can experience sexual violence, including children, teens, adults, and elders. Those who sexually abuse can be acquaintances, family members, trusted individuals, or strangers. This violence includes rape or sexual assault, child sexual assault and incest, intimate partner sexual assault, unwanted sexual contact or touching, sexual harassment, sexual exploitation, showing one's genitals or naked body to others without consent, masturbating in public, and watching someone in a private act without their knowledge or permission.

According to the Centers for Disease Control and Prevention, 1 in 3 women and 1 in 4 men experience sexual violence involving physical contact during their lifetimes. Nearly 1 in 5 women and 1 in 38 men have experienced completed or attempted rape, and 1 in 14 men were made to penetrate someone (completed or attempted) during their lifetime. In addition, 1 in 3 female rape victims experienced rape for the first time between 11 and 17 years old, and 1 in 8 reported that it occurred before age 10 years. Nearly 1 in 4 male rape victims experienced rape for the first time between 11 and 17 years old, and about 1 in 4 reported that it occurred before age 10 years.

Typically, stranger rape is what comes to mind when one thinks of sexual assault; however, more than half of assaults are committed by someone known to the survivor. Although both males and females can be sexually assaulted, females are at greatest risk. Adolescents are at high risk for sexual assault; other high-risk groups include survivors of childhood sexual or physical abuse; persons who are disabled; persons with substance abuse problems; sex workers; persons who are poor or homeless; and persons living in prisons, institutions, or areas of military conflict. Sexual assault remains underreported for multifactorial reasons.

An understanding of the legal definitions of sexual assault, rape, acquaintance rape, and statutory rape is essential for the nurse to identify, treat, and manage adolescent victims (Box 16.2).

Statutory rape laws have been revised in many states across the country. The motivation for tougher laws and greater enforcement is to decrease teen pregnancy, increase male responsibility, and decrease welfare dependency. Traditionally, statutory rape laws have been

BOX 16.2 Definitions of Sexual Assaults

Sexual assault: Comprehensive term that includes various types of forced or inappropriate sexual activity. Sexual assault includes both physical and psychologic coercion as well as touch, penetration, and other sexual contact.

Rape: Forced sexual intercourse that occurs by physical force or psychologic coercion. Rape includes vaginal, anal, or oral penetration by body parts or inanimate objects.

Acquaintance rape (date rape): Applied to situations in which the assailant and victim know each other.

Statutory rape: Consensual sexual contact by a person 18 years old or older with a person under the age of consent or unable to consent because of developmental disability. Age of consent varies by state.

concerned with the protection of girls. In the past 20 years, many laws have been rewritten to be gender neutral. Statutory rape laws require reporting to child protective services or local law enforcement. One risk of strict statutory rape enforcement is that girls may not seek health care for reproductive care, prenatal care, or domestic violence. Young people may fear not only for themselves but also for their partners. However, sexual coercion of teens by adults remains a problem and results in STIs and adolescent pregnancy.

Nurses can obtain information about their state's rape reporting responsibilities from state or local child protective services agencies, legal counsel, rape crisis organizations, state or local law enforcement agencies, or the state nurses' association. The limits of confidentiality should be clearly reviewed with each adolescent patient before beginning an interview about sexual activity.

Sexual assault victims may be targets of sex trafficking. Sex trafficking is a type of human trafficking and is a form of modern-day slavery. It is a serious public health problem that negatively affects the well-being of individuals, families, and communities. Human trafficking occurs when a trafficker exploits an individual with force, fraud, or coercion to make them perform commercial sex or work. Perpetrators of human trafficking often target people who are poor, vulnerable, living in an unsafe situation, or searching for a better life. Victims are trapped and controlled through assault, threats, false promises, perceived sense of protection, isolation, shaming, and debt. Signs and symptoms of sex trafficking can be found at https://humantraffickinghotline.org/human-trafficking/recognizing-signs.

Diagnostic Evaluation

Sexual assault victims may exhibit a variety of reactions (Box 16.3), and the circumstances of the initial medical evaluation may be frightening and stressful. The initial contact with the assault victim must be supportive, because the interrogation and associated activities have the potential to add to the trauma of the sexual assault. First, the victim needs to know that she (or he) is (1) all right and (2) not being blamed for the situation.

It is important to obtain a clear account of the circumstances of an alleged assault without forcing the victim to relive a painful experience. Information includes the date, time, location, and an accurate description of any type of sexual contact. The physical examination is carried out as soon as possible because physical evidence deteriorates rapidly. The victim should not bathe or shower before the examination.

The young person is always told in advance in understandable terms exactly what to expect in the way of tests and procedures, and

BOX 16.3 Clinical Manifestations of Sexual Assault Victims

May display a variety of emotions and behaviors, such as:

- Hysterical crying
- Giggling
- Agitation
- Feelings of degradation
- Anger and rage
- Helplessness
- Nervousness
- Rapid mood swings
- Appearing calm and controlled (masking inner turmoil)
- Confusion
- Self-blame
- Fear—of the rape and of injury

There may be evidence of physical force from the following:

- Roughness
- Nonbrutal beating (slapping)
- Brutal beating (slugging, kicking, beating repeatedly with fists)
- Choking or gagging

Medical examination provides evidence of:

- Penetration
- Ejaculation
- Use of force

! NURSING ALERT

It is common for sexual assault victims to delay seeking help, especially in cases of acquaintance or date rape. Nurses can be most supportive by acknowledging the painful and sometimes confusing feelings that surround such experiences and by focusing on the fact that the victim is seeking assistance now.

the explanation is accompanied by strong emotional support. The victim is examined thoroughly, including nongenital areas, for evidence of injury that might substantiate the use of force.

The forensic examination of a sexual assault victim must follow strict legal requirements. The medical record may provide key evidence for the legal case. Practitioners specially trained for rape examination should be used when possible. Nurses are often members of this group and are known as **sexual assault nurse examiners (SANEs)**. Evaluation for STIs is an important part of the examination. The following procedures are recommended for the initial examination: nucleic acid amplified testing (NAAT) for chlamydia and gonorrhea; wet mount and culture or point-of-care testing of a vaginal swab specimen for trichomoniasis; and a serum sample for HIV infection, hepatitis B, and syphilis. Decisions to perform these tests should be made on an individual basis. Repeat testing for chlamydia and gonorrhea can be done at 2 weeks if prophylactic treatment was not administered. Serologic tests for syphilis and HIV infection can be repeated 6 weeks, 3 months, and 6 months after the assault if infection in the assailant could not be ruled out (Centers for Disease Control and Prevention, 2015).

Prophylactic treatment for chlamydia, gonorrhea, and trichomoniasis is recommended. Vaccination for hepatitis B should be administered if the patient has not been vaccinated previously. Follow-up doses of vaccine should be administered 1 to 2 and 4 to 6 months after the first dose. Female victims should be provided with emergency contraception. The recommendation for HIV prophylaxis varies depending on the geographic area, the circumstances of the assault, and the known HIV status of the perpetrator. The Centers for Disease Control

and Prevention (2015) maintains updates and recommendations for treatment of STIs incurred as a result of sexual assault.[a]

Therapeutic Management

Adolescents who have been sexually assaulted arrive at the emergency department or practitioner's office under a variety of circumstances. They are usually brought by parents, friends, or police officers, but some may seek medical help on their own. It is advisable to obtain parental consent for examination, but the examination may be performed without parental consent if the adolescent is mature and the parents are unavailable. A female observer or chaperone should be present during the history and examination of female victims who are examined by a male practitioner. Whether a parent should be present during the examination is determined on an individual basis. The parent's presence is usually encouraged if the parent is supportive and the young person agrees.

Nursing Care Management

Many of the approaches that have been described for sexually abused children (see Chapter 13) also apply to adolescents. Sexual assault is a devastating experience with long-lasting effects. The primary goal of nursing care is to avoid inflicting further stress on the adolescent, who is often angry, confused, frightened, embarrassed, and filled with self-blame. The nurse must do everything possible to reduce the stress of the interrogation and examination. Although most health professionals and law enforcement officers are sensitive to the needs of adolescents and attempt to make the process as nonstressful as possible, the nurse should be alert to cues that indicate that the victim is being overstressed.

The consequences of sexual violence are physical, such as bruising and genital injuries, and psychologic, such as depression, anxiety, and suicidal thoughts. The consequences may also be chronic. Victims may suffer from PTSD and experience recurring gynecologic, gastrointestinal, cardiovascular, and sexual health problems. Sexual violence is also linked to negative health behaviors. For example, victims are more likely to smoke (Centers for Disease Control and Prevention, 2015).

Follow-up care of the assault victim is essential and extends over a long period. Aside from the universal need for emotional support, the needs of assault victims vary widely and depend on the nature of the incident, the victim's age when the assault occurred, the physical and emotional injuries sustained by the victim, the legal actions being considered as a result, the resources available for informal support, and the anticipated reactions of persons in the informal support network (see Family-Centered Care box).[b] https://www.cdc.gov/violenceprevention/pdf/SV-Prevention-Technical-Package.pdf

FAMILY-CENTERED CARE

Supporting the Sexual Assault Victim's Parents

In addition to the needs of the adolescent assault victim, the nurse should also be sensitive to the needs and reactions of the adolescent's parents. Some parents will be angry and blame the adolescent; others will feel guilty and embarrassed. Many reactions can be expected at the time of the incident, ranging from despair to extreme agitation. Frequently the parents require as much support and reassurance as the victim. Agitated, angry, or incapacitated parents are unable to provide support for their adolescent. Meeting their needs can foster their ability to support the teenager during the crisis.

NUTRITION AND EATING DISORDERS

Obesity

Few problems in childhood and adolescence are so obvious to others, are so difficult to treat, and have such long-term effects on health as obesity. Several different definitions have been proposed for obesity and overweight. **Obesity** has been defined as an increase in body weight resulting from an excessive accumulation of body fat relative to lean body mass. **Overweight** refers to the state of weighing more than average for height and body build. Currently, the **body mass index (BMI)** measurement is recommended as the most accurate method for screening children and adolescents for obesity. The BMI measurement is strongly associated with subcutaneous and total body fat and with skinfold thickness measurements. It is also highly specific for children with the greatest amount of body fat. Pediatric growth charts that include BMI for age and gender are available from the Centers for Disease Control and Prevention.[c] A new classification system recognizes BMI at the 95th percentile or greater as class I obesity, BMI at 120% or greater of the 95th percentile as class II obesity, and BMI at 140% or greater of the 95th percentile as class III obesity. Classes II and III obesity are strongly associated with greater cardiovascular and metabolic risk (Skinner, Perrin, Moss, et al., 2015).

It is important to note that for children with high levels of muscle mass (e.g., athletes), the BMI measurement may misclassify these youth into overweight or obesity. Clinical judgment is needed to understand whether these youth are at risk for obesity.

Numerous studies dating back to the early 1960s have documented childhood overweight through comprehensive evaluations of dietary intake, physical activity, and anthropometric measures; examples include the National Health and Nutrition Examination Surveys [NHANESs], I, II, III, and IV) (Ogden, Carroll, Kit, et al., 2014; Ogden, Kuczmarski, Flegal, et al., 2002; Ogden, Troiano, Briefel, et al., 1997). In the 1960s and 1970s, the rate of childhood overweight remained fairly constant at approximately 4% to 5.5%. However, surveys conducted during the 1990s and early 2000s demonstrated a steady climb to reach a rate of 17% in both children and adolescents (Flegal, Carroll, Kit, et al., 2012; Ogden et al., 2014). This prevalence has remained stable since 2003, but overall the incidence remains high (Ogden et al., 2014). Non-Hispanic African American and Hispanic children had higher prevalence rates of overweight and all classes of obesity compared with other races. Asian American children had markedly lower rates of overweight and all classes of obesity. The prevalence of overweight and obesity increased with age, with 41.5% of 16- to 19-year-old adolescents having obesity and 4.5% meeting the criteria for class III obesity.

Because adult obesity is associated with increased mortality and morbidity from a variety of complications, both physical and psychologic, adolescent obesity is a serious condition. For the first time in US history, the current generation of children will have a shorter life expectancy than their parents (American Heart Association, 2014). Children, adolescents, and young adults now have obesity-related conditions—type 2 diabetes, liver disease, hypertension, sleep apnea, and more—that were once rarely seen before adulthood and are compromising their current and future health.

Parental obesity increases the risk of overweight by twofold to threefold (Altman & Wilfley, 2015). The probability that overweight children will become obese adolescents is significant. In a large longitudinal study, overweight kindergarteners were four times more likely to become obese by 14 years old than normal-weight kindergarteners (Cunningham, Kramer, & Narayan, 2014).

[c]http://www.cdc.gov/growthcharts

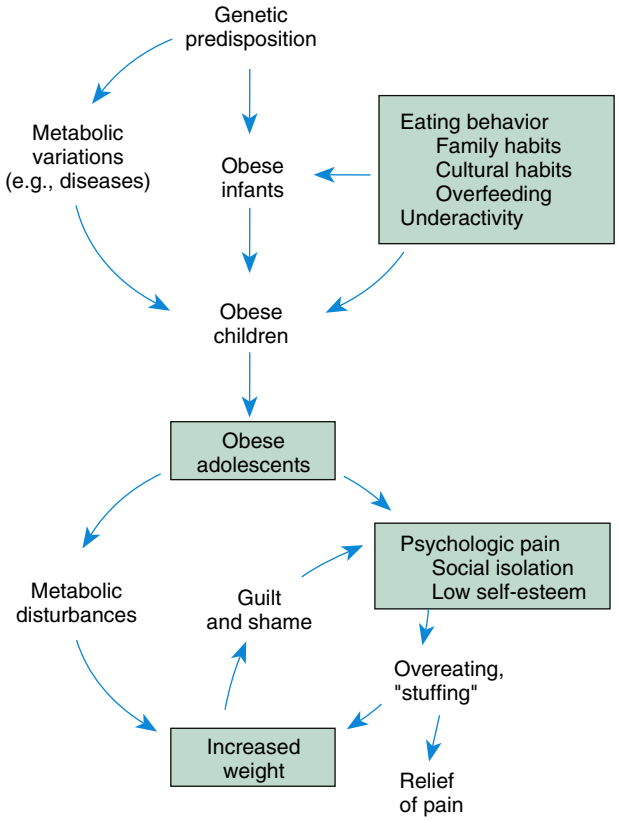

Fig. 16.2 Complex relationships in obesity.

Common emotional consequences of obesity include low self-esteem, social isolation, anxiety, depression, and an increased risk for the development of eating disorders (Altman & Wilfley, 2015).

Etiology and Pathophysiology

Obesity results from a caloric intake that consistently exceeds caloric requirements and expenditure, and may involve a variety of interrelated influences, including metabolic, hypothalamic, hereditary, social, cultural, and psychologic factors (Fig. 16.2). Because the etiology of obesity is multifactorial, the treatment requires multilevel interventions.

A balance between **energy intake** and **energy expenditure** is a critical factor in regulating body weight. For example, eating one small chocolate chip cookie (50 calories) is equivalent to walking briskly for 10 minutes. Factors that raise energy intake or decrease energy expenditure by even small amounts can have a long-term impact on the development of overweight and obesity.

Genetic influence is an epidemiologic consideration regarding children's weight. Genetic mutations, such as FTO (fat mass and obesity), are rare but can predispose individuals to becoming overweight or obese (Gahagan, 2020). Studies have also suggested a tendency for a combination of genetic and environmental factors. Obesity is determined by the genetics as well as the obesogenic environment. Obesogenic environment refers to the cheap and easy availability of a high-calorie diet and sedentary lifestyle. Genetics, the environment, and their complex interaction need to be considered to have a better understanding of obesity. More research is needed to better understand the influences of family behavior and adolescent overweight.

Fewer than 5% of the cases of childhood obesity can be attributed to an underlying disease. Such diseases include hypothyroidism; adrenal hypercorticoidism; hyperinsulinism; and dysfunction or damage to the CNS as a result of tumor, injury, infection, or vascular accident. Obesity is a frequent complication of muscular dystrophy, paraplegia, Down syndrome, spina bifida, and other chronic illnesses that limit mobility.

A major focus of obesity research has been **appetite regulation**. The expression of appetite is chemically coded in the hypothalamus by distinctive circuitry involved in drive and motivation. Orexigenic substances produce signals that increase appetite, and anorexigenic substances promote the cessation of eating behaviors. Feedback loops between signals have been identified where one signal peptide is able to alter the secretion of another signal peptide. No one signal has been identified as the gatekeeper of appetite. It is apparent that an entire network of signals, including their frequency and amplitude, is responsible for triggering eating behaviors.

There is little evidence to support a relationship between obesity and **low metabolism**. Small differences may exist between obese and nonobese children in regulation of dietary intake or metabolic rate that could lead to an energy imbalance and inappropriate weight gain, but these small differences are difficult to accurately quantify. Obese children tend to be less active than lean children, but it is uncertain whether inactivity creates the obesity or obesity is responsible for the inactivity. The tendency toward obesity is manifested whenever environmental conditions are favorable toward excessive caloric intake, such as an abundance of food, limited access to low-fat foods, reduced or minimum physical activity, and snacking combined with excessive screen time (computer, television, video games, cell phone). Family and cultural eating patterns as well as psychologic factors play important roles; many families and cultures consider fat to be an indication of good health. It is common for obese children to have families that emphasize large meals, admonish children for leaving food on their plates, or use food as a reward or punishment. Parents may have an exaggerated concept of the amount of food children require and expect them to eat more than they need.

Particular individuals at increased risk of having low levels of physical activity have been identified and include children who are from ethnic minorities (especially girls) in the preadolescent and adolescent age-groups, children living in poverty, children with disabilities, children residing in apartments or public housing, and children living in neighborhoods where outdoor physical activity is restricted by climate, safety concerns, or lack of facilities (Cradock, Barrett, Kenney, et al., 2017).

Some **community factors** that influence eating and activity patterns include a lack of built environment (food deserts, community gardens, farmers markets, sidewalks, parks, bike paths) or affordable and accessible facilities for low-income youth to be active, thus limiting their opportunities to participate in physical activities or healthful eating. Social policies also contribute to obesity. The increased availability of energy-dense foods, pricing strategies that promote unhealthy food choices, and overzealous food advertising that targets children and adolescents with high-fat and high-sugar foods are some examples (Schwartz & Ustjanauskas, 2012).

Institutional factors also influence patterns of obesity and decreased physical activity. Many school policies allow students to leave school for lunch. Vending machines in school often are filled with high-fat and high-calorie foods and soft drinks. Although well-balanced, nutritious school lunches may be available to students, they often opt for less nutritious choices, such as high-fat and high-sugar snacks.

Physical inactivity has also been identified as an important contributing factor in the development and maintenance of childhood overweight. There is little doubt that physical activity has decreased in elementary and secondary schools in the United States.

The Institute of Medicine recommends that schools take a "whole-of-school approach" to provide students with 60 daily minutes of physical activity, at least half of which should occur during the school day. Many children do not meet the recommended physical activity levels.

Consequently, most of children's physical activity must occur within the family or outside of school, which is often limited by community factors (e.g., unsafe neighborhoods). Decreased physical activity within the family is a powerful influence on children because children imitate their parents and other adults.

The growing attraction and availability of many sedentary activities, including television, video games, computers, and the Internet, have greatly influenced the amount of exercise that children get. Studies have shown the association between screen time and obesity among children (Robinson, Banda, Hale, et al., 2017):

- The American Academy of Pediatrics (2016) issued recommendations for children's media use. For children younger than 18 months of age, avoid use of screen media other than video chatting. Parents of children 18 to 24 months of age who want to introduce digital media should choose high-quality programming and watch it with their children to help them understand what they're seeing.
- For children ages 2 to 5 years, limit screen use to 1 hour per day of high-quality programs. Parents should co-view media with children to help them understand what they are seeing and apply it to the world around them.
- For children ages 6 years and older, place consistent limits on the time spent using media, and the types of media, and make sure that media do not take the place of adequate sleep, physical activity, and other behaviors essential to health.
- Designate media-free times together, such as dinner or driving, as well as media-free locations at home, such as bedrooms.
- Have ongoing communication about online citizenship and safety, including treating others with respect both online and offline.

Psychologic factors also affect eating patterns. Infants experience relief from discomfort through feeding and learn to associate eating with a sense of well-being, security, and the comforting presence of a nurturing person. Eating is soon associated with the feeling of being loved. In addition, the pleasurable oral sensation of sucking provides a connection between emotions and early eating behavior. Many parents use food as a positive reward for desired behaviors. This practice may become a habit, and the child may continue to use food as a reward, a comfort, and a means of dealing with depression or hostility. Many individuals eat when they are not hungry or in response to stress, boredom, loneliness, sadness, depression, or tiredness. Difficulty in determining feelings of satiety can lead to weight problems and may compound the factor of eating in response to emotional rather than physical hunger cues.

Diagnostic Evaluation

A careful history is obtained regarding the development of obesity, and a physical examination is performed to differentiate simple obesity from increased fat that results from organic causes. A family history of obesity, diabetes, coronary heart disease, and dyslipidemia should be obtained for all children who are overweight or at risk for overweight. Specific information from the patient and family about the effects of obesity on daily functioning—for example, problems with nighttime breathing and sleep, daytime sleepiness, joint pain, ability to keep up with family activities and peers at school—is helpful. The physical examination should focus on identifying comorbid conditions and identifiable causes of obesity. For some, psychologic assessment, by interviews and standardized personality tests, may provide insight into the personality and emotional problems that contribute to obesity and that might interfere with therapy.

It is useful to estimate the degree of obesity to determine the component of body weight that can be modified. All of these methods have been used to assess obesity: BMI, body weight, weight-height ratios, weight-age ratios, hydrostatic weight, dual-energy x-ray absorptiometry (DXA), skinfold measurements, bioelectrical analysis, computed tomography (CT), magnetic resonance imaging (MRI), and neutron activation. Each of these methods has advantages and disadvantages. Hydrostatic weighing provides the most accurate measurement of lean body weight.

TABLE 16.5 Pediatric Quality Indicator[a]

Weight Assessment and Counseling for Nutrition and Physical Activity	
Measure	Children and adolescents 3 to 17 years of age who had an outpatient visit and had evidence of the following during the measurement period: height, weight, and body mass index (BMI) percentile documentation, and counseling on nutrition and physical activity.
Numerator	Number of children with BMI percentile documentation, counseling on nutrition, and counseling on physical activity during the measurement time.
Denominator	Number of children 3 to 17 years of age with at least one outpatient visit.

[a]Endorsed by the National Quality Forum NQF #0024 and 2019 Core Set of Children's Health Care Quality Measures for Medicaid and CHIP. https://www.medicaid.gov/federal-policy-guidance/downloads/cib112018.pdf.

BMI is currently considered the best method to assess weight in children and adolescents. The calculation is based on the individual's height and weight. In adults, BMI definitions are fixed measures without regard for sex and age. The BMI in children and adolescents varies to accommodate age- and gender-specific changes in growth. The formula for BMI calculation is weight in kilograms divided by height in meters squared: weight (kg) ÷ (height [m]^2). BMI measures in children and adolescents are plotted on growth charts that enable health care professionals to determine BMI for age for the patient.

$$\frac{\text{Weight in pounds} \div \text{Height in inches} \times 703}{\text{Height in inches}}$$

The initial assessment of obese children and adolescents should include screening to evaluate for comorbidities. The history is an important guide to determine the workup. A complete physical examination is important. Some areas to focus on include (1) skin for stretch markings and discolorations (e.g., acanthosis nigricans), (2) joints for swelling and evidence of pain, and (3) airway for evidence of obstruction and enlarged tonsils. Basic laboratory studies include a fasting lipid panel, fasting insulin level, and fasting glucose hepatic enzymes, including gamma-glutamyl transferase (GGT) and, in some institutions, hemoglobin A1c. Other studies, such as a polysomnogram (sleep study), metabolic studies, and radiographic evaluations, may be added based on the history and physical examination. These assessments may determine whether the patient needs a referral to specialty services for more focused evaluation and treatment, such as endocrinology (insulin resistance, diabetes), hepatology (elevated liver enzymes, nonalcoholic fatty liver disease [NAFLD]), orthopedics (Blount disease), or pulmonary medicine (sleep-disordered breathing, continuous positive airway pressure [CPAP]).

Therapeutic Management

The best approach to the management of obesity is a preventive one. The Pediatric Quality Indicator for weight assessment and counseling for nutrition and physical activity is found in Table 16.5. Early recognition and control measures are essential before the child or adolescent

BOX 16.4 Recommended Behaviors for Preventing Obesity

In counseling adolescents whose body mass index (BMI) is between the 5th and 84th percentiles, physicians and health care providers should recommend the following steps to prevent obesity:

- Limit consumption of sugar-sweetened beverages.
- Consume recommended quantities of fruits and vegetables.
- Limit screen time to no more than 2 hours per day.
- Remove television and computer screens from primary sleeping areas.
- Eat breakfast daily.
- Limit eating at restaurants.
- Have frequent family meals in which parents and youth eat together.
- Limit portion sizes.

Adapted from Davis, D. M., Gance-Cleveland, B., Hassink, S., et al. (2007). Recommendations for prevention of childhood obesity. *Pediatrics, 120*(Suppl), S229–S253.

reaches an obese state. Health care providers need to educate families about the medical complications of obesity.

Currently, the only treatments recommended for children are diet, exercise, behavior modification, and in some situations pharmacologic agents, such as orlistat. The treatment of obesity is difficult. Many approaches do not achieve long-term success. The average individual loses only about 5% to 10% of his or her weight with available therapies. Losing weight can have a significant positive effect on many comorbidities, but unfortunately the lost weight is frequently regained in a year or two. A number of multidisciplinary programs offer interventions combining medical, dietary, exercise, and psychologic support. This therapy is labor intensive and costly. **Diet modification** is an essential part of weight reduction programs. Dietary counseling focuses on improving the nutritional quality of the diet rather than on dietary restriction. Children and adolescents should avoid fad diets. Most dietitians and nutrition experts recommend a diet with no trans fats, low in saturated fat, moderate in total fat (≤30%), low in sodium, and with at least nine servings of fruits and vegetables, consistent with the MyPlate[d] food guide for children. Also, promoting high-fiber foods and avoiding highly refined starches and sugars decrease caloric intake. Many programs recommend using a food diary as a helpful tool to increase awareness of food choices and eating behaviors. The goal is to encourage the individual to make healthy choices in food selection and discourage using food by habit or to appease boredom. Box 16.4 contains helpful suggestions.

In patients with severe obesity, strict diets have been used, such as the protein-sparing modified fast, hypocaloric diet, or ketogenic diet (Castaldo, Palmieri, Galdo, et al., 2016; Sukkar, Signori, Borrini, et al., 2013). These diets are designed to provide enough protein to minimize loss of lean body mass during weight loss. Such diets need to be closely monitored and should be used only with multidisciplinary teams that include a physician, nutritionist, and behavioral therapist. Generally, the diet consists of 1.5 to 2.5 g of protein per kilogram. The intake of carbohydrates is low enough to induce ketosis. The benefits of the diet are relatively rapid weight loss and anorexia induced by ketosis. Potential complications include protein losses, hypokalemia, hypoglycemia, inadequate calcium intake, orthostatic hypotension, and increased risk for osteoporosis. It is difficult to sustain these diets over the long term, and the long-term outcomes of using these diets have not been established. Treatment of childhood and adolescent obesity is an active area of research. Comprehensive behavioral interventions including changes in diet, physical activity, and lifestyles involving individual patients or families are commonly used and generally considered primary modes of treatment.

Behavioral modification approaches to weight loss are based on the observation that obese individuals have abnormal eating practices that can be altered. Attention is focused not on food but on the social and behavioral aspects surrounding food consumption. Successful behavior modification weight programs help adolescents identify and eliminate inappropriate eating habits and include a problem-solving component that enables adolescents to identify problems and determine solutions. Programs including family-based behavioral modification, dietary modification, and exercise have been shown to be successful in reducing obesity in some children (Altman & Wilfley, 2015). Behavior modification is an important part of multidisciplinary intervention programs.

Surgical techniques (bariatric surgery) that bypass portions of the intestine or occlude a segment of the stomach to produce a marked diet restriction and weight loss are hazardous and cause many metabolic complications. These complications include severe water and electrolyte depletion, persistent diarrhea, vitamin deficiency, internal herniation, and fatty infiltration and degeneration of the liver. Bariatric surgery may be the only practical alternative for increasing numbers of severely overweight adolescents who have failed organized attempts to lose or maintain weight loss through conventional nonoperative approaches and who have serious life-threatening conditions. Physicians must define clear, realistic, and restrictive guidelines to apply with younger patients when surgery is considered. Candidates for surgery should be referred to centers that offer a multidisciplinary team experienced in the management of childhood and adolescent obesity. The surgery should be performed by surgeons who have participated in subspecialty training in bariatric medical and surgical care as detailed by the American College of Surgeons and the American Society for Metabolic and Bariatric Surgery.

Nursing Care Management

Nurses play a key role in the adherence and maintenance phases of many weight reduction programs. Nurses assess, manage, and evaluate the progress of many overweight adolescents. They also play an important role in recognizing potential weight problems and assisting parents and adolescents in preventing obesity.

The presence of obesity may not be obvious from appearance alone. Regular assessment of height and weight and computation of the BMI facilitate early recognition of risk. Evaluation includes a height and weight history of the adolescent and family members, eating habits, appetite and hunger patterns, and physical activities. A psychosocial history is also helpful in understanding the impact of obesity on the child's life. Steps to approaching behavior change with youth are described in Box 16.5.

Before initiating a treatment plan, it is important to be certain that the family is ready for change. Lack of readiness may result in failure, frustration, and reluctance to address the problem in the future. The nurse should explore with adolescents the reasons behind the desire to lose weight because motivation to lose weight is the key to success. Adolescents need to take personal responsibility for their dietary habits and physical activity. Young persons who are forced by their parents to seek help are seldom motivated, become rebellious, and are unwilling to control their dietary intake.

Nutritional counseling. Preventing an increase in body fat during growth is a realistic approach. This is often accomplished by adjusting four aspects of eating: (1) reducing the quantity eaten by purchasing, preparing, and serving smaller portions; (2) altering

[d]http://www.choosemyplate.gov.

BOX 16.5 Pediatric Obesity Prevention Protocol for Primary Care

Step 1: Assess

Explain and conduct assessments of:

- Weight, height, and body mass index (BMI) percentile
- Dietary intake (fruit, vegetables, sweetened beverages, fast food)
- Activity (screen time, moderate to vigorous activity)
- Eating behaviors (breakfast, portion sizes, family meals)

Provide and elicit feedback on BMI and behaviors found to be inside and outside the optimal range.

Step 2: Set Agenda

Explore interest in changing behaviors not in the optimal range.

Agree on target behaviors with the patient and caregiver.

Step 3: Assess Motivation and Confidence

Regarding interest in changing weight status or behaviors, assess:

- Willingness and ability to make change
- Perceived importance
- Confidence in having success

Probe the patient regarding ratings of willingness, perceived importance, and confidence to explore the advantages and disadvantages of changing.

Step 4: Summarize and Probe Possible Changes

Summarize the advantages and disadvantages of change.

Query possible next steps. Allow the adolescent to suggest ideas.

Provide guidance for getting started in making a change as needed. Encourage achievable goals.

Summarize the change plan.

Provide positive feedback.

Step 5: Schedule Follow-Up Visit

If a change plan is made, agree on a follow-up appointment within a specified number of weeks or months.

If no change plan is made, agree to revisit the topic within a specific number of weeks or months.

Adapted from Davis, D. M., Gance-Cleveland, B., Hassink, S., et al. (2007). Recommendations for prevention of childhood obesity. *Pediatrics, 120*(Suppl), S229–S253.

the quality consumed by substituting low-calorie, low-fat foods for high-calorie foods (especially snacks); (3) eating regular meals and snacks, particularly breakfast; and (4) altering situations by severing associations between eating and other stimuli, such as eating while watching television. Nutrition counseling incorporates health behavior theories to help motivate and maintain behavior change. The most successful changes are those that are attainable, reasonable, and sustainable. The emphasis of counseling should be on health outcomes, not weight. Studies have shown that focusing on weight can be detrimental to therapies and may promote eating disorders (Altman & Wilfley, 2015).

The American Academy of Pediatrics recommends that children older than 2 years of age and adolescents whose weight falls in the overweight category be put on a weight maintenance program to slow the progress of weight gain. This strategy allows the child to add inches in height but not pounds, causing the BMI to drop over time into a healthier range. Children ages 6 to 11 years who are obese might be encouraged to modify their eating habits for gradual weight loss of no more than 1 pound (or about 0.5 kg) a month. Older children and adolescents who are obese or severely obese might be encouraged to modify their eating habits to aim for weight loss of up to 2 pounds (or about 1 kg) a week.

Behavioral therapy. Altering eating behavior and eliminating inappropriate eating habits are essential to weight reduction, especially in maintaining long-term weight control. Most behavioral modification programs include the following concepts:

- A description of the behavior to be controlled, such as eating habits
- Attempts to modify and control the stimuli that govern eating
- Development of eating techniques designed to control speed of eating
- Positive reinforcement for these modifications through a suitable reward system that does not include food
- Creating environments in which the healthy choice is the easy choice

Group involvement. Commercial groups or diet workshops composed primarily of adults may be helpful to some teenagers; however, a peer group is often more effective. Adolescent groups include summer camps designed for obese young people and conducted by health professionals, school groups organized and led by a school nurse or health professional, and groups associated with special clinics.

These groups are concerned not only with weight loss but also with the development of a positive self-image and the encouragement of physical activity. Nutrition education, diet planning, and the improvement of social skills are essential components of these groups. Improvement is determined by positive changes in all aspects of behavior.

Family involvement. There is a definite connection among family environment, interaction, and obesity. The nurse needs to educate parents in the purposes of the therapeutic measures and their role in management. The family needs nutrition education and counseling regarding the reinforcement plan, alterations in the food environment, and ways to maintain proper attitudes. They can support their child in efforts to change eating behaviors, food intake, and physical activity.

Physical activity. The current recommendation for physical activity for children and adolescents is to participate in a combined total of 60 minutes of physical activity daily; this can be moderate- to vigorous-intensive exercise or activity (Centers for Disease Control and Prevention, 2015). Regular physical activity is incorporated into all weight reduction programs. Recommendations for physical activity need to consider the current health status and developmental level of the child or adolescent. The best choice for exercise is any form that is enjoyable and likely to be sustainable. Light exercises, such as walking, may provide an opportunity for the family to increase time together and increase caloric expenditure. Weight training can increase the basal metabolic rate and replace fat mass with muscle mass. However, weight training is not generally recommended for prepubertal children until they have reached physical and skeletal maturity. In prepubertal children, increasing outdoor play time is likely to be beneficial. Limiting sedentary activities such as television viewing while eating snacks is very beneficial.

Prevention. Gradual accumulation of adipose tissue during childhood establishes a pattern of eating that is difficult to reverse in adolescence. Prevention of obesity should begin in early childhood with the development of healthy eating habits, regular exercise patterns, and a positive relationship between parents and children. Prevention of adolescent obesity is best accomplished by early identification of obesity in the preschool, school-age, and preadolescent periods. Health care professionals should encourage frequent health care visits for children who are overweight or obese and incorporate a dietary history and counseling into each well-infant, well-child, and well-adolescent visit.

Anorexia Nervosa and Bulimia Nervosa

Anorexia nervosa (AN) is an eating disorder characterized by a refusal to maintain a minimally normal body weight and by severe weight loss in the absence of obvious physical causes. It is a disorder with social, psychologic, behavioral, cultural, and physiologic components that result in significant morbidity and mortality. The disorder is a clinical diagnosis listed in the DSM-5 (American Psychiatric Association, 2013). Individuals with AN are described as perfectionists, academically high achievers, conforming, and conscientious.

Bulimia (from the Greek meaning "ox hunger") refers to an eating disorder similar to AN. Bulimia nervosa (BN) is characterized by repeated episodes of **binge eating** followed by inappropriate compensatory behaviors, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise (American Psychiatric Association, 2013). The binge behavior consists of secretive, frenzied consumption of large amounts of high-calorie (or "forbidden") foods during a brief time (usually ≈2 hours). The binge is counteracted by a variety of weight control methods (**purging**). These binge–purge cycles are followed by self-deprecating thoughts, a depressed mood, and an awareness that the eating pattern is abnormal.

Eating disorder not otherwise specified (EDNOS) is an additional diagnosis for eating disorders. These disorders have components of both AN and BN that are not characteristics of the established diagnostic criteria for AN and BN. Binge eating disorder (BED) is a type of EDNOS. Binge eating disorder (BED) is a distinct diagnostic category that is very similar to BN, with the exception that purging is not involved. EDNOS includes subthresholds of the aforementioned disorders, as well as purging disorder, night eating syndrome, and a residual category for clinically significant problems that meet the definition of a feeding or eating disorder but do not satisfy the criteria for any other disorder or condition (American Psychiatric Association, 2013).

According to eating disorders statistics estimated by the National Eating Disorders Association, in the United States up to 30 million people suffer from an eating disorder such as AN, BN, or BED. Worldwide the figure is more like 70 million sufferers. The problem with statistics on eating disorders is that many sufferers do not come forward for diagnosis due to embarrassment, denial, or confusion as to what their symptoms are. Based on diagnostic interview data from the National Comorbidity Survey Replication Adolescent Supplement (NCS-A), the lifetime prevalence of eating disorders among US adolescents ages 13 to 18 years was 2.7%. Eating disorders were more than twice as prevalent among females (3.8%) than males (1.5%).

These prevalences will likely climb as practitioners begin to use the new DSM-5 criteria. The DSM-5 Feeding and Eating Disorders chapter includes six entities: anorexia nervosa, bulimia nervosa, binge eating disorder, avoidant/restrictive food intake disorder (ARFID), rumination disorder, and pica. Unlike DSM-IV criteria for AN, DSM-5 does not include a requirement for amenorrhea, increasing the applicability of the diagnosis in males, premenarchal females, and postmenopausal females.

Etiology and Pathophysiology

The etiology of these disorders remains unclear. A combination of genetic, neurochemical, psychodevelopmental, sociocultural, and environmental factors appears to cause the disorder (Salafia, Jones, Haugen, et al., 2015). Dieting and body dissatisfaction appear to be common to the initiation of both AN and BN. Also characteristic is a childhood preoccupation with being thin reinforced by sociocultural and environmental factors, supporting the concepts of an ideal body shape. The dominant aspects of AN are a relentless pursuit of thinness and a fear of fatness, usually preceded by a period of mood disturbances and behavior changes.

These causes of anorexia nervosa are not necessarily black and white. Therefore if someone displays several risk factors, this does not guarantee that they will develop an eating disorder. On the other hand, the more of these contributing factors and causes of anorexia that a person possesses, the more likely they are to develop an eating disorder. There is also some evidence to support that some people may be genetically more likely to develop eating disorders. For example, eating disorders tend to run in families. A careful family history is therefore essential when assessing suspected eating disorders in patients

There are no strong empirical data to indicate that one particular family prototype is responsible for the development of an eating disorder. However, many experts have associated the development of an eating disorder with family characteristics, such as an adolescent perception of high parental expectations for achievement and appearance, difficulty managing conflict, poor communication styles, enmeshment and occasionally estrangement among family members, devaluation of the mother or the maternal role, marital tension, and mood and anxiety disorders. Adolescents whose parents focus on weight report higher levels of disordered eating (Salafia et al., 2015). Families struggling with an eating disorder have been characterized as often having difficulties responding positively to the changing physical and emotional needs of the adolescent. Family stress of any kind may become a significant factor in the development of an eating disorder (Salafia et al., 2015)

Individuals with eating disorders commonly have psychiatric problems, including affective disorder, anxiety disorder, obsessive-compulsive disorder (OCD), and personality disorder. Adult women with eating disorders were found to have higher rates of obsessive-compulsive behavior traits in their childhoods. It is important to note that many of the clinical findings are directly related to the state of starvation and improve with weight gain. Research continues in an effort to better understand the etiology and pathogenesis of eating disorders.

Many sports and artistic endeavors that emphasize leanness (e.g., ballet and running) and sports in which the scoring is partly subjective (e.g., figure skating and gymnastics) or where weight class is a prerequisite to participation (e.g., wrestling) have been associated with a higher incidence of eating disorders, as were described by some patients with an eating disorder (Salafia et al., 2015). The term **female athlete triad** was revised in 2007 to its current meaning to include one or more of the following three components: low energy availability (with or without disordered eating), menstrual dysfunction, and low bone mineral density (Ranson, Patterson, & Colvin, 2018). Published guidelines for determining triad risk stratification and providing guidance for clearance and return to play represent a critical step in the advancement of an evidence-based translation and need to be refined and validated going forward (De Souza, Nattiv, Joy, et al., 2014). It is critical that sports medicine practitioners and researchers continue to work together with these challenges in mind to achieve the goal of reducing the prevalence of the female athlete triad.

Diagnostic Evaluation

Diagnosis is made based on clinical manifestations (Box 16.6) and conformity to the criteria established by the American Psychiatric Association (2013). Characteristics of BN and AN are listed in Table 16.6.

BOX 16.6 Clinical Manifestations of Anorexia Nervosa

- Severe and profound weight loss
- Secondary amenorrhea (if menarche attained)
- Primary amenorrhea (if menarche not attained)
- Sinus bradycardia
- Low body temperature
- Hypotension
- Intolerance to cold
- Dry skin and brittle nails
- Appearance of lanugo hair
- Thinning hair
- Abdominal pain
- Bloating
- Constipation
- Fatigue
- Lightheadedness
- Evidence of muscle wasting (cachectic appearance)
- Bone pain with exercise

A complete history and physical examination are important to rule out other causes of weight loss. The medical assessment of an eating disorder focuses on the complications of altered nutritional status and purging. A careful history assesses weight changes, dietary patterns, and the frequency and severity of purging and excessive exercise. Purging behaviors include vomiting or other methods, such as abuse of laxatives, enemas, diuretics, anorexic drugs, caffeine, or other stimulants. Measure the patient's weight and height and evaluate it for appropriateness according to standard weight for height, age, and sex determined according to the percentile of his or her expected body weight or BMI.

Particularly important parts of the physical examination are vital sign measurement (heart and blood pressure, both supine and standing, and temperature). Hypotension, bradycardia, and hypothermia are often seen in association with extremely low weight. Prolongation of the QT interval may be detected in some patients. Dry skin, lanugo, acrocyanosis, and breast atrophy are findings that have been associated with AN. Distinctive hand lesions (Russell sign) have been observed; the backs of the hands are often scarred and cut from repeated abrasion of the skin against the maxillary incisors during self-induced vomiting.

The diagnosis of eating disorder is made clinically, but additional laboratory diagnostic tests may be obtained to identify malnutrition or other associated complications. Laboratory assessment may include a complete blood count to evaluate for anemia and other hematologic abnormalities; erythrocyte sedimentation rate or C-reactive protein to detect evidence of inflammation; electrolytes as well as calcium, magnesium, phosphorus, blood urea nitrogen, and creatinine; and urinalysis, including specific gravity to detect water loading. In patients with prolonged amenorrhea, human chorionic gonadotropin is assessed to determine the presence of pregnancy. Other tests for patients with amenorrhea include thyroid function tests and measurement of serum prolactin and follicle-stimulating hormone to help rule out prolactinoma (hormone-secreting pituitary tumor), hyperthyroidism, hypothyroidism, and ovarian failure. A bone density study may be ordered to detect bone loss, which is a complication of AN. In addition, a comprehensive cardiac evaluation is often recommended in those with AN. Further diagnostic tests may be required based on the history and findings from these diagnostic tests.

TABLE 16.6 Characteristics of Individuals With Eating Disorders

Factors	Anorexia Nervosa	Bulimia
Food	Turns away from food to cope	Turns to food to cope
Personality	Introverted	Extroverted
	Avoids intimacy	Seeks intimacy
	Negates feminine role	Aspires to feminine role
Behavior	"Model" child	Often acts out
	Obsessive-compulsive	Impulsive
School	High achiever	Variable school performance
Control	Maintains rigid control	Loses control
Body image	Body image distortion	Less frequent body image distortion
Health	Denies illness	Recognizes illness
		Health fluctuates
Weight	Body weight <85% of expected norm	Within 2.3-7 kg (5-15 pounds) of normal body weight or may be overweight
Sexuality	Usually not sexually active	Often sexually active

Screening tools. Annual health supervision examinations and preparticipation sports physicals are ideal screening opportunities. In addition to weight, height, and BMI measurements, a screening tool such as the SCOFF questionnaire can be used to screen for disordered eating. The SCOFF questionnaire has been validated only in adults but suggests an approach that can also be used with children (Rosen, 2010).

The medical history is most important for diagnosing eating disorders because the physical examination findings may be normal, especially early in the illness. A number of screening questionnaires are available to assist with the interview. In the SCOFF questionnaire, 1 point is scored for every "yes." A score of 2 or more indicates a likely case of AN or BN. The questions related to the mnemonic **SCOFF (Sick, Control, One, Fat, Food)** are (Harrington, Jimerson, Haxton, et al., 2015):

1. Do you make yourself ***sick*** because you feel uncomfortably full?
2. Do you worry that you have lost ***control*** over how much you eat?
3. Have you recently lost more than 6.4 kg (14 pounds or ***one*** stone) in a 3-month period?
4. Do you believe yourself to be ***fat*** when others say that you are too thin?
5. Do thoughts and fears about *food* and weight dominate your life?

Therapeutic Management

The treatment and management of AN involve three major goals: (1) reinstitution of normal nutrition or reversal of the severe state of malnutrition, (2) resolution of disturbed patterns of family interaction, and (3) individual psychotherapy to correct deficits and distortions in psychologic functioning. Treatment of eating disorders requires interventions of an interdisciplinary team composed of a primary practitioner, nurse, dietitian, and mental health provider with pediatric and adolescent health care experience. Because of the psychogenic nature of the disorder, the treatment may be long.

Most adolescents with AN are treated on an outpatient basis, but those with problems requiring immediate medical attention, such as severe malnutrition, electrolyte disturbances, vital sign abnormalities, or psychiatric disturbances (e.g., severe depression or suicidal ideation), may require hospitalization. Persons with BN may benefit from

CBT, psychotherapy, family-based therapy, and nutritional counseling (Kreipe & Starr, 2020).

Nutrition therapy. The most important goal is to treat any life-threatening malnutrition and to restore dietary stability and weight gain. This may require intravenous or tube feedings if the malnutrition is severe. The patient should avoid rapid weight gain because in some patients this has been associated with severe metabolic abnormalities, such as **refeeding syndrome**, which consists of cardiovascular, neurologic, and hematologic complications that occur when nutritional replacement is given too rapidly. This syndrome can be avoided with slow refeeding and the addition of phosphorus when total body phosphorus is depleted. Treatment goal weights are individualized and based on age, height, stage of puberty, premorbid weight, and previous growth charts. In young women who have reached menarche, resumption of menses is an objective measure of return to biologic health.

Dietary interventions are combined with behavioral therapy to improve the underlying psychologic misconceptions about weight loss. Another aspect of treatment is to relieve the anxiety related to eating and the depression that accompanies the disorder. Weight gain alone cannot be considered a cure for the disease and is an unreliable sign of progress. Relapses are frequent, as the person may revert to previous eating patterns when removed from the therapeutic environment.

Behavioral therapy. Behavioral modification, usually through CBT or motivational interviewing, has met with varying degrees of success. The goal is to increase the patient's feelings of control and responsibility toward achieving recovery. Providing privileges or activities for weight gain or positive eating behaviors may be successful, but treatment should also address the conflict precipitating the disorder. Individual psychotherapy is aimed at helping the young person resolve the adolescent identity crisis, particularly as it relates to a distorted body image. If the disorder is related to a dysfunctional family situation, therapy is most successful when it is started soon after the onset of illness and directed toward disengagement and redirection of malfunctioning processes in the family.

The team responsible for the management of young people with AN arranges a carefully structured environment. First, there must be consistency. The team decides on an approach and adheres to it. The plan is structured with reality testing regarding caloric intake and body image perception as an essential component. The team members provide a unified front to avoid any possibility of manipulation or inconsistency. Second, all team members are involved; responsibility for the program cannot be left to one person. The role and boundaries of each member are clearly spelled out. Third, continuity of team members is important; it is helpful to have the same team members all the time. Fourth, communication among team members is essential. Communication with the patient regarding what is expected is also important. Sometimes the limit setting may seem unreasonable. If the adolescent does not understand the rationale for the limits, he or she may sabotage the entire program. It is also important to communicate with the family. Fifth, the plan must provide for support of the adolescent, the family, and team members. Support the adolescent's efforts and provide positive feedback for accomplishments made in normalizing eating habits. Meetings are held to discuss the feelings and concerns of the patient, immediate caregivers, and team members.

Pharmacotherapy. There is no medication that specifically treats anorexia. However, doctors do sometimes prescribe certain antidepressants or other types of medicines to help some of the symptoms sometimes associated with anorexia, such as depression or anxiety.

The few studies that have been done have primarily evaluated medications' efficacy in the treatment of comorbid disorders, such as OCD and depression. SSRIs such as fluoxetine have not been shown to treat weight loss or prevent relapses in anorexia. Nevertheless, they are sometimes used to treat symptoms of depression or anxiety in people with anorexia.

The SSRI Prozac (fluoxetine) is approved by the US Food and Drug Administration to treat bulimia. There also is some evidence that other SSRIs may also treat symptoms of bulimia.

In addition, there is some evidence that tricyclic antidepressants such as desipramine, imipramine, and amitriptyline; monoamine oxidase inhibitors; and buspirone are more effective compared with a placebo in decreasing bingeing and vomiting in patients with BN. Topiramate, an antiepileptic agent, and the selective serotonin antagonist ondansetron have demonstrated some benefit in treating patients with BN. The American Psychiatric Association's guidelines have discouraged using medication as the only therapy.

The antidepressant bupropion (often marketed as Wellbutrin) has been associated with seizures in patients with purging bulimia and is not recommended for patients with eating disorders.

Medication should generally not be the initial or primary treatment for AN. There is far more evidence supporting nutritional rehabilitation and psychotherapy for treating AN, compared with that supporting medication.

Psychotherapy. Recent guidelines recommend that anorexia nervosa programs should focus on engaging the patient, on nutritional and physical rehabilitation in order to regain weight, and on provision of structured psychologic treatment. In addition, treatment outcome should aim at supporting quality-of-life changes needed for improvement or recovery.

Psychotherapy is central to the treatment of eating disorders. Patients need to be active participants in the treatment process to better understand the impulses, feelings, and needs that have resulted in their eating disorder. The goal is to increase the patient's feelings of control and responsibility toward achieving recovery. Eating disorders are complex and multifaceted. Family therapy addresses dysfunctional roles, conflicts, alliances, and patterns that the eating disorder is precipitating or maintaining, while helping family members to deal with the eating disorder.

Although evidence is yet insufficient to support outpatient versus inpatient programs, the treatment of AN has moved clinically from long-term inpatient programs with outpatient follow-up to a more common model of individual outpatient treatment with hospital backup.

Nursing Care Management

Nurses need to adopt and maintain a kind and supportive yet firm manner in managing the care of the adolescent with eating disorders without creating a passive-dependent attitude. The individual requires sustained support and reassurance to cope with ambivalent feelings related to body concept and the desire to be seen as cooperative, reliable, and worthy of receiving kindness. Encouraging the adolescent with education and activities that strengthen self-esteem facilitates the resocialization process and promotes social acceptance among peers.

It is important for nurses to be aware of the physical side effects of AN. Patients with AN frequently limit their fluid intake. Urinary tract problems are common, and ketones and protein may be detected in the urine as a result of breakdown of fat and protein. Vital sign instability can be severe and can include orthostatic hypotension; the pulse becomes irregular, and the rate decreases markedly. Bradycardia and hypothermia can result in cardiac arrest (see Critical Thinking Case Study box).

CRITICAL THINKING CASE STUDY

Anorexia Nervosa

Jane is a 13-year-old girl whose grades have been excellent and whom the teachers describe as a "model student." Recently, Jane's teacher told the nurse practitioner that Jane's parents were in the middle of a "messy divorce." In addition, several of Jane's friends told the nurse practitioner that they are concerned about Jane because she runs every day at lunchtime and seldom eats lunch with them. Jane told her friends that she gained weight over the winter months and that she is running because she wants to qualify for the track team this spring. At the time of her routine health interview and sports physical examination, the nurse practitioner notes that Jane's oral temperature is 36°C (96.8°F) and she weighs 34 kg (75 pounds). Jane has lost 9 kg (20 pounds) since her last sports physical. Jane tells the nurse practitioner that she has not had her menstrual period for 3 months.

Initial Assessment. What would be your initial concerns for Jane?

Clinical Reasoning. Discuss immediate interventions that are appropriate for Jane at this time.

Teaching Points

- Numerous factors can influence the development of anorexia nervosa.
- Indicators for concern in Jane's case include the traumatic family event, concern with qualifying for the track team, and pulling away from her friends.

Critical Thinking Answers

Initial Assessment. Jane has had a traumatic life experience and has lost considerable weight. The absence of her menstrual period causes concern with the effect of rapid weight loss on her body.

Clinical Reasoning. Jane needs immediate support to help her sort through her emotions related to the divorce and actions she is taking regarding her health.

Nursing care of the adolescent with BN is similar to that for the patient with AN. Acute care involves careful monitoring of fluid and electrolyte alterations and observation for signs of cardiac complications. Nutritional consultation and follow-up care are essential. The nurse should encourage the adolescent and family members to structure the environment to reduce the bingeing behavior. Avoiding and eliminating trigger foods that would result in binges; restricting eating to one room of the house to avoid hiding and the shame related to overeating; being mindful and not engaging in other activities while eating; and substituting exercise, crafts, visualization, and relaxation techniques prior to and during urges to binge are helpful interventions.

Nurses, patients, and families can find assistance and information from several organizations. The National Association of Anorexia Nervosa and Associated Disorders[e] provides counseling, referral, and self-help programs for young people with AN. The National Eating Disorders Association[f] provides information and support services for both patients and families.

ADOLESCENT DISORDERS WITH A BEHAVIORAL COMPONENT

Substance Abuse

Monitoring the Future (MTF) is a long-term study of American adolescents, college students, and adult high school graduates through age 55 years. It has been conducted annually by the University of Michigan's Institute for Social Research since its inception in 1975 and is supported under a series of investigator-initiated, competitive research grants from the National Institute on Drug Abuse (Johnston, O'Malley, Miech, et al., 2016). The 2016 survey found that annual marijuana use among 8th-graders increased from 2007 to 2010, decreased slightly from 2010 to 2012, and then declined significantly in 2016. Among 10th-graders, use increased somewhat from 2008 to 2013 and then declined after that. Among 12th-graders, use increased from 2006 to 2011 and then held level through 2016 (Johnston et al., 2016).

Binge drinking (five or more alcoholic drinks at least once in the prior 2 weeks) has been on the decline since the early 1980s; by 2016, proportional declines since the peaks reached in the 1990s were 75%, 60%, and 51% for grades 8, 10, and 12, respectively. The observed prevalence of binge drinking continued its decline from 2015 to 2016 (significant in eighth grade), to 2016 rates of 3%, 10%, and 16% for the three grades (Johnston et al., 2016).

Cigarette use was on a steady decline from the mid-1990s until 2004; by 2016, 30-day prevalence levels had fallen from peak levels by 87%, 84%, and 71% in grades 8, 10, and 12, respectively (Johnston et al., 2016).

Smokeless tobacco use among American young people is almost exclusively a male behavior. Among males, the 30-day prevalence rates in 2016 were 3.6%, 5.8%, and 11.9% in grades 8, 10, and 12, respectively, whereas among females they were 1.4%, 1.3%, and 1.5% (Johnston et al., 2016).

Vaping continues to have higher use among teens than traditional tobacco cigarettes or any other tobacco product. As a point of comparison, prevalence for tobacco cigarettes was 2.6%, 4.9%, and 10.5% among 8th-, 10th-, and 12th-grade students, respectively. In 8th and 10th grades, vaping is more than twice as common as use of regular cigarettes (Johnston et al., 2016).

Between January 2017 and January 2018, the percentage of 12th-graders who reported vaping nicotine (not flavoring or other substances) during the past 30 days nearly doubled, from 11% to nearly 21%; among 10th-graders, the increase was almost as great, from 8.2% to 16.1%. These are the biggest 1-year increases ever seen for any substance in the history of the MTF survey (Johnston et al., 2016). In 2016 the use of illicit drugs, other than marijuana, showed some decline among 8th- and 10th-graders, whereas annual prevalence among 12th-graders showed essentially no change (Johnston et al., 2016).

Drug abuse, **misuse**, and **addiction** are culturally defined and are voluntary behaviors. **Drug tolerance** and **physical dependence** are involuntary physiologic responses to the pharmacologic characteristics of drugs, such as opioids and alcohol. Consequently, an individual can be addicted to a narcotic with or without being physically dependent. A person can also be physically dependent on a narcotic without being addicted (e.g., patients who use opioids to control pain).

Motivation

Most drug use begins with experimentation. The drug may be used only once, may be used occasionally, or may become part of a drug-centered lifestyle. Children and adolescents initiate drug use out of curiosity. Adolescents who use drugs may fall into one of two broad categories—experimenters and compulsive users—or they may fall into a third category somewhere on the continuum between these extremes, referred to as *recreational users,* principally of drugs such as

marijuana, cocaine, alcohol, and prescription drugs. For many, the goal is peer acceptance; these users fit more closely with the experimenting, intermittent users. For others, the goal is intoxication or the sustained intense effects from using a particular drug. These users resemble the compulsive users; they may engage in periodic heavy use, or binges. The groups of greatest concern to health care workers are those whose patterns of use involve high doses or mixed drugs with the danger of overdose and compulsive users with the threat of dependence, withdrawal syndromes, and altered lifestyle.

Types of Drugs Abused

Any drug can be abused, and most are potentially harmful to adolescents still going through formative life experiences. Although rarely considered drugs by society, the chemically active substances frequently abused are the xanthines, theobromines, and caffeine contained in such products as chocolate, tea, coffee, colas, and energy drinks. Ethyl alcohol and nicotine are other drugs that are legal and socially sanctioned. Any of these substances can produce mild to moderate euphoric or stimulant effects and can lead to physical and psychologic dependence. Nonmedical use of pharmaceuticals gained renewed attention in the last decade. The increase in deaths from prescription opioids has been called an epidemic, and overdoses from opioids (prescription and illicit) led the US Department of Health and Human Services (2018) to declare a public health emergency in 2017.

In addition, concerns have arisen about nonmedical use of pharmaceuticals other than opioids, such as benzodiazepines, nonbenzodiazepine sleeping aids, stimulants, and cough and cold products.

The primary OTC drug of abuse in the United States is dextromethorphan (DXM), which is found in more than 120 nonprescription cough and cold medications. Using DXM as directed is safe and produces only infrequent side effects. However, it presents a significant potential for abuse, recreational use, and psychologic dependence effects. Individuals who use DXM recreationally primarily are interested in experiencing the dissociative effects associated with consuming large quantities. Prescription cough syrup containing promethazine and codeine is another common medicine-cabinet staple associated with teenage drug abuse. A popular method of consumption involves mixing the cough medicine with a fruit-flavored soda and dropping in a Jolly Rancher candy for coloring and flavor. Teens often call this drink "sizzurp," "purple drank," "syrup" or "lean."

Drugs with mind-altering abilities that are available on the "street" and are of medical and legal concern are the hallucinogenic, narcotic, hypnotic, and stimulant drugs. In addition, health professionals are concerned about the use of alcohol and volatile substances that are inhaled to achieve altered sensation (e.g., gasoline, nail polish remover, household cleaners, deodorant spray cans, liquid paper correction fluid, markers, plastic model cement, organic solvents). Huffing causes a sense of euphoria that lasts about 15 to 45 minutes. Most inhalant users report starting using before age 15 years. The initial euphoria of huffing might be followed by dizziness; headache; slurred speech; and loss of coordination, inhibition, and control. Hallucinations and delusions are possible. If an inhalant causes the heart to work too hard, a dysrhythmia could trigger lethal heart failure, even for first-time inhalers. Chronic inhalant use can cause serious liver and kidney damage.

The online drug trade is also flourishing on a hidden network of websites that are not indexed by normal search engines and are accessible only through special web browsers such as Tor. In January 2016 alone, drug revenues in cryptomarkets totaled between $12 million and $21.1 million, according to an analysis by RAND Europe. Some tech-savvy teens are finding their way to these illicit markets. Adolescents can use numerous methods to get drugs through various avenues. They can use fake IDs, attend parties, or meet dealers on the street. They can also access prescriptions by visiting a physician or by rifling through the cabinets of family members, friends, or neighbors. In addition, medications can be obtained through school, online, and through social media.

Tobacco. Cigarette smoking has been on a slow decline since its peak in 1999 despite multiple efforts, including increased costs, changes in community attitudes about smoking, media campaigns with counteradvertising, and tobacco-free environments. Use of all tobacco products among youth has not changed significantly between 2004 and 2016 (Johnston et al., 2016).

Cigarette smoking is still considered a chief avoidable cause of death. The hazards of smoking at any age are undisputed; however, a preventive approach to teenage smoking is especially important. Because of its addictive nature, smoking begun in childhood and adolescence can result in a lifetime habit, with increased morbidity and early mortality.

The effects of secondhand smoke exposure are well known and include increased incidence of low birth weight and subsequent illness, increased incidence of sudden infant death syndrome (maternal smoking during and after pregnancy), increased incidence of lower respiratory tract infections and ear infections, exacerbation of asthma attacks, sleep disturbances, and intellectual impairment (Al-Sayed & Ibrahim, 2014; Homa, Neff, King, et al., 2015).

Etiology. Teenagers begin smoking for a variety of reasons, including imitation of adult behavior, peer pressure, a desire to imitate behaviors and lifestyles portrayed in movies and advertisements, and a desire to control weight, especially among young women. Teenagers who do not smoke usually have family members and friends who do not smoke or who oppose smoking. Most teens who refrain from smoking have a desire to succeed in academics or athletics and plans to go to college (see Community Focus box). Although smoking among college students has increased in recent years, rates of smoking are highest among adolescents who do not complete high school.

COMMUNITY FOCUS

Early Sexual Maturation, Alcohol, and Cigarettes

Smoking cigarettes and drinking alcohol among adolescents are complex behaviors that are not explained by any one cause or factor. Some theorists and investigators believe that there is a relationship between biologic maturation and risk-taking behaviors. For example, young girls who are sexually mature at an earlier age than their peers are often attracted to older girls and boys who may engage in risk-taking behaviors. If older teens smoke, drink, and drive while under the influence of alcohol with no adverse consequences (e.g., no motor vehicle crashes), young girls may believe that they, too, will be safe while smoking, drinking, or riding in an automobile with friends who are drinking.

Although parents and nurses cannot influence the time of biologic maturation, they can identify young girls who are at risk for the initiation of risk-taking behaviors because of early puberty. Parents need to understand that an early-maturing daughter may be uncomfortable with her body, and they should take advantage of opportunities to build her self-esteem. Parental sensitivity to the importance of peer group acceptance and parental support of a teenage daughter who feels left out or different are crucial. School nurses can provide anticipatory guidance to these girls and help them role-play coping strategies for situations that involve offers to smoke and drink. In addition, school nurses can provide information about physical development during puberty and emphasize the fact that not all teenagers mature at the same time or rate.

Teachers, coaches, and community and church leaders can provide opportunities for these girls to "fit in" with their same-age peers through activities that stress mutual goals. For example, an early-maturing girl is typically taller than her age-mates and can be an asset in sports, such as basketball and track and field events.

Smokeless tobacco. The term *smokeless tobacco* refers to tobacco products that are placed in the mouth but not ignited (e.g., snuff, chewing tobacco). This substitute for cigarettes continues to pose a hazard to adolescents, although use had steadily declined by about 50% since the peak prevalence in 1995. Children and adolescents continue to recognize the risk of smokeless tobacco and have expressed high rates of disapproval (Johnston et al., 2016). These products have also been proven to be carcinogenic, and regular use can cause dental problems, foul-smelling breath, and tooth erosion or loss.

Nursing care management. Prevention of regular smoking in teenagers is the most effective way to reduce the overall incidence of smoking. A variety of methods have been used. Posters, charts, displays, statistics, and the use of examples of actual damaged lungs to communicate the hazards of smoking all have their supporters and doubters. Some schools also use films and demonstrations in science classes.

For the most part, smoking prevention programs that focus on the negative, long-term effects of smoking on health have been ineffective. Youth-to-youth programs and those emphasizing the immediate effects are more effective but primarily in improving teenagers' attitudes toward not smoking. Because smoking and smoking-related behaviors are social symbols, antismoking campaigns must address the norms of potential smokers. Anything that ridicules or threatens the social norms of the peer group can be unproductive or counterproductive. Investigators have found that teaching resistance to peer pressure to smoke is effective in early adolescence. Although the effects of these programs may decrease with time, they can be enhanced in older adolescents by presenting information in class instead of simply handing out written material to the students.

Two areas of focus for antismoking programs are peer-led programs and use of media in smoking prevention (e.g., CDs, videotapes, films). Peer-led programs emphasizing the social consequences of smoking have proved most successful. If a significant number of influential peers can "sell" their classmates on the idea that the habit is not popular, the followers will imitate their behavior. Such programs emphasize short-term rather than long-term consequences (e.g., the effects of smoking on personal appearance, such as unattractive stains on teeth and hands, and unpleasant odor of breath and clothing).

The impact of school-based antismoking programs can be strengthened by expanding these programs to include parents, mass media, youth groups, and community organizations. For example, mass media efforts that involve antismoking radio campaigns have been identified as the most cost-effective mass media intervention.

Smoking bans in schools also accomplish several goals, including discouraging students from starting to smoke, reinforcing knowledge of the health hazards of cigarette smoking and exposure to environmental tobacco smoke, and promoting a smoke-free environment as the norm (see Community Focus box).

Alcohol. Acute or chronic abuse of alcohol (ethanol) is responsible for many acts of violence, suicide, accidental injury, and death. Alcohol drinking is likely to begin in the middle school years and increase with age. By 18 years of age, 80% to 90% of adolescents have tried alcohol. Ethanol is a depressant that reduces inhibitions against aggressive and sexual acting out. Severe physical and psychologic symptoms accompany abrupt withdrawal, and long-term use leads to slow tissue destruction, especially of the brain and liver cells. The most noticeable effects of alcohol occur within the CNS and include changes in cognitive and autonomic functions, such as judgment, memory, learning ability, and other intellectual capacities. Young people with alcoholism often drink alone and cannot control their use of alcohol. They often rely on the substance as a defense against depression, anxiety, fear, or anger. Not all of these characteristics are observed in adolescents who are abusing alcohol, but if several signs are evident, the child or adolescent should be considered at risk. Referral to a health care professional and detoxification therapy may be necessary. Information about alcohol and answers to questions are available through the Alcohol Hotline.[g] Other groups that provide support and counseling for families are Al-Anon, Alateen, Alatot, and Alcoholics Anonymous (an organization that has listings in all local directories).

Cocaine. Although cocaine is not pharmacologically considered a narcotic, it is legally categorized as such. Cocaine is available in two forms: water-soluble cocaine hydrochloride, which is administered by "snorting" or intravenous injection, and nonsoluble alkaloid (freebase) cocaine, which is used primarily for smoking. Crack, or "rock," is a

COMMUNITY FOCUS

Considerations for Nonsmoking Strategies

Nurses who work in schools, hospitals, and community agencies can take advantage of all opportunities to provide education about the dangers of smoking, to discourage smoking initiation by children and adolescents, to encourage smoking cessation, and to promote smoke-free environments. In particular, school nurses must be alert to the vulnerability of young preteens when they enter junior high or middle school. These nurses are in an ideal position to assess stress, personal conflict, weight concerns, peer pressure, and other factors that place preteens at risk for smoking initiation. Nurses should serve as counselors to student, teacher, and parent groups and as advocates for antismoking legislative efforts. The following additional strategies are recommended[a]:

- Provide only brief information about long-term health consequences (e.g., cardiovascular, cancer risks).
- Discuss immediate physiologic consequences (e.g., changes in heart rate, blood pressure, respiratory symptoms, and blood carbon monoxide concentrations).
- Mention alternatives to smoking that also establish a self-image that appears independent, mature, or sophisticated (e.g., weightlifting; jogging; dancing; joining a boys or girls club; volunteering for a hospital or political, religious, or community group).
- Mention the negative effects in detail (e.g., earlier wrinkling of skin; yellow stains on teeth and fingers; tobacco odor on breath, hair, and clothing).
- Mention the increasing ostracism of smokers by nonsmokers, both legal and informal, in the workplace and in public places.
- Mention the increasing evidence that secondhand smoke is injurious to the health of nonsmokers who are regularly exposed, especially small children.
- Acknowledge that many adults who were enticed to start smoking as teenagers because of its social benefits now wish they could stop smoking.
- Give cooperative adolescents effective arguments to deal with peer pressure (e.g., by not smoking, a teenager demonstrates independence and nonconformity, traits normally prized by youth).
- Request posters or pamphlets from local agencies (e.g., American Cancer Society, American Heart Association, American Lung Association) to display in prominent places at school.

[a]The Centers for Disease Control and Prevention has information on the effects of tobacco, smoking cessation, and tobacco control programs: 1600 Clifton Rd., Atlanta, GA 30333; 800-232-4636; email: tobaccoinfo@cdc.gov; http://www.cdc.gov/tobacco.

[g]Toll free 800-331-2900.

purer, more menacing form of the drug. It can be produced cheaply and smoked in either water pipes or mentholated cigarettes.

Cocaine creates a sense of euphoria, or an indefinable high. Withdrawal does not produce the dramatic symptoms observed in withdrawal from other substances. The effects are those commonly seen in depression, including lack of energy and motivation, irritability, appetite changes, psychomotor delay, and irregular sleep patterns. More serious symptoms include cardiovascular manifestations and seizures. Physical withdrawal should not be confused with the so-called crash after a cocaine high, which consists of a long period of sleep. Answers to questions about the risks of using cocaine are available at the National Cocaine Hotline,[h] which also provides referrals to support groups and treatment centers.

Narcotics. Narcotic drugs include opiates, such as heroin and morphine, and opioids (opiate-like drugs), such as hydromorphone (Dilaudid), hydrocodone, fentanyl, meperidine (Demerol), and codeine. These drugs produce a state of euphoria by removing painful feelings and creating a pleasurable experience and a sense of success accompanied by clouding of the consciousness and a dreamlike state. Physical signs of narcotic abuse include constricted pupils, respiratory depression, and often cyanosis. Needle marks may be visible on the arms or legs in chronic users. Physical withdrawal from opiates is extremely unpleasant unless controlled with supervised tapering doses of the opioid or substitution of methadone.

As important as the physical effects are the indirect consequences related to the illegal status of narcotic use and the problems associated with securing the drug (e.g., the time-consuming searches to obtain the drug and the often illegal methods used to meet the high cost of purchasing it). Health problems also result from self-neglect of physical needs (nutrition, cleanliness, dental care); overdose; contamination; and infection, including HIV and hepatitis B and C infection.

Central nervous system depressants. CNS depressants include a variety of hypnotic drugs that produce physical dependence and withdrawal symptoms on abrupt discontinuation. They create a feeling of relaxation and sleepiness but impair general functioning. Drugs in this category include barbiturates, nonbarbiturates, and alcohol. Barbiturates combined with alcohol produce a profound depressant effect. Flunitrazepam (Rohypnol), known as the "date rape drug," is a hypnotic drug abused by adolescents. Many women and men report being raped after unknowingly being given Rohypnol in a drink. Rohypnol is 10 times more powerful than diazepam (Valium). It produces prolonged sedation, a feeling of well-being, and short-term memory loss.

Central nervous system stimulants. Amphetamines and cocaine do not produce strong physical dependence and can be withdrawn without much danger. However, psychologic dependence is strong, and acute intoxication can lead to violent aggressive behavior or psychotic episodes characterized by paranoia, uncontrollable agitation, and restlessness. When combined with barbiturates, the euphoric effects are particularly addictive.

Methamphetamine can be snorted, injected, swallowed, or smoked and produces a burst of energy in its users, along with intense, alternating attacks of boldness and paranoia. It provokes excitement far more intense than that caused by cocaine. The drug, with the street names *crank, meth,* and *crystal,* is inexpensive and has a longer period of action than cocaine. Instead of a short (few minutes) high, as achieved with cocaine, a user can remain "up" for hours on a similar dose of crank.

Health care professionals are concerned about the use of various volatile substances, or **inhalants** such as gasoline, model cement, and organic solvents; these substances are inhaled by the user to achieve an altered sensation, and the most recent surveillance has indicated a modest increase in use after nearly a decade of decline. Adolescents breathe or place these substances in paper or plastic bags or soda cans from which they rebreathe the fumes to produce a feeling of euphoria and altered consciousness. These substances contain chemical solvents and are extremely hazardous. Dusters contain Freon, a substance that can cause fatal cardiac arrhythmias. Inhalants are the only substance that has a higher incidence of use among young adolescents. This is probably related to the fact that the products are readily available and may be the only substances available to young teens. Many young children are unaware of the dangers of "sniffing" or "huffing." In addition to rapid loss of consciousness and respiratory arrest, these substances may cause visual scanning problems, language deficiencies, motor instability, memory deficits, and attention and concentration problems.

Mind-altering drugs. Hallucinogens (psychedelics, psychotomimetics, psychotropics, or illusionogenics) are drugs that produce vivid hallucinations and euphoria. These drugs do not produce physical dependence, and they can be abruptly withdrawn without ill effect. However, the acute and long-term effects are variable, and in some individuals the dissociative behavior may be prolonged. Cannabis (marijuana, hashish) and lysergic acid diethylamide (LSD) are also included in this category of drugs.

Nursing Care Management and Therapeutic Management

Nurses who have contact with children and adolescents are in an excellent position to provide information about substance abuse and to serve as patient advocates. Nurses most often encounter young drug abusers when they are (1) experiencing overdose or withdrawal symptoms, (2) manifesting bizarre behavior or confusion secondary to drug ingestion, (3) worried that they are or will become addicted, or (4) worried about a friend or family member who is addicted.

Nurses who care for hospitalized adolescents need to know if these youths use drugs compulsively. Drug withdrawal can seriously complicate other illnesses. Nurses should be alert for any physical or behavioral clues that indicate the onset of withdrawal or the effects of drugs. School nurses and nurses who work in the community play an essential role in identifying children, adolescents, and families with substance abuse problems. The school nurse may be the first to identify a child or adolescent who has ingested a particular drug by the child's erratic behavior in class or on the school grounds. Early identification of those at risk for substance abuse problems is an essential aspect of prevention. Pediatric health care professionals also prevent substance abuse by creating trusting relationships so that children and adolescents feel comfortable asking questions about drugs, and health professionals can alert them to websites and other aspects of society that encourage experimentation with drugs.

Acute care. Adolescents experiencing toxic drug effects or withdrawal symptoms are usually seen initially in the emergency department. Experienced emergency department personnel are familiar with the management of acute drug toxicity and the signs, symptoms, and behavioral characteristics associated with a variety of substances. When the drug is questionable or unknown, knowledge of these factors facilitates management and treatment. Often observation or description of the child's or adolescent's behavior is more valuable than reports by patients or their friends.

The treatment for drug toxicity or withdrawal varies according to the drug and the method used. Every effort is made to determine the type, time of ingestion, amount of drug taken, mode of administration, and factors related to the onset of presenting symptoms. It is helpful to know the individual's pattern of use. For example, if two types of drugs are involved, they may require different treatments. Historically,

[h]800-COCAINE (800-262-2463).

gastric lavage has been used when the drug has been ingested recently and the cough reflex is intact, but it is of little value when the drug has been administered by the intravenous ("mainlined") or intranasal ("sniffed") route. More commonly, the administration of a drug antidote such as naloxone and the early (within 1 to 2 hours of ingestion) administration of activated charcoal may be used for opioid overdose. Because the actual content of most street drugs is highly questionable, other pharmaceutical agents are administered with caution, except perhaps the narcotic antagonists in cases of suspected opiate overdoses. It is also necessary to assess for possible trauma sustained while the patient was under the influence of the drug.

Long-term management. A major factor in the treatment and rehabilitation of young drug users is careful assessment in the nonacute stage to determine the function that the drug plays in the adolescent's life. The motivation phase is directed toward exploring the factors that influence drug use. It also involves establishing a feeling of self-worth and a commitment to self-help in the teen.

Rehabilitation begins when adolescents decide they can and are willing to change. **Rehabilitation** involves fostering healthy interdependent relationships with caring and supportive adults and exploring alternate mechanisms for problem solving, while simultaneously reducing or eliminating drug use. Persons working with troubled youth must be prepared for **recidivism**, or the tendency to relapse, and maintain a plan for reentry into the treatment process.

Family support. Most treatment programs for substance abusers are based on adult 12-step models, such as Alcoholics Anonymous. Research is needed to determine whether these adult models are effective for adolescents. Tough Love[i] is one program that is based on the conviction that parents have the right and responsibility to be the policymakers in the family, to set limits on the behavior of their children, and to take control of the household from out-of-control adolescents. The premise is that allowing teenagers to experience the negative consequences of their behavior will bring them closer to accepting help or changing their behavior. Another group that provides support and counseling for families experiencing substance abuse and seeking strategies to cope with their children is Parents Anonymous.[j] Another source of information is the Substance Abuse and Mental Health Services Administration's National Clearinghouse for Alcohol and Drug Information.[k]

Prevention. Nurses play an important role in education efforts, as well as in individual observation, assessment, and therapy related to substance abuse. In recent years, a variety of educational programs have been applied with promising results. The most effective prevention strategies are those that are part of a broader, more general effort to promote overall health and success. Health-compromising behaviors are often interconnected and have common antecedents. Prevention efforts that focus on changing only one behavior (e.g., alcohol, other drug use) are less likely to be successful. Successful programs are those that have promoted parenting skills, social skills among distractible children, academic achievement, and skills to resist peer pressure.

Peer pressure is a powerful tool and can be used effectively in substance abuse prevention. A group that has had some success in reducing injury from drunk driving is Students Against Destructive Decisions.[l] Techniques used by this group include peer counseling, parental guidelines for teenage parties, and community awareness. Nurses should encourage the formation of Students Against Destructive Decisions chapters in the high schools in their communities.

Suicide

Suicide is defined as the deliberate act of self-injury with the intent that the injury results in death. Most experts distinguish among suicidal ideation, suicide attempt (or parasuicide), and suicide.

Suicidal ideation involves a preoccupation with thoughts about committing suicide and may be a precursor to suicide. Although it is common for adolescents to experience occasional suicidal thoughts, expressions of preoccupation with suicide should be taken seriously, and an assessment should be conducted for appropriate referral. A **suicide attempt** is intended to cause injury or death. The term **parasuicide** is used to refer to behaviors ranging from gestures to serious attempts to kill oneself. *Parasuicide* is a preferred term because it makes no reference to intent and because a person's motive may be too difficult or complex to determine. However, all parasuicidal activity should be taken seriously.

! NURSING ALERT

A history of a previous suicide attempt is a serious indicator for possible suicide completion in the future. Studies of adolescent suicides have found that as many as half of the adolescents had made previous attempts.

Results from the Youth Risk Behavior Surveillance (2017) found that, in 2017, 31.5% of high school students had experienced periods of persistent feelings of sadness or hopelessness (i.e., almost every day for 2 or more consecutive weeks so that the student stopped doing some usual activities) in the past year. The percentage of students who experienced persistent feelings of sadness or hopelessness in the past year increased significantly from 2007 to 2017. That same report found that, in 2017, 17.2% of high school students had seriously considered attempting suicide in the past year. In 2017, 13.6% of high school students had made a suicide plan in the past year. In that same year, 7.4% of high school students had attempted suicide one or more times in the past year.

Suicide is currently the third leading cause of death during the teenage years, surpassed only by death from accidents (unintentional injuries and homicides; see Chapter 1).

Etiology

Environmental, psychologic, and biologic factors play a role in suicide (Cha, Franz, Guzmán, et al., 2017). Some of the environmental factors include a history of child maltreatment, victimization (bullying), and peer and media influence (Cha et al., 2017). Psychologic influences consist of affective issues of worthlessness and low self-esteem, cognitive factors such as impulsivity, and social processes of connectedness and loneliness (Cha et al., 2017). Biologic factors of suicide encompass neural responses, brain circuits, serotonin, and genetics (Cha et al., 2017). The single most important individual factor is the presence of an active psychiatric disorder (depression, bipolar disorder, psychosis, substance abuse, or conduct disorder). For some teenagers, suicide becomes the final pathway for release from their psychiatric and social problems. Child and adolescent suicide victims are reported to have higher rates not only of depression but also of conduct disorders; bipolar disorders; substance abuse; interpersonal problems with parents; and a family history of depression, substance abuse, and suicidal behavior.

Family factors influencing suicide include parental loss; family disruption; a family history of suicide, depression, substance abuse, or emotional disturbance; child abuse or neglect; unavailable parents; poor communication and isolation within the family; family conflict; and unrealistically high parental expectations or parental indifference with low expectations. Families who respect individuality are cohesive and caring, balance discipline with a supportive and understanding relationship, have good systems of communication, and have at least one attentive and caring parent available to the child to protect adolescents from suicidal outcomes. Social or environmental risk factors include incarceration, isolation, acute loss of a boyfriend or girlfriend, lack of future options, and availability of firearms in the home.

! NURSING ALERT

Given what is known about youth suicide, nurses should ask parents, especially those with at-risk teenagers, if firearms are available in the house and, if so, recommend their removal. Parents must ensure that their children—especially those who are depressed, have poor problem-solving skills, or use drugs or alcohol—do not have access to firearms. Parents must also be educated on the warning signs of suicide (Box 16.7).

Motivation

Suicidal ideation is common in adolescents. It represents numerous fantasies, such as relief from suffering, a means of gaining comfort and sympathy, or a means of revenge against those who have hurt them. Adolescents have the erroneous perception that the act of suicide will evoke remorse and pity and that they will be able to return and witness the grief. Angry children or adolescents who are unable to directly punish those who have injured or insulted them may take revenge on those who love them through self-destruction (e.g., "They'll be sorry when they find me dead." "They'll be sorry they were mean to me.").

BOX 16.7 Warning Signs of Suicide

- Preoccupation with themes of death—focuses on morbid thoughts
- Wants to give away cherished possessions
- Talks of own death, desire to die
- Loss of energy, loss of interest, listlessness
- Exhaustion without obvious cause
- Changes in sleep patterns—too much or too little
- Increased irritability, argumentativeness, or stubbornness
- Physical complaints—recurrent stomach aches, headaches
- Repeated visits to physician, nurse practitioner, or emergency department for treatment of injuries
- Reckless behavior
- Antisocial behavior—engages in drinking, uses drugs, fights, commits acts of vandalism, runs away from home, becomes sexually promiscuous
- Sudden change in school performance—lowered grades, cutting classes, dropping out of activities
- Resists or refuses to go to school
- Remains distant, sad, remote—flat affect, frozen facial expression
- Describes self as worthless
- Sudden cheerfulness following deep depression
- Social withdrawal from friends, activities, and interests that were previously enjoyed
- Impaired concentration
- Dramatic change in appetite

For adolescents who are severely depressed, suicide seems to be the only release from their despair. These adolescents rarely provide evidence of their intent and frequently conceal their suicidal thoughts. Many adolescents, however, tell peers of their suicidal thoughts or plans but avoid telling adults. Social isolation is a significant factor in distinguishing adolescents who will kill themselves from those who will not. It is also more characteristic of those who complete suicide than of those who make attempts or threats.

The frequency of **contagion**, or **copycat suicides** (i.e., an increase in youth suicide that occurs after the suicide of one teenager is publicized) is disturbing and may indicate that teenagers perceive suicide as glamorous. In addition, young people may not realize the finality of suicide because they have become desensitized from constantly viewing violence and death on television.

Diagnostic Evaluation

Depression is common among adolescents who attempt suicide. Depression is characterized by both subjective symptoms and objective signs that reflect the adolescent's sadness and despair. Adolescents describe feelings of sadness, despair, helplessness, hopelessness, boredom, loss of interest, and isolation. They may also feel self-reproach, self-deprecation, and guilt. Subjective symptoms of depression or specific changes in behavior place an adolescent at risk for suicide.

Therapeutic Management

Threats of suicide should always be taken seriously. There has been a tendency to dismiss suicide attempts as impulsive acts resulting from temporary crises or depression. If a suicide attempt fails to draw attention to his or her problems or makes them worse, the child or adolescent may conclude that suicide is the only answer. Children and adolescents need to know that someone cares and must be provided with swift and efficient crisis intervention. Although ordinary practitioners can manage an acute depressive reaction without difficulty, the adolescent who has made a serious attempt or has a specific plan for suicide should receive immediate attention and competent psychiatric care.

Youths who are actively suicidal need inpatient care, monitoring, and treatment. Medications for depression and bipolar disorder often take several weeks to reach therapeutic dosages. The time until medications and therapy begin to take effect can be trying for the adolescent and the family. It is important to encourage families to support their teen in adhering to the regimen prescribed. SSRIs are often prescribed for depression, but teens who are taking such medications need careful, frequent monitoring.

! NURSING ALERT

Adolescents who express suicidal feelings and have a specific plan should be monitored at all times. They should not have access to firearms, prescription or over-the-counter drugs, belts, scarves, shoestrings, sharp objects, matches, or lighters. If they are intoxicated, they must be restrained or placed in a protective environment until a psychiatrist or psychologist can assess them.

Nursing Care Management

Nurses play a pivotal role in reducing adolescent suicide. Nurses can provide anticipatory guidance to parents and adolescents. They can teach parents to be supportive and to develop positive communication patterns that help teens feel connected with and loved by their families. To foster healthy development, parents can be encouraged to provide teens with creative outlets and to assist young people in accepting strong emotions—pain, anger, and frustration—as a normal part of the human experience.

Care of suicidal adolescents includes early recognition, management, and prevention. The most important aspect of management is the recognition of warning signs that indicate that an adolescent is troubled and might attempt suicide. The nurse must take any suicidal remarks seriously and not leave the young person alone until the degree of suicidality is assessed. A mnemonic for the assessment process is **SLAP: S**pecificity, **L**ethality, **A**ccessibility, and **P**roximity. The first step (specificity) is to ask adolescents whether they feel suicidal or as though they would like to take their own lives. If so, have they chosen a means of suicide, and do they have a specific plan? The second stage of assessment (lethality) involves determining the lethality of the methods available to them. Do they plan to use a gun or knife? Have they chosen highly lethal medications, hanging, or carbon monoxide poisoning? The third stage (accessibility) involves determining the availability of the means of suicide, and the fourth stage (proximity) involves assessing whether they have determined a time to commit suicide and when that time is.

Health professionals must be alert to the signs of depression, and anyone who exhibits such behavior should be referred for thorough psychologic assessment. Depression is manifested differently in children and adolescents than in adults. In teenagers, it may be masked by impulsive aggressive behaviors. Defiance, disobedience, behavior problems, and psychosomatic disturbances can indicate underlying depression, suicidal ideation, and impending suicide attempts.

! NURSING ALERT

No threat of suicide should be ignored or challenged. Threats are a symptom that must be taken seriously. Too often, suicidal threats or minor attempts are confused with bids for attention. It is also a mistake to be lulled into a false sense of security when an adolescent's depression is apparently relieved. The improvement in attitude may mean that the adolescent has made the decision and found the means to carry out the threat.

Peers and other confidants are valuable observers and excellent sources of information about potential suicide attempts. They may not be able to diagnose depression, but they are able to sense when a friend has undergone a marked personality change. It is important to emphasize that the peer who detects any changes in a friend is a potential rescuer and should not remain silent about the observations. Friendship does not imply collusion. A peer who believes that a friend may be suicidal should alert someone who can help (e.g., a parent, teacher, guidance counselor, school nurse).

Routine health assessments of adolescents should include questions that assess the presence of suicidal ideation or intent. There are several assessment tools intended to assist clinicians in the identification and initial management of adolescents with depression in an era of great clinical need and shortage of mental health specialists. These tools cannot replace clinical judgment and are not meant to be the sole source of guidance for depression management in adolescents. Of the many tools available, the most relevant are in publications by Richardson and colleagues (2010), in which they validated the Patient Health Questionnaire–2 (PHQ-2) and the Patient Health Questionnaire–9 (PHQ-9).

Any previous suicide attempt indicates an increased risk for a future attempt. The risk of a suicide attempt in the near future increases as the frequency of suicidal ideation increases.

! NURSING ALERT

The National Suicide Prevention Lifeline (800-273-TALK [8255]; in Spanish, 888-628-9454) offers someone to talk to 24/7.

If children or adolescents express suicidal intent, nurses can make a contract, asking them to sign an agreement that they will not attempt suicide during an agreed-upon period and that they will call the 24-hour crisis line immediately if they feel that they cannot keep to their contract. The amount of time an adolescent feels comfortable contracting to is usually an indication of his or her risk and stability.

Because a suicide attempt is frequently an outgrowth of family distress, it is essential to intervene with the family. It is important to assess family interactions and to recognize disturbed relationships. The most effective approach is recognition of susceptible adolescents during the early stages of family distress so that family counseling can be started. Prevention must be directed toward improving childrearing practices through support and education of parents and changing societal conditions that generate defeat, despair, and maladaptive behavior.

Although confidentiality is an essential part of adolescent counseling, in the case of self-destructive behaviors, it cannot be honored. Suicidal behavior is reported to the family and other professionals, and adolescents are informed that this will be done. Such action conveys an important message to the youth: that the professionals understand and care.

Many schools have instituted suicide prevention programs. These programs include services such as drop-in counseling and a peer counseling telephone line. Information can also be obtained from the American Association of Suicidology.[m]

Adverse Childhood Experiences (ACEs)

From 1995 to 1997 Kaiser Permanente's Health Appraisal Clinic, in collaboration with the Centers for Disease Control and Prevention, implemented one of the largest studies ever conducted on the origins of risk factors that have negative health and social consequences and on the cumulative incidence and influence of psychologic and physical abuse. Risk factors included neglect, sexual abuse, witnessing violence, exposure to substance abuse, mental illness, suicidal behavior, and imprisonment of a family member. The impact of these risk factors on mental health (depression, suicidality), physical health (heart disease, cancer, chronic lung disease, skeletal fractures, liver disease, obesity), health-related behaviors (alcoholism, drug abuse, smoking, high numbers of sexual partners), and poor self-rated health were evaluated (Felitti, Anda, Nordenberg, et al., 1998). The recommendation from the 2012 American Academy of Pediatrics policy statement was to infuse a trauma-informed perspective into pediatrics, and this may be accomplished by introducing caregivers to adverse childhood experiences (ACEs).

An ACE questionnaire[n] (ACE-Q) was constructed using selected questions from published surveys (American Journal of Preventive Medicine, 2017). The findings showed that the more negative events a child experienced, the more likely that child would be to suffer an array of health and behavior problems, including alcoholism, chronic pulmonary disease, depression, illicit drug use, liver disease, and adolescent pregnancy, later in life.

By bringing attention to the powerful impact that negative childhood experiences have on future health and functioning, the ACE study demonstrates the importance of gathering information early in the lives of children and their families and designing early intervention programs that target violence and neglect. It also points to the importance of collecting trauma histories from clients.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A 14-year-old female with severe cystic acne is taking isotretinoin as treatment. She has been on the agent for the past 2 months. During the history assessment by the nurse, the following is noted. She has dry eyes and reports decreased night vision and headaches. She has had increased urination and vomiting the 24 hours. The mother reports that she is depressed and has frequent mood swings. **Highlight the assessment findings in the narrative above that are side-effects of isotretinoin that require follow-up by the nurse.**

2. A 13-year-old female patient visits the clinic for follow-up of a urinary tract infection. The nurse performs a history and physical assessment and notes the adolescent is extremely obese. She has gained considerable weight in the past year. Which of the following conditions listed below are associated with the development of obesity in adolescents and need to be explored further? **Select all that apply.**
   A. Physical inactivity
   B. Hereditary low metabolism
   C. Presence of a chronic illness
   D. Use of food as a positive reinforcer of desired behaviors
   E. Availability of energy-dense foods and drinks
   F. Positive self-esteem

3. A 15-year-old girl is being seen because she is in a relationship and wants to begin a contraceptive. She has had no previous sexual relationships and is healthy with no physical concerns based on her history and physical examination. What information would the nurse need to know to help this teenager make an informed decision about contraception? **Choose the most likely options for the missing information by selecting from the lists of options provided.**

Contraceptive Methods	Advantages	Disadvantages
Withdrawal	No medical visit necessary	High failure rate from noncompliance
Condom	**2**	May decrease sensation, requires consistent use
Spermicidal Foam	Available without a prescription	**3**
1	99% effective is used correctly	Need to follow precise instructions
Diaphragm	Can be fitted in virgins, may be reused	**4**

Option 1	Option 2	Option 3	Option 4
Abstinence	>99% effective	Irregular menstrual bleeding	Not recommended for women >90 kg
Calendar methods	Regulates menses	Latex sensitivity may occur	Risk of perforation
Oral contraceptives	Prevents ovarian cancers	High failure rate unless combined with condom	May cause headaches
Progestin	Easy to use, minimal side effects	May cause nausea	May cause dysmenorrhea
Cervical Cap	Prevents endometriosis	May cause vaginitis	Requires fitting by medical personnel, minimal STI protection

4. A 15-year-old girl visits the clinic with fever, chills, abdominal pain that is dull, cramping and at times incapacitating. She is sexually active and reports vaginal discharge in the past few days. In caring for this adolescent what is **most important** for the nurses to know about sexually transmitted infections? **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**
   _____1_____ is the most frequently reported infectious disease in the United States and is often difficult to diagnose because symptoms may be nonspecific. _____2_____ presents with warts found on any part of the female genitalia. _____3_____can present with discharge, dysuria and dyspareunia and is the oldest communicable disease in the United States.

Option 1	Option 2	Option 3
Neisseria gonorrhoeae	*Neisseria gonorrhoeae*	*Neisseria gonorrhoeae*
Chlamydia trachomatis	*Chlamydia trachomatis*	*Chlamydia trachomatis*
Treponema pallidum	*Treponema pallidum*	*Treponema pallidum*
Human papillomavirus (HPV)	Human papillomavirus (HPV)	Human papillomavirus (HPV)
Trichomonas vaginalis	Trichomonas vaginalis	Trichomonas vaginalis

Impact of Chronic Illness, Disability, or End-of-Life Care on the Child and Family

Joy Hesselgrave, Gina Santucci

http://evolve.elsevier.com/wong/essentials

CONCEPTS

- Chronic Illness
- Palliative Care

PERSPECTIVES ON THE CARE OF CHILDREN AND FAMILIES LIVING WITH OR DYING FROM CHRONIC OR COMPLEX CONDITIONS

SCOPE OF THE PROBLEM

A complex chronic condition (CCC) can be defined as any medical condition that persists for more than a year and affects several organ systems or one system critically enough that additional specialty expertise is crucial (Feudtner, Feinstein, Zhong, et al., 2014). With innovations in medical technology, we are seeing a decrease in the mortality of children living with CCCs. These children are living longer, often beyond the age that can be cared for at a pediatric tertiary care center. Many are being discharged to home with sophisticated technology, complex plans of care, and burdensome medication schedules. Transitioning children with medical complexity from hospital to home has some inherent challenges, including determining parent readiness (Leyenaar, O'Brien, Leslie, et al., 2017) and the likelihood of readmission (Bucholz, Toomey, & Schuster, 2019). Advances in neonatology and other subspecialties have increased the viability of premature infants or those who have a congenital or genetic anomaly. Life-sustaining technology that was once available only in a tertiary care center has been adapted for home use, allowing children with complex conditions a chance of living in their community. Families, home care agencies, and schools are being taught how to care for children with increasing technology, complicated treatments, and demanding medication schedules (Feudtner, Dai, & Hexem, 2012). It is not uncommon for a medically fragile child with complex needs to have one or more life-sustaining technologies (e.g., tracheostomy, ventilator, gastrostomy, ventricular peritoneal shunt, parental nutrition), which has increased that child's survival rate (Burke & Alverson, 2010; Elias, Murphy, & Council on Children With Disabilities, 2012; Simon, Berry, Feudtner, et al., 2010).

Children with complex conditions require not only multiple medical specialists, but also nurses and therapists (respiratory, physical, occupational, rehabilitative, and speech) with advanced training and expertise who can support their care in the community (Kuo & Houtrow, 2016). The complex high level of skill required to meet their daily health care needs and the continuous nature and potential volatility of their conditions sets this group apart from the broader population of children with special health care needs (Cohen, Kuo, Agrawal, et al., 2011; Kuo, Cohen, Agrawal, et al., 2011; Simon et al., 2010). A range of terms, such as *complex chronic condition, medically complex, technology dependent,* and *multiply handicapped,* have been used to describe this vulnerable population of children (Cohen et al., 2011; Feudtner et al., 2014). Children with complex and chronic conditions are a diverse group, but they share some common characteristics, including high health care use, caregiver burden, and social isolation (Barnert, Coller, Nelso, et al., 2017). Frequent and prolonged hospitalizations, reliance on technology, and care that traverses all settings are key characteristics that differentiate these children from others (Berry, Hall, Hall, et al., 2013; Cohen et al., 2011; Feudtner et al., 2014).

The nature and severity of childhood chronic and complex conditions are widely heterogeneous. Table 17.1 includes a nonexhaustive sampling of conditions, organized by specialty. However, affected children and families are similar in the vulnerability they experience due to the health and developmental consequences of these diagnoses on the child, such as ongoing functional impairment, neurodevelopmental disability, dependence on medical technology, and the need for ongoing skilled and supportive care from health care providers and family members. Although many authors have described the rise in prevalence that has come with advances in medical care (American Academy of Pediatrics, 2019; Simon et al., 2010), accurate estimates of the number of affected families do not exist. The impact of chronic and complex illness in children is wide ranging. Parents report experiencing grief and loss of

TABLE 17.1 Chronic Conditions of Childhood

Specialty	Examples of Chronic Conditions
Cardiology	Complex congenital heart disease, congestive heart failure, cardiac dysrhythmias, Kawasaki disease, rheumatic fever, hyperlipidemia, hypertrophic cardiomyopathy, dilated cardiomyopathy
Endocrinology	Diabetes, congenital adrenal hyperplasia, Cushing syndrome, Turner syndrome
Gastroenterology	Short bowel syndrome, biliary atresia, inflammatory bowel disease, hepatitis, cirrhosis, peptic ulcer disease, celiac disease
Hematology	Sickle cell anemia, thalassemia, aplastic anemia, hereditary anemias, hemophilia
Immunology	Immune deficiency, human immunodeficiency virus, Wiskott-Aldrich syndrome, severe combined immunodeficiency disease
Nephrology	Prune belly syndrome, renal disease
Neurology	Cerebral palsy, ataxia telangiectasia, muscular dystrophy, epilepsy, spina bifida, traumatic brain injury, hydrocephalus, adrenal leukodystrophy, Chiari malformations
Oncology	Brain tumor, leukemia, lymphoma, solid tumors, bone tumors, rare tumors
Pulmonology	Asthma, chronic lung disease, cystic fibrosis, tuberculosis, pulmonary hypertension
Rheumatology	Systemic lupus erythematosus, juvenile rheumatoid arthritis, dermatomyositis

identity once a diagnosis is made; initial feelings of sorrow and self-blame have been reported along with being both physically and emotionally exhausted (Smith, Cheater, & Bekker, 2015). Health care providers have also reported challenges in caring for children with CCCs, including the complexity of care coordination, managing technology, and the persistent and all-encompassing psychosocial needs of the family (Bogetz, Bogetz, Rassbach, et al., 2015). The challenges the family experiences fluctuate with the needs of the child and have been described at times as both frustrating and rewarding and likened to a "roller-coaster ride" with highs and lows (Goudie, Narcisse, Hall, et al., 2014; Kuo et al., 2011; Nurullah, 2013; Smith, Cheater, & Bekker, 2013). Children with CCCs may be at increased risk for behavior or emotional problems. Children lose school days and parents may lose days from work, which compound feelings of physical, emotional, and financial exhaustion.

Many children with CCCs are living at home, and parents are tasked with their care. Even though many children qualify for home nursing, the reality is that parents must assume readiness at any time when nursing is not available (Nageswaran & Golden, 2017).

Siblings are also affected by having a "different" brother or sister, and they may simultaneously feel guilt, anger, or jealousy toward their ill sibling. Clinicians need to know that siblings of children with chronic illnesses are at risk for negative psychologic effects (Hartling, Milne, Tjosvold, et al., 2014). Parents need encouragement and assistance with understanding the reactions of siblings to having a chronically ill family member (e.g., behavioral regression, anxiety, withdrawal, apathy). In addition, secondary losses (such as the ability to participate in extracurricular activities or social events) occur because of routines imposed by the affected child's chronic condition.

TRENDS IN CARE

Developmental Focus

Focusing on the child's developmental level rather than chronologic age or diagnosis emphasizes the child's abilities and strengths rather than their disabilities. Attention is directed to normalizing experiences, adapting the environment, and promoting coping skills. Nurses often are in vital positions to redirect attention from the pathologic model, with its focus on weaknesses and problems, to the developmental model to meet the unique needs of the child and family.

A developmental focus also considers family development. The life cycle of the family unit reflects changing ages and needs of family members, as well as changing external demands. A family member's serious illness can cause significant stress or crisis at any stage of the family life cycle. Just as with individual development, family development may be interrupted or even regress to an earlier level of functioning. Nurses can use the concept of family development to plan meaningful interventions and evaluate care.

Family-Centered Care

Family-centered care is a method of care delivery and a philosophy of care that values the integral role the family plays in the health and well-being of their child (Smith, Swallow, & Coyne, 2015).

Having a child with a chronic condition can be an added source of stress for the family unit, putting additional strain on how a family functions, their cohesiveness, and the family members' relationships with each other (Herzer, Godiwala, Hommel, et al., 2010). A child's physical and emotional health, as well as his or her cognitive and social functioning, is strongly influenced by how well the family functions (Kuhlthau, Bloom, Van Cleave, et al., 2011; Treyvaud, 2014). The importance of family-centered care—a philosophy that considers the family as the constant in the child's life—is especially evident in the care of children with special needs. As parents learn about the child's health care needs, they often become experts in delivering care. Nurses and other health care providers are key to the success of family-centered care and the need to form partnerships with the child's parent and/or caregiver (Coats, Bourget, Starks, et al., 2018). Effective communication and negotiation between parents and nurses are essential to forming trusting and effective partnerships and finding the best ways to meet the needs of the child and family (Corlett & Twycross, 2006; Kuo, Houtrow, Arango, et al., 2012). Collaborative relationships are characterized by communication, dialogue, active listening, awareness, and acceptance of others' differences (Kuhlthau et al., 2011).

Family and Health Care Provider Communication

The disclosure of a serious chronic or complex condition of a child is one of the most stressful aspects of communication between families and health care professionals. Health care providers often struggle with minimizing parental distress and maintaining hope when giving prognostic information, but some parents have reported that honest, clear information can promote hope by clarifying uncertainty. Similarly, being overly optimistic or withholding information was felt to undercut hope (Nyborn, Olcese, Nickerson, et al., 2016). After a diagnosis is made, factors that influence parent dissatisfaction with the way in which information is communicated include disrespectful attitudes, breaking bad news in an insensitive manner, withholding information, and changing a treatment course without preparing the child and family (Barnes, Gardiner,

Gott, et al., 2012). Conversely, parents report satisfaction when they perceive health care providers to be available, demonstrate competence, and engage the child and parent in care decision making. Parents report wanting regular, coordinated team updates on their child's condition (Barnes et al., 2012; Hill, Knafl, & Santacroce, 2017; Kuo, Sisterhen, Sigrest, et al., 2012). Similar factors are important in communicating changes in the child's condition throughout the course of the illness.

Providing information to families with a chronically ill child should be a practice of repeated discussions to allow the family time to process the information. Nurses play an important role in ensuring that families' needs are met during discussions related to the child's diagnosis, condition, and treatment (Kavanaugh, Moro, & Savage, 2010). This requires assessment of how families want to receive information, how much information they are comfortable with, their comprehension of the information given to them, and how they are coping with the information both cognitively and emotionally. Nurses should ensure that the appropriate health care professionals address any concerns or further questions that families may have.

Establishing Therapeutic Relationships

Another important aspect of family-centered care of children with chronic and complex conditions is establishing a therapeutic relationship with the child and family, which has been shown to predict improved health-related outcomes (Kuhlthau et al., 2011). Family members, most often the mother, take on enormous responsibility in providing technical care and symptom management of their child's condition outside of the health care institution (Goudie et al., 2014; Smith et al., 2015). To build successful therapeutic relationships with families, it is necessary for nurses to recognize parents' expertise with regard to their child's condition and needs. Health care environments for children with serious illnesses are fraught with obstacles that serve as barriers to successful therapeutic relationships with families. Individual discussions, especially with the case manager, primary nurse, clinical nurse specialist, or nurse practitioner, help establish a consistent and flexible care plan that can prevent conflicts or deal with these conflicts before they disrupt care.

The Role of Culture in Family-Centered Care

Issues of culture, ethnicity, and race affect access to services, health care use, and follow-through with referrals and recommendations (Coker, Rodriguez, & Flores, 2010; Toomey, Chien, Elliott, et al., 2013). For some ethnic and minority populations, cultural understandings of illness, the structure of family life, social roles for individuals with disabilities, and other factors related to the perception of children may differ from those of mainstream American culture.

Although culture cannot completely explain how an individual will think and act, understanding cultural perspectives can help the nurse anticipate and understand why families may make certain decisions. Cultural attributes such as values and beliefs regarding illness or chronic condition and its causation, social roles for people who are ill or disabled, family structure, the role of children, childrearing practices, self versus group orientation, spirituality, and time orientation also affect a family's response to illness or chronic condition in a child (Wiener, McConnell, Latella, et al., 2013).

When parents are informed of their child's chronic illness, interpreters familiar with both culture and language should be used. Children, family members, and friends of the family should not be used as translators because their presence may prevent parents from openly discussing issues. When working with people of cultural backgrounds different from their own, nurses must listen carefully with an initial goal of understanding and articulating the family's perspective. The ability to interpret the mainstream medical culture to the family is also important. Furthermore, every effort is made to incorporate traditional cultural beliefs of a family into treatment plans. It is important to keep in mind that "cultural norms" may not always apply to every family from a shared background. Developing a care plan in conjunction with the family, considering their preferences and priorities, is an important first step in formulating a plan that best meets the family's needs, no matter what their cultural background may be (Coker et al., 2010; Wiener et al., 2013).

BOX 17.1 Facilitating Shared Decision Making

- Continually assess the impact of the child's illness and treatment on the family.
- Provide honest, accurate information on the trajectory of the disease, anticipated complications, and prognostic information.
- Discuss what the family desires for the child's quality of life.
- Avoid personal opinion or judgment of the family's questions and decisions.
- Be aware of nurses' personal and cultural assumptions and the ways in which these assumptions affect communication, decision making, and judgment.

Shared Decision Making

Shared decision making refers to a model of care in which health care providers and patients share information on treatments and interventions, discuss risks and benefits based on clinical evidence and best practices, and take into account patient preferences and values (Elwyn, Frosch, Thomson, et al., 2012; National Learning Consortium, 2013).

Shared decision making among the child, family, and health care team can result from open, honest, culturally sensitive communication and the establishment of a therapeutic relationship among the family and health care providers. In a shared decision-making model, the health care professionals provide honest, clear information on diagnosis, prognosis, treatment options, and risk–benefit assessment. The patient and family then share information on important family values, acceptable levels of discomfort or inconvenience, and the ability to comply with recommended treatments (Wiener et al., 2013; Wyatt, List, Brinkman, et al., 2015). This process allows for the careful examination of options and consideration of the impact on the child and family. To promote shared decision-making the risks and benefits to the child and family, prognosis or expected course of the illness, and the impact on the family's resources should be discussed (Box 17.1). Together, the parents and health care team can make decisions that are best for the family and child at the time the decision is made (Kon, 2010).

Normalization and Transition

Normalization refers to the effort family members make to create a normal family life, their perceptions of the consequences of these efforts, and the meanings they attribute to their management efforts (Knafl, Darney, Gallo, et al., 2010). For chronically ill children, such efforts may include attending school, pursuing hobbies and recreational interests, and achieving employment and a level of independence. For their families, it may entail adapting the family routine to accommodate the ill or disabled child's health and physical needs (Kuo et al., 2011).

Transition is a term often used when a child's care is transferred to adult care services. However, it is also used to convey the discharge from an acute or chronic care facility to home for children with complex health care needs (Brenner, Larkin, Hilliard, et al., 2015).

Children with chronic and complex conditions and their families face numerous challenges in achieving normalization and transitioning care. Families move between the "normal" of living with the experience of chronic childhood illness and the "normal" of the healthy outside world; they often redefine "normal" based on their particular experiences, needs, and circumstances (Knafl et al., 2010).

Normalization may be an important mediator of illness-related stressors (e.g., treatment demands, uncertainty) on family outcomes.

Nurses can assist families in normalizing their lives by assessing the family's everyday life, social support systems, coping strategies, family cohesiveness, and family and community resources. Interventions include encouraging families to reduce stress through delegation of care and family tasks, identifying ways to incorporate care into current routines, structuring the home environment to encourage the child's engagement in age-appropriate activities, and ensuring that families have access to appropriate community support services (Knafl & Santacroce, 2010). Being supportive of the child's illness and treatment and actively including the family in all aspects of care will improve their self-esteem and promote further development (Jones & Prinz, 2005; Knafl & Santacroce, 2010).

Home care represents the return to a system and set of priorities in which family values are as important in the care of a child with a chronic health problem as they are in the care of other children. Home care seeks to achieve goals that are consistent with the developmental model (Stein, 1985):

- Normalize the life of the child, including those with technologically complex care, in a family and community context and setting.
- Minimize the disruptive impact of the child's condition on the family.
- Foster the child's maximum growth and development.

With appropriate training and support, families provide complex procedures and treatments in the home. Parents are challenged to retain a homelike setting among monitors, ventilators, and other sophisticated equipment. Throughout the text, home care is discussed as appropriate for specific conditions. The process of transition from hospital to home is elaborated on in Chapters 19 and 20.

Paralleling normalization and home care is the process of **mainstreaming**, or integrating children with disabilities into regular classrooms. Children who attend school have the advantages of learning and socializing with a wide group of peers. There is an increased focus on individualization as plans are made to meet the academic needs of these children along with those of the rest of the students.

A variety of supplemental programs have been designed in the school system to accommodate special needs, both at school age and younger, through **early intervention**, which consists of any sustained and systematic effort to assist developmentally vulnerable or disabled children from birth to 3 years old. Increased opportunities for normalization for children with disabilities have resulted in large part from the passage of (1) the Education for All Handicapped Children Act of 1975 (Public Law 94-142) and its 1990 amendments (Public Law 101-476), which changed the name of the Act to the Individuals with Disabilities Education Act (IDEA); (2) the Education of the Handicapped Act Amendments of 1986 (Public Law 99-457), which directs states to develop and implement statewide comprehensive, coordinated, interprofessional interagency programs of early intervention services for infants and toddlers with disabilities, as well as support services for their families; and (3) the Americans with Disabilities Act of 1990. Nurses can provide parents with information about these laws and in some cases may participate in the development of individualized educational programs (IEPs) or individualized family service plans (IFSPs) for children with disabilities.

THE FAMILY OF THE CHILD WITH A CHRONIC OR COMPLEX CONDITION

A major goal in working with the family of a child with a chronic or complex illness is to support the family's coping and promote their optimal functioning throughout the child's life. Long-term, comprehensive care involves forming parent-professional partnerships that can support a family's adaptation across the trajectory of the illness to the many changes that may be necessary in day-to-day life, determine expectations of and for the child, and provide a long-term perspective (Box 17.2).

BOX 17.2 Adaptive Tasks of Parents Having Children With Chronic Conditions

1. Accept the child's condition.
2. Manage the child's condition on a day-to-day basis.
3. Meet the child's normal developmental needs.
4. Meet the developmental needs of other family members.
5. Cope with ongoing stress and periodic crises.
6. Assist family members to manage their feelings.
7. Educate others about the child's condition.
8. Establish a support system.

From Canam, C. (1993). Common adaptive tasks facing parents of children with chronic conditions. *Journal of Advanced Nursing, 18,* 46–53.

Often the impact of a child's medical or developmental condition is first experienced as a crisis at the time of diagnosis, which may occur at birth, after a long period of diagnostic testing, or immediately after a tragic injury. However, the impact may also be felt before the diagnosis is made, when parents are aware that something is wrong with their child but before medical confirmation (Smaldone & Ritholz, 2011).

The diagnosis and initial discharge home are critical times for parents (Coffey, 2006). Several factors can make this particularly difficult, including a long duration of uncertainty in the diagnostic process, negative perceptions of chronic illness, insufficient information, and lack of mutual trust between parents and their child's health care team (Huang, Kenzik, Sanjeev, et al., 2010; LeGrow, Hodnett, Stremler, et al., 2014; Monterosso, Kristjanson, Aoun, et al., 2007; Nuutila & Salanterä, 2006). Parental feelings of shock, helplessness, isolation, fear, and depression are common (Coffey, 2006; Nuutila & Salanterä, 2006). Throughout the first year, parents struggle to accept the child's diagnosis, care, and uncertainty of the future (Coffey, 2006). Optimal support at the time of diagnosis and initial discharge home can be encouraged by providing explicit and uncomplicated information to parents in an empathic way (Nuutila & Salanterä, 2006); assessing the family's daily routine, living conditions, background knowledge, skills and abilities, and coping behaviors; and evaluating the family's understanding of the information. It is also necessary to reassess parents' needs for information and support on a routine basis (Nuutila & Salanterä, 2006).

Other critical times include the exacerbation of the child's physical symptoms, which increases parental care. These crises often involve medical intervention and rehospitalization. Frequently the child does not return to his or her precrisis level of functioning, and parents and family must adapt to new care needs and schedules. Instability may also follow transition points on the illness trajectory. Supporting parents, respecting their stress and emotions, and acknowledging their role as team members in the care of their child are important aspects of nursing care (Coffey, 2006; Nuutila & Salanterä, 2006; Panicker, 2013).

IMPACT OF THE CHILD'S CHRONIC ILLNESS

Each member in the family of a child with a chronic or complex illness is affected by the experience (Goudie et al., 2014; Kuo et al., 2011). The effects on the parents and their responses may be so intense that they directly influence the other members' reactions and the child's own coping.

BOX 17.3 Anticipated Parental Stress Points

Diagnosis of the condition: Parents require considerable education while dealing with an emotional response.
Developmental milestones: Times that children normally achieve walking, talking, and self-care are delayed or impossible for the child.
Start of schooling: Particularly stressful are situations in which appropriate schooling will not be in a regular class placement.
Reaching the ultimate attainment: Parents must handle situations such as realizing that ambulation will be impossible or that the child will not learn to read.
Adolescence: Issues such as sexuality and independence become prominent.
Future placement: Decisions about placement must be made when the child becomes an adult or when the parents can no longer care for the child.
Death of the child

Parents

In addition to the stress of grieving for the loss of hope for a perfect child, parents are affected by whether they receive positive feedback from interactions with their child. Many parents feel satisfaction and fulfillment from the parenting role. For others, parenting may be a series of unrewarding experiences that contribute to feelings of inadequacy and failure (Box 17.3). These responses may be most evident in parents who are responsible for the child's care. For example, parents may become preoccupied with their ability to carry out certain procedures, overlooking the child's personal comfort and satisfaction or failing to offer praise for anything less than perfect cooperation or performance. They may pursue a frustrating activity until they achieve "success"—long after the child has become irritable and uncooperative. As a result, parents can become caught in a pattern of interaction that is mutually unrewarding and minimally productive. This situation may become exacerbated by disagreements or lack of support from other family members and judgment from caregivers and others in the community. For these parents, several strategies may be helpful, including education about what can reasonably be expected of their child, assistance in identifying the child's strengths, praise for a parental job well done, and respite care so that parents can renew their energies.

Parental Roles

Parenting a child with a CCC requires attending to the routine aspects of parenting with the added responsibilities of performing complex technical care, symptom management, and advocating for their child (Morawska, Calam, & Fraser, 2015; Woodgate, Edwards, Ripat, et al., 2015). These added responsibilities must then be balanced with the needs of other family members, extended family and friends, and personal health and obligations to minimize consequences to the overall functioning of the family (Cousino & Hazen, 2013; Pinquart, 2018). Measures to help decrease the stress of parenting a child with a CCC include providing mental health support and teaching parents how to deal with stressors.

Often one parent or partner remains at home to manage existing family responsibilities while the other remains with the ill child. The partner who is not included in the caregiving activities may feel neglected because all of the attention is directed toward the child and may be resentful that he or she is not sufficiently informed to be competent in the care. Without active participation in the child's care, the parent has little appreciation of the time and energy involved in performing care activities. When this partner does attempt to participate, the other parent may criticize the less skillful efforts. As a result, communication and support for each other may be adversely affected.

The nurse can assist parents in avoiding role conflicts by providing anticipatory guidance early on. Teaching should address stressors often identified as having an impact on the marriage, including (1) the burden of care at home assumed by primarily one parent, (2) the financial burden, (3) the fear of the child dying, (4) pressure from relatives, (5) the hereditary nature of the disease (if applicable), and (6) fear of pregnancy. Other causes of tension may center on the inconveniences associated with care, such as long waits for an appointment, lack of parking near care facilities, or lack of overnight accommodations.

Mother-Father Differences

Mothers and fathers of a child with a complex condition often adjust and cope differently. Mothers are often the primary caregiver and are more likely than fathers to give up their jobs to care for their children, often resulting in social isolation (Coffey, 2006). Mothers often have greater needs for social support and positive appraisal of the situation than do fathers.

Fathers of children with disabilities struggle with issues that may be distinct from those of the mothers (Swallow, Macfadyen, Santacroce, et al., 2012). Fathers may think that their role as protector is challenged, because they do not know how to help and cannot protect their family from the seemingly overwhelming recurring problems. The extensive stresses in the family can leave fathers feeling depressed, weak, guilty, powerless, isolated, embarrassed, and angry. Fearful that they will lose control or be viewed as weak or ineffectual, however, fathers often hide their feelings and display an outward confidence that may lead others to believe that everything is fine. Fathers worry about what the future holds for their children, their ability to manage the increasing financial burden, and the daily disruptions of the entire family (Nicholas, Beune, Barrera, et al., 2016; Swallow et al., 2012).

Single-Parent Families

Single-parent families are of special concern. As the only parent of a child who may require extensive, sophisticated, and lifelong care, the single parent may feel an enormous burden. Available financial and emotional resources may already be stretched to the limit. A special effort should be made to assist the single parent in finding financial and support services that can ease the burden of care. Nurses can also assist the single parent in identifying helping roles that may be acceptable to relatives and friends.

Siblings

Results of studies are less clear regarding the ways in which siblings are affected by having a brother or sister with a complex condition (Anderson & Davis, 2011; Hartling et al., 2014). Some evidence shows a negative effect on siblings of children with chronic illnesses compared with siblings of healthy children (Gold, Treadwell, Weissman, et al., 2011; Hartling et al., 2014). Siblings of children with chronic illnesses report psychosocial problems more often than their peers (Gold et al., 2011). A number of factors increase the risk of negative effects for siblings of ill children. Responsibility for caregiving, less attention from parents, and limitations on family resources and recreational time are often the experiences of siblings of ill or disabled children (Barr & McLeod, 2010) (Box 17.4). Siblings may experience a decrease in school attendance and academic functioning, which may be somewhat ameliorated by the support of teachers and peers (Gan, Lum, Wakefield, et al., 2017). An important factor in sibling adjustment and coping is information and knowledge regarding the

BOX 17.4 Supporting Siblings of Children With Special Needs

Promote Healthy Sibling Relationships

Value each child individually and avoid comparisons. Remind each child of his or her positive qualities and contribution to other family members.

Help siblings see the differences and similarities between themselves and the child with special needs. Create a climate in which children can achieve successes without feeling guilty.

Teach siblings ways to interact with the child.

Seek to be fair in terms of discipline, attention, and resources; require the affected child to do as much for himself or herself as possible.

Let siblings settle their own differences; intervene only to prevent siblings from hurting one another.

Legitimize reasonable anger. Even children with special needs behave badly sometimes.

Respect a sibling's reluctance to be with or to include the child with special needs in activities.

Help Siblings Cope

Listen to siblings to let them know that their thoughts and suggestions are valued.

Praise siblings when they have been patient, have sacrificed, or have been particularly helpful. Do not expect siblings to always act in this manner.

Acknowledge the personal strengths that siblings have and their ability to cope with stress successfully.

Provide age-appropriate information about the child's condition and update it when appropriate.

Let teachers know what is happening so that they can be understanding and helpful.

Recognize special stress times for siblings and plan to minimize negative effects.

Schedule special time with siblings; have a friend or family member substitute when parent is unavailable.

Encourage siblings to join or help establish a sibling support group.

Use the services of professionals when needed. If parent feels that such a service is necessary, it should be provided in as vigorous a manner as a service for the child with special needs.

Involve Siblings

Seek out ways to realistically include siblings in the care and treatment of the child with special needs.

Limit caregiving responsibilities and give recognition when siblings perform them.

Develop a library of children's books on special needs.

Invite siblings to attend meetings to develop plans for the child with special needs (e.g., individualized educational program [IEP], individualized family service plan [IFSP]).

Discuss future plans with them.

Solicit their ideas on treatment and service needs.

Have them visit professionals who work with the child.

Help them develop competencies to teach the child new skills.

Provide opportunities for siblings to advocate for the child.

Allow siblings to set their own pace for learning and involvement.

Data from Powell, T., & Ogle, P. (1985). *Brothers and sisters—A special part of exceptional families.* Baltimore, MD: Paul H. Brooks; Spokane Washington Deaconess Medical Center, Pediatric Oncology Unit. (1987); Carlson, J., Leviton, A., & Mueller, M. (1993). Services to siblings: An important component of family-centered practice. *ACCH Advocate, 1*(1), 53–56.

brother's or sister's illness or complex condition. What siblings piece together or overhear is often much worse than the truth. Often they imagine gruesome things regarding the experiences related to the illness, treatment, and hospitalization (Knafl & Santacroce, 2010). Hispanic siblings have reported less accurate information about their siblings' condition than non-Hispanic siblings (Lobato, Kao, & Plante, 2005). Parents are usually in the best position to impart information, although they are often overwhelmed by the medical crisis at hand (Fleitas, 2000). Nurses can encourage parents to talk with the siblings about how they perceive their sick brother or sister, and to be accepting of the siblings' feelings. Nurses can be ideal educators and counselors of siblings during the course of their brother's or sister's illness.

COPING WITH ONGOING STRESS AND PERIODIC CRISES

Professionals can help families cope with stress by providing anticipatory guidance, providing emotional support, assisting the family in assessing and identifying specific stressors, aiding the family in developing coping mechanisms and problem-solving strategies, and working collaboratively with parents so that they become empowered in the process (Anderson & Davis, 2011).

Concurrent Stresses Within the Family

The ability to deal with the overwhelming stress of a chronic illness is challenged further when additional stresses are present. Stressors may be situational or developmental. They may be related to marital difficulties, sibling needs, homelessness, or social isolation. Some families may simultaneously be struggling with a family member's alcohol or other drug problem. Even relatively minor stressors, such as arranging care for siblings, managing the home, and traveling to distant treatment centers, can challenge a family's ability to cope successfully.

Most families, regardless of their income or insurance coverage, have financial concerns. The costs of caring for a child with a complex illness can be overwhelming. Nurses and social workers can help a family review various options for financial assistance, including insurance, managed care, or health maintenance organization policies; Medicaid; Supplemental Security Income; Women, Infants, and Children program; the state Program for Children with Special Health Needs; disease-related associations; and local philanthropic organizations.

Coping Mechanisms

Coping mechanisms are behaviors aimed at reducing the tension caused by a crisis. **Approach behaviors** are coping mechanisms that result in movement toward adjustment and resolution of the crisis. **Avoidance behaviors** result in movement away from adjustment and represent maladaptation to the crisis. Several approach and avoidance behaviors used in coping with a chronic illness are listed in the Nursing Care Guidelines box. Each behavior must be viewed in the context of all of the variables affecting the family. For example, the observation of several avoidance behaviors in an emotionally healthy family may denote significantly less risk to the successful resolution of the crisis than an equal number of avoidance behaviors in an individual who has few available supports.

NURSING CARE GUIDELINES

Assessing Coping Behaviors

Approach Behaviors

Asks for information on diagnosis and child's present condition
Seeks help and support from others
Anticipates future problems; actively seeks guidance and answers
Endows the chronic illness or complex condition with meaning
Shares burden of disorder with others
Plans realistically for the future
Acknowledges and accepts child's awareness of diagnosis and prognosis
Expresses feelings (such as sorrow, depression, and anger) and realizes reason for the emotional reaction
Realistically perceives child's condition; adjusts to changes
Recognizes own growth through passage of time, such as earlier denial and nonacceptance of diagnosis
Verbalizes possible loss of child

Avoidance Behaviors

Fails to recognize seriousness of child's condition despite physical evidence
Refuses to agree to treatment
Intellectualizes about the illness but in areas unrelated to child's condition
Is angry and hostile to members of the staff regardless of their attitude or behavior
Avoids staff, family members, or child
Entertains unrealistic future plans for child with little emphasis on the present
Is unable to adjust to or accept a change in progression of disease
Continually looks for new cures with no perspective toward possible benefit
Refuses to acknowledge child's understanding of disease and prognosis
Uses magical thinking and fantasy; may seek "occult" help
Places complete faith in religion to point of relinquishing own responsibility
Withdraws from outside world; refuses help
Punishes self because of guilt and blame
Makes no change in lifestyle to meet needs of other family members
Resorts to excessive use of alcohol or drugs to avoid problems
Verbalizes suicidal intents
Is unable to discuss possible loss of child or previous experiences with death

Parental Empowerment

Empowerment can be seen as a process of recognizing, promoting, and enhancing competence. For parents of children with chronic conditions, empowerment may occur gradually as strength and capabilities are drawn on to master the child's care, manage family life, and plan for the future. Advocating for the child and developing parent-professional partnerships are part of taking charge (Panicker, 2013).

ASSISTING FAMILY MEMBERS IN MANAGING THEIR FEELINGS

Although some previous research has postulated stages of adaptation to a chronic illness, there is a great deal of individual variation in responses to the diagnosis, adjustments made, and time frames for coming to terms with a diagnosis. It is important that professionals recognize and respect a wide range of reactions and coping mechanisms. In fact, members of the family of a child with a CCC may experience a number of difficult emotions, including fear, guilt, anger, resentment, and anxiety. Learning to manage these emotions promotes adaptive coping (see Nursing Care Guidelines box). Support from professionals, other family members, and friends can assist family members in managing their feelings. The following discussion examines some common phases of adjustment and emotional reactions.

Shock and Denial

The initial diagnosis of a chronic illness or complex condition is often met with intense emotion and is characterized by shock, disbelief, and sometimes denial. Denial as a defense mechanism is a necessary cushion to prevent disintegration and is a normal response to grieving for any type of loss. Probably all family members experience various degrees of adaptive denial as they learn of the impact the diagnosis has on their lives.

Shock and denial can last from days to months, sometimes even longer. Examples of denial that may be exhibited at the time of diagnosis include:

- Physician shopping
- Attributing the symptoms of the actual illness to a minor condition
- Refusing to believe the diagnostic tests
- Delaying consent for treatment
- Acting happy and optimistic despite the revealed diagnosis
- Refusing to tell or talk to anyone about the condition
- Insisting that no one is telling the truth, regardless of others' attempts to do so
- Denying the reason for admission
- Asking no questions about the diagnosis, treatment, or prognosis

Generally, these mechanisms should be respected as short-term responses that allow individuals to distance themselves from the tremendous emotional impact and to collect and mobilize their energies toward goal-directed, problem-solving behaviors.

In children, the importance of denial has repeatedly been demonstrated as a factor in their positive coping with the diagnosis. Denial allows the child to maintain hope in the face of overwhelming odds and to function adaptively and productively. Similar to hope, denial may be an adaptive mechanism for dealing with loss that persists until a family or patient is ready or needs other responses.

Denial is probably the least understood and most poorly dealt-with reaction. If denial is labeled as maladaptive, it can lead to inappropriate attempts to strip away the reaction by repeated and sometimes blunt explanations of the prognosis. However, denial becomes maladaptive only when it prevents recognition of treatment or rehabilitative goals necessary for the child's optimal survival or development.

Adjustment

For most families, adjustment gradually follows shock and is usually characterized by an open admission that the condition exists. This stage may be accompanied by several responses, which are normal parts of the adaptation process. Probably the most universal of these feelings are **guilt** and **self-accusation**. Guilt is often greatest when the cause of the disorder is directly traceable to the parent, as in genetic diseases or accidental injury. However, it can occur even without any scientific or realistic basis for parental responsibility. Frequently the guilt stems from a false assumption that the child's condition is a result of personal failure or wrongdoing, such as not doing something correctly during pregnancy or the birth. Guilt may also be associated with cultural or religious beliefs. Some parents are convinced that they are being punished for some previous misdeed. Others may see the illness as a trial sent by God to test their religious strength and faith. With correct information, support, and time, most parents master guilt and self-accusation.

Children, too, may interpret their serious illness as retribution for past misbehavior. The nurse should be particularly sensitive to the child who passively accepts all painful procedures. This child may

believe that such acts are inflicted as deserved punishment. It is vital that parents and health care professionals reassure children that their illnesses are not their fault.

Other common and normal reactions to a diagnosis are bitterness and anger. Anger directed inward may be evident as self-reproaching or punitive behavior, such as neglecting one's health and verbally degrading oneself. Anger directed outward may be manifested in either open arguments or withdrawal from communication and may be evident in the person's relationship with any number of individuals, such as the spouse, the child, and siblings. Passive anger toward the ill child may be evident in decreased visiting, refusal to believe how sick the child is, or an inability to provide comfort. Health care providers are among the most common targets for parental anger. Parents may complain about the nursing care, the insufficient time physicians spend with them, or the lack of skill of those who draw blood or start intravenous infusions.

Children are apt to respond with anger as well, and this includes the affected child and the well siblings. Children are aware of the loss engendered by their illness or complex condition and may react angrily to the restrictions imposed or the feelings of being different. Siblings may also feel anger and resentment toward the ill child and parents for the loss of routine and parental attention. It is difficult for older children and almost impossible for younger children to comprehend the plight of the affected child. Their perception is of a brother or sister who has the undivided attention of their parents, is showered with cards and gifts, and is the focus of everyone's concern.

During the period of adjustment, four types of parental reactions to the child influence the child's eventual response to the disorder:

- **Overprotection:** The parents fear letting the child achieve any new skill, avoid all discipline, and cater to every desire to prevent frustration.
- **Rejection:** The parents detach themselves emotionally from the child but usually provide adequate physical care or constantly nag and scold the child.
- **Denial:** The parents act as if the disorder does not exist or attempt to have the child overcompensate for it.
- **Gradual acceptance:** The parents place necessary and realistic restrictions on the child, encourage self-care activities, and promote reasonable physical and social abilities.

Reintegration and Acknowledgment

For many families, the adjustment process culminates in the development of realistic expectations for the child and reintegration of family life with the illness or complex condition in a manageable perspective. Because a large portion of this phase is one of grief for a loss, total resolution is not possible until the child dies or leaves home as an independent adult. One can regard adjustment as "increased comfort" with everyday living rather than a complete resolution.

This adjustment phase also involves social reintegration in which the family broadens its activities to include relationships outside of the home with the child as an acceptable and participating member of the group. This last criterion often differentiates the reaction of gradual acceptance during the adjustment period from total acceptance or perhaps is more descriptive of the acknowledgment process.

Many parents of children with chronic illnesses experience **chronic sorrow**, which are feelings of sorrow and loss that recur in waves over time. As the child's condition progresses, parents experience repeated losses that represent further declines and new caregiving demands. Even common occurrences can trigger feelings of sorrow well after the initial event; consequently, families must be assessed on an ongoing basis and offered appropriate support and resources as their needs change over time. This represents a critical period because the manner in which the nursing and medical team approach and provide support can directly affect the experience of complicated grief after the death of the child. Complicated grief, which is characterized as persistent distress and chronic stress response, may last for 6 months or longer after the death of a child and has a significant impact on quality of life of the family members left behind (Meert, Shear, Newth, et al., 2011). *Persistent complex bereavement disorder* is a new diagnostic entity included in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychological Association, 2013).

BOX 17.5 Concept of Functional Burden

Impact of the Child With Special Needs

The child's need for medical and nursing care
The child's fixed deficits
The child's age-appropriate dependency in activities of daily living
The disruptions in the family routine caused by the care
The psychologic burden of the prognosis on the family

Family Resources and Ability to Cope

The family's physical resources
The family's emotional resources
The family's educational resources
The family's social supports and available help
The competing demands for family members' time and energy

Data from Stein, R. E. K. (1985). Home care: A challenging opportunity. *Child Health Care, 14*(2), 90–95.

ESTABLISHING A SUPPORT SYSTEM

The diagnosis of a child with a CCC is a major situational crisis that affects the entire family system. However, families can experience positive outcomes as they successfully deal with the many challenges that accompany a child with chronic illness (Hungerbuehler, Vollrath, & Landolt, 2011).

One nursing goal is to assess which families are at risk for succumbing to the effects of the crisis. Several variables—available support system, perception of the event, coping mechanisms, reactions to the child, available resources, and concurrent stresses within the family—influence the resolution of a crisis. Although most families cope well, the needs of families at risk are great. If they receive emotional support and guidance early, there is an increased likelihood that they will also cope successfully.

Although it is easy to assume that families of children with the most severe illnesses or disabilities would have the poorest adjustment, the severity of the condition reflects only one part of the overall picture. The level of adjustment is significantly influenced by the **functional burden** on the family (Stein, 1985). This concept considers the issues related to caring for and living with the child in relation to the family's resources and ability to cope (Box 17.5). The family of a child with a high level of technology dependence demanding complex care yet having many resources and coping skills may adjust more successfully to the child's situation than the family of a child with a less serious condition and few resources to counterbalance.

Intrafamilial resources, social support from friends and relatives, parent-to-parent support, parent-professional partnerships, and community resources interweave to provide a flexible web of support for families of children with chronic conditions.

Fig. 17.1 Children with any type of impairment should have the opportunity to develop their skills. (Courtesy Poyo/Hinton Photography.)

THE CHILD WITH A CHRONIC OR COMPLEX CONDITION

The child's reaction to chronic illness depends to a great extent on his or her developmental level, temperament, and available coping mechanisms; on the reactions of family members or significant others; and, to a lesser extent, on the condition itself. A child's conceptual understanding of his or her own illness is based not only on age and developmental level but also on the duration and type of experience accumulated with the disease. Knowledge of these variables is essential to providing the kind of information and support needed by these children to cope with an often overwhelming situation.

DEVELOPMENTAL ASPECTS

The impact of a complex chronic illness is influenced by the age at onset. Chronic illness affects children of all ages, but the developmental aspects of each age-group dictate particular stresses and risks for the child. The nurse must also recognize that children need to redefine their condition and its implications as they develop and grow. For example, appearance, skills, and abilities are highly valued by peers (Fig. 17.1). A teenager who is limited in any of these qualities is subject to rejection. This is especially marked when an illness interferes with sexual attractiveness.

Children's developmental concepts of illness are discussed in Chapter 19. An understanding of these developmental factors facilitates planning care to support the child and minimize the risks. Developmental effects of chronic illness on children are described in Table 17.2.

COPING MECHANISMS

Children with chronic conditions tend to use five distinct patterns of coping (Box 17.6). Children with more positive and accepting attitudes about their chronic illness use a more adaptive coping style characterized by optimism, competence, and compliance. They show fewer behavior problems at home and at school. The two maladaptive coping patterns—"Feels different and withdraws" and "Is irritable, is moody, and acts out"—are associated with poorer adaptation; children using these strategies have poorer self-concepts, more negative attitudes about their conditions, and more behavior problems at home and at school.

Well-adapted children gradually learn to accept their physical limitations and find achievement in a variety of compensatory motor and intellectual pursuits. They function well at home, at school, and with peers. They have an understanding of their disorder that allows them to accept their limitations, assume responsibility for their care, and assist in treatment and rehabilitation regimens. They express appropriate emotions, such as sadness, anxiety, and anger, at times of exacerbations but confidence and guarded optimism during periods of clinical stability (Fig. 17.2). They are able to identify with other similarly affected individuals, promoting positive self-images and displaying pride and self-confidence in their ability to master a productive, successful life despite their illnesses.

Hopefulness

Children, particularly adolescents, are sensitive to the presence or absence of hope. Hopefulness is an internal quality that mobilizes humans into goal-directed action that may be satisfying and life sustaining. Higher levels of hope have been associated with higher levels of resiliency and the ability to see obstacles as opportunities (Griggs & Walker, 2016).

Health Education and Self-Care

Health education is an intervention that promotes coping. Children need information about their condition, the therapeutic plan, and how the disease or the therapy might affect their particular situation. Children nearing puberty also need to understand the maturation process and how their chronic illness may alter this event. For example, a youngster with Crohn disease should understand that this disorder is associated with growth failure and delayed puberty, a child with diabetes needs to know that hormonal changes and increased growth needs will alter food and insulin requirements at this time, and a sexually active girl with sickle cell anemia or systemic lupus erythematosus needs to be aware of the risks of pregnancy. The information should not be given all at once but should be timed appropriately to meet children's changing needs, and it should be described and repeated as often as the situation demands.

RESPONSES TO PARENTAL BEHAVIOR

Parental behavior toward the child is one of the most important factors influencing the child's adjustment. Children's perceptions of their mothers' support and maternal perceptions of the psychosocial impact of the child's chronic illness on the family were shown to be two of the greatest predictors of children's psychologic adjustment (Immelt, 2006). In addition, family organization, illness-related support, and involvement of the parents influence children's adjustment to chronic illness (Schor, 2003). They often display pride and confidence in their ability to cope successfully with the challenges imposed by their disorder. Anticipatory guidance by the nurse and encouragement of normalizing practices may assist parents in facilitating positive adjustment in their children.

TYPE OF ILLNESS OR CONDITION

The type of illness or condition also influences the child's emotional response. Interestingly, children with *more* severe disorders often cope better than those with milder conditions. However, the presence of multiple conditions may place a child at risk for more behavioral problems (Newacheck & Halfon, 1998). Because of children's cognitive

TABLE 17.2 Developmental Effects of Chronic Illness or Disability on Children

Developmental Tasks	Potential Effects of Chronic Illness or Disability	Supportive Interventions
Infancy		
Develop a sense of trust	Multiple caregivers and frequent separations, especially if hospitalized Deprived of consistent nurturing	Encourage consistent caregivers in hospital or other care settings. Encourage parental presence, "rooming in" during hospitalization, and participation in care.
Bond, or attach, to parent	Delayed because of separation; parental grief for loss of "dream" child; parental inability to accept the condition, especially a visible defect	Emphasize healthy, perfect qualities of infant. Help parents learn special care needs of infant for them to feel competent.
Learn through sensorimotor experiences	More exposure to painful experiences than pleasurable ones Limited contact with environment from restricted movement or confinement	Expose infant to pleasurable experiences through all senses (touch, hearing, sight, taste, movement). Encourage age-appropriate developmental skills (e.g., holding bottle, finger feeding, crawling).
Begin to develop a sense of separateness from parent	Increased dependency on parent for care Overinvolvement of parent in care	Encourage all family members to participate in care to prevent overinvolvement of one member. Encourage periodic respite from demands of care responsibilities.
Toddlerhood		
Develop autonomy	Increased dependency on parent	Encourage independence in as many areas as possible (e.g., toileting, dressing, feeding).
Master locomotor and language skills	Limited opportunity to test own abilities and limits	Provide gross motor skill activity and modification of toys or equipment, such as modified swing or rocking horse.
Learn through sensorimotor experience; beginning preoperational thought	Increased exposure to painful experiences	Give choices to allow simple feeling of control (e.g., choice of what book to look at, what kind of sandwich to eat). Institute age-appropriate discipline and limit setting. Recognize that negative and ritualistic behaviors are normal. Provide sensory experiences (e.g., water play, sandbox play, finger painting).
Preschool Age		
Develop initiative and purpose Master self-care skills	Limited opportunities for success in accomplishing simple tasks or mastering self-care skills	Encourage mastery of self-help skills. Provide devices that make tasks easier (e.g., self-dressing).
Begin to develop peer relationships	Limited opportunities for socialization with peers; may appear "like a baby" to age-mates Protection within tolerant and secure family, causing child to fear criticism and withdraw	Encourage socialization (e.g., inviting friends to play, daycare experience, trips to park). Provide age-appropriate play, especially associative play opportunities. Emphasize child's abilities; dress appropriately to enhance desirable appearance.
Develop sense of body image and sexual identification	Awareness of body centering on pain, anxiety, and failure Sex-role identification focused primarily on mothering skills	Encourage relationships with same-sex and opposite-sex peers and adults.
Learn through preoperational thought (magical thinking)	Guilt (thinking he or she caused the illness or disability or is being punished for wrongdoing)	Help child deal with criticisms; realize that too much protection prevents child from realities of world. Clarify that cause of child's illness or disability is not his or her fault or a punishment.
School Age		
Develop a sense of accomplishment	Limited opportunities to achieve and compete (e.g., many school absences, inability to join regular athletic activities)	Encourage school attendance; schedule medical visits at times other than school; encourage child to make up missed work.
Form peer relationships	Limited opportunities for socialization	Educate teachers and classmates about child's condition, abilities, and special needs. Encourage sports activities (e.g., Special Olympics). Encourage socialization (e.g., Girl Scouts, Campfire, Boy Scouts, 4-H Club; having a best friend or club membership).

TABLE 17.2 Developmental Effects of Chronic Illness or Disability on Children—cont'd

Developmental Tasks	Potential Effects of Chronic Illness or Disability	Supportive Interventions
Learn through concrete operations	Incomplete comprehension of the imposed physical limitations or treatment of the disorder	Provide child with information about his or her condition. Encourage creative activities (e.g., VSA Arts).
Adolescence		
Develop personal and sexual identity	Increased sense of feeling different from peers and reduced ability to compete with peers in appearance, abilities, special skills	Help teenager realize that many of the difficulties he or she is experiencing are part of normal adolescence (rebelliousness, risk taking, lack of cooperation, and hostility toward authority).
Achieve independence from family	Increased dependency on family; limited job or career opportunities	Provide instruction on interpersonal and coping skills. Encourage increased responsibility for care and management of the disease or condition (e.g., assuming responsibility for making and keeping appointment [ideally alone], sharing assessment and planning stages of health care delivery, contacting resources). Discuss planning for future and how condition can affect choices.
Form heterosexual relationships	Limited opportunities for heterosexual friendships; less opportunity to discuss sexual concerns with peers Increased concern with issues such as why did he or she get the disorder and whether he or she will marry and have a family	Encourage socialization with peers, including peers with special needs and those without special needs. Encourage activities appropriate for age (e.g., attending mixed-sex parties, sports activities, driving a car). Be alert to cues that signal readiness for information regarding implications of condition on sexuality and reproduction. Emphasize good appearance and wearing stylish clothes, use of makeup. Understand that adolescent has same sexual needs and concerns as any other teenager.
Learn through abstract thinking	Decreased opportunity for earlier stages of cognition impeding achievement of level of abstract thinking	Provide instruction on decision making, assertiveness, and other skills necessary to manage personal plans.

BOX 17.6 Coping Patterns Used by Children With Special Needs

Develops competence and optimism: Accentuates the positive aspects of the situation and concentrates more on what he or she has or can do than on what is missing or on what he or she cannot do; is as independent as possible

Feels different and withdraws: Sees self as being different from other children because of the chronic health condition; views being different as negative; sees self as less worthy than others; focuses on things he or she cannot do and sometimes overrestricts activities needlessly

Is irritable, is moody, and acts out: Uses proactive and self-initiated coping behaviors, although usually counterproductive in that the behaviors are not ego enhancing or socially responsible and do not result in desired outcomes; acts out irritability, which may or may not be associated with condition's symptoms

Complies with treatment: Takes necessary medications and treatments; adheres to activity restrictions; also uses behaviors that indicate developing independence (e.g., assumes responsibility for taking medication)

Seeks support: Talks with adults, children, physicians, and nurses; develops plans to handle problems as they occur; uses downward comparison (i.e., realizes that others have it worse)

Modified from Austin, J., Patterson, J., & Huberty, T. (1991). Development of the coping health inventory for children. *Journal of Pediatric Nursing, 6*(3), 166–174.

Fig. 17.2 Periods of sadness and anger are appropriate in the child's adjustment to a chronic illness or disability, especially during exacerbations of the disorder.

ability and the timing of onset of abstract thinking in adolescence, an obvious condition may be easier for them to accept because its limitations are concrete.

The onset of a disabling condition may generate a state of confusion for children, who may have trouble differentiating between actual bodily functions and their image of their bodies. They may also experience problems in identifying themselves and those extensions of self (e.g., wheelchairs, braces, crutches, other mechanical or prosthetic devices) and may have difficulty in accepting functional aids.

TABLE 17.3 Assessment of Factors Affecting Family Adjustment

Factors Affecting Adjustment	Assessment Questions
Available Support System	
Status of marital relationship	To whom do you talk when you have something on your mind? (If answer is not the spouse, ask for the reason.)
Alternate support systems	When something is worrying you, what do you do? What helps you most when you are upset?
Ability to communicate	Does talking seem to help when you feel upset?
Perception of the Illness or Disability	
Previous knowledge of disorder	Have you ever heard the word (name of diagnosis) before? Tell me about it (if answer is yes).
Imagined cause of disorder	What are your thoughts about the causes of the disorder?
Effects of illness or disability on family	How has your child's illness or disability affected you and your family? How has your lifestyle changed?
Coping Mechanisms	
Reactions to previous crises	Tell me one time you've had another crisis (problem, bad time) in your family. How did you solve that problem?
Reactions to the child	Do you find yourself being a little more cautious with this child than with your other children?
Childrearing practices	Do you feel as comfortable disciplining this child as your other children?
Influence of religion	Has your religion or faith been of help to you? Tell me how (if answer is yes).
Attitudes	How is this child different from the siblings or other children of similar age? Describe your child's personality. Is it easy, difficult, or in between? When you think of your child's future, what thoughts come to mind?
Available Resources	
	What parts of your child's care are causing the most difficulty for you or your family?
	What services are available to help?
	What services do you need that currently are not available?
Concurrent Stresses	
	What other problems are you facing now? (Be specific; ask about financial, marital, sibling, and extended family or friends concerns.)

NURSING CARE OF THE FAMILY AND CHILD WITH A CHRONIC OR COMPLEX CONDITION

ASSESSMENT

Because the nurse may meet a family during any phase of the adjustment process, several assessment areas are important. The family's ability to cope with previous stresses influences the current situation, and answers to questions about their usual coping skills are enlightening. Knowledge of concurrent stresses, such as financial, marital or nonmarital, and career or unemployment, helps identify families who may have fewer resources to cope with the child's needs.

Finally, awareness of the family members' reactions to the child and the illness or condition is important. Sample questions that the nurse and family can use to evaluate the support system, perception of the illness, coping mechanisms, resources, and concurrent stresses are listed in Table 17.3. Because factors affecting the family's response may change at any point during the illness, assessment must be a continuous process.

Special challenges exist in assessing the child's feelings about having a chronic illness. Though they may develop an understanding of their condition, this may not always translate to an understanding of the long-term implications of their chronic complex diagnosis. Chapter 4 presents several approaches to encourage children to discuss their feelings about their conditions. The nurse should use a variety of communication techniques, such as drawing and play, as assessment tools rather than relying solely on parental reports.

The needs of working parents and siblings also should be assessed; this is a goal that requires flexibility in scheduling appointments. When working parents know that their input is valuable, they will often change their work schedule to meet with a health professional. Because siblings can be of any age, the use of appropriate communication strategies for assessment must be considered. Nonverbal techniques, such as those discussed in Chapter 4, should be considered for these children.

PROVIDE SUPPORT AT THE TIME OF DIAGNOSIS

The diagnosis is a critical time for parents and can influence how they perceive their health care providers across the trajectory of care. Although they may not hear or remember all that is said to them, they frequently sense a certain attitude of acceptance, rejection, hope, or despair that may influence their ability to absorb the shock and begin adapting to the family's altered future.

Parents may be encouraged to be together when they are informed of their child's condition, thus avoiding the problem of one parent having to interpret complex information and deal with the initial emotional reaction of the other. The informing session should take place in a private, comfortable setting free of distractions and interruptions in an atmosphere in which the parents feel free to express their emotions (Fig. 17.3). Their emotional needs are acknowledged by showing acceptance of expressions, such as crying, sadness, anger, and disappointment. Emotional support is offered by having tissues available if a family member cries and demonstrating through facial and body language that indeed this is a difficult and painful period. Although touching is a powerful expression of empathy, it must be used wisely. For example, it can prematurely terminate free expression of feelings, especially when combined with statements such as "Everything will be all right." Nurses should also be aware of cultural issues regarding touching (see Chapter 4).

Parents should receive the kind of information they desire. This can be assessed by asking questions such as "Do you prefer to hear detailed information?" Parents or other family members may have different preferences regarding the amount of information that they wish to hear. Most parents want a clear, simple explanation of the diagnosis; a prediction of possible futures for the child; advice on what to do next; an opportunity to ask questions; a warm, sympathetic listener; and, most important, time. Understanding of explanations is elicited with questions such as "Do you see what I mean?" or "Is this clear to you?" Technical terms are used with simple definitions. If the parents are unaware of the term, they are given written literature or at least a written summary of the diagnosis.

Fig. 17.3 Information sessions should take place in a private, comfortable setting free of distractions and interruptions.

Finally, the informing conference does not end with the presentation of devastating news. Instead, the child's strengths, appealing behaviors, and potential for development are stressed, as are available rehabilitation efforts or treatments. Parents can be encouraged to view their experiences as a series of challenges that they are capable of handling, particularly with available professional feedback. The parents are assured that the nurse will be available to answer questions and to provide further assistance as needed.

The preceding discussion relates primarily to the initial informing interview. However, because of the need for long-term follow-up, it is only one in a series of continuing discussions. In all interactions, the family's input is solicited and incorporated into the care plan. Some situations require consideration of special problems (see Nursing Care Guidelines box).

NURSING CARE GUIDELINES

Situations Requiring Special Consideration

Congenital Anomaly

Tension in the delivery room conveys the sense that something is seriously wrong. Communication is often delayed while the physician is involved with the mother's care. The manner in which the infant is presented may well set the tone for the early parent-child relationship.

Clarify role with physician in regard to revealing information to enable immediate parental support.

Explain to parents briefly in simple language what the defect is and something concerning the immediate prognosis before showing them the infant. Later more information can be given when they are more ready to "hear" what is said.

Be aware of nonverbal communication. Parents watch facial expressions of others for signs of revulsion or rejection.

Present infant as something precious.

Emphasize well-formed aspects of infant's body.

Allow time and opportunity for parents to express their initial response.

Encourage parents to ask questions and provide honest, straightforward answers without undue optimism or pessimism.

Cognitive Impairment

Unless cognitive impairment is associated with other physical problems, it is often easy for parents to miss clues to its presence or to make defensive excuses regarding the diagnosis.

Plan situations that help parents become aware of the problem.

Encourage parents to discuss their observations of child but withhold diagnostic opinions.

Focus on what the child can do and appropriate interventions to promote progress (e.g., infant stimulation programs) to involve parents in their child's care while helping them gain an awareness of the child's condition.

Physical Disability

If loss of motor or sensory ability occurs during childhood, the diagnosis is readily apparent. The challenge lies in helping the child and parents over the period of shock and grief and toward the phase of acceptance and reintegration.

Institute early rehabilitation (e.g., using a prosthetic limb, learning to read braille, learning to read lips).

Be aware that physical rehabilitation usually precedes psychologic adjustment.

When the cause of the disability is accidental, avoid implying that parents or child was responsible for the injury but allow them the opportunity to discuss feelings of blame.

Encourage expression of feelings (see Chapter 4, Communication Techniques).

Chronic Illness

Realization of the true impact may take months or years. Conflict over parents' versus child's concerns may result in serious problems. When condition is inherited, parents may blame themselves or child may blame the parents.

Help each family member gain an appreciation of the others' concerns.

Discuss hereditary aspect of condition with parents at time of diagnosis to lessen guilt and accusatory feelings.

Encourage child to express feelings by using third-person technique (e.g., "Sometimes when a person has an illness that was passed on by the parents, that person feels angry or bitter toward them").

Multiple Disabilities

The child or parent may require additional time for the shock phase and may be able to attend to only one diagnosis before hearing significant information about other disorders.

Acknowledge parents' understanding and acceptance of all diagnoses, especially when an obvious and more hidden disability coexists.

Appreciate the devastating consequences of more than one disability for a child, especially if they interfere with expressive-receptive abilities.

Terminal Illness

Parents require much support to deal with their own feelings and guidance in how to tell the child the diagnosis. They may want to conceal the diagnosis from the child. They may believe that the child is too young to know, will not be able to cope with the information, or will lose hope and the will to live.

Approach the subject of disclosure in a positive way by asking, "How will you tell your child about the diagnosis?"

Help parents understand the disadvantages of not telling the child (e.g., deprives child of the opportunity to discuss feelings openly and ask questions, incurs the risk of child learning the truth from outside and sometimes less tactful sources, may lessen child's trust and confidence in the parents after learning the truth).

Guide parents to see the potential problems involved in fostering a conspiracy.

Offer parents guidelines for how and what to tell the child about the disease or the possibility of death. Explanations should be tailored to child's cognitive ability, be based on knowledge child already has, and be honest. Honesty must be tempered with concern for child's feelings.

Assure parents that telling a child the name of the illness and the reason for treatment instills hope, provides support from others, and serves as a foundation for explaining and understanding subsequent events.

Acknowledge that being honest is not always easy because the truth may prompt the child to ask other distressing questions, such as "Am I going to die?" However, even this difficult question must be answered.

SUPPORT THE FAMILY'S COPING METHODS

For the family to meet the stresses of optimally adjusting to the child's condition, each member must be individually supported so that the family system is strong. Although the family can indefinitely support a member who is in need of assistance, its greatest strength lies in every member supporting each other. The nurse should bear in mind that the family member in greatest need is not necessarily the affected child but may be a parent or sibling who is dealing with stresses that require intervention.

Parents

The nurse can provide support by being attentive to families' responses to their children. Mothers and fathers need to experience success, joy, and pride in their children to give the support they need. It is important for nurses to examine their attitudes to determine their ability to engage in parent-professional partnerships. An essential characteristic is the belief that parents are equal to professionals and are experts on their child (see Nursing Care Guidelines box).

NURSING CARE GUIDELINES

Developing Successful Parent-Professional Partnerships

Promote primary nursing; in nonhospital settings, designate a case manager.
Acknowledge parents' overall competence and their unique expertise with their child.
Respect parents' time as having value equal to that of other members of child's health care team.
Explain or define any medical, technical, or discipline-specific terms.
Tell families, "I am not sure" or "I don't know" when appropriate.
Facilitate family's effectiveness in team meetings (e.g., provide parents with same information as other participants).

Parents can be encouraged to discuss their feelings toward the child, the impact of this event on their marriage, and associated stresses such as financial burdens. For most families, regardless of their income or insurance coverage, financial concerns exist. The costs of caring for a child with special needs can be overwhelming. In addition, one or both parents may have to sacrifice job opportunities to remain close to a medical facility or to avoid losing insurance benefits. Numerous volunteer and community resources that provide assistance, rehabilitation, equipment, and funding for a variety of health problems are available. National and local disease-oriented organizations may provide needed assistance and support to families that qualify. Many of these are discussed elsewhere in the text under the specific diagnosis. State and federal departments of health, mental health, social services, and labor may be able to help locate appropriate regional resources. For example, state programs for Children with Special Health Needs provide financial assistance for children with many disabling conditions. Local and national sources of respite care and medical daycare may be useful to families. Nurses should become acquainted with those in their communities and with vocational programs for special groups.

Parent-to-Parent Support

Just being with another parent who has shared similar experiences is helpful. It may not need to be a parent of a child with the same diagnosis, because parents in the process of adjusting to a child with special needs—or finding respite services, educational or rehabilitative services, special equipment vendors, and financial counseling—tread a common path. If the agency does not have a parent staff position, the nurse can contact parent groups that will often send a representative. Another strategy is to ask another parent to talk to the parents. The nurse should seek out a parent who is a good listener, has a nonjudgmental approach to differences in families, and possesses good advocacy and problem-solving skills.

The parent self-help group can promote parent-to-parent support.[a] Group members feel less alone and have the opportunity to observe both coping and mastery role modeling from other members. Parent groups are rich resources for information. Even if parents are unable to attend meetings, they can still benefit from group newsletters and other literature that often accompany membership. Nurses can assist in starting a group by identifying one or two parents as leaders; sharing with them the names, telephone numbers, and addresses of other families who have expressed both an interest and a willingness to release their phone numbers and addresses; and guiding them in how to initiate a first meeting.

Advocate for Empowerment

Nurses can advocate for methods that foster opportunities for parent empowerment. For example, nurses can suggest reimbursement for travel and child care plus stipends to enable parents' voices to be heard at meetings and conferences. They can encourage parent membership on committees and advisory boards. They can keep parents informed of pending legislation on child health issues or take action when parents inform them.

The Child

Through ongoing contacts with the child, the nurse (1) observes the child's responses to the disorder, ability to function, and adaptive behaviors within the environment and with significant others; (2) explores the child's own understanding of his or her illness or condition; and (3) provides support while the child learns to cope with his or her feelings. Children are encouraged to express their concerns rather than allowing others to express them for them because open discussions may reduce anxiety (see Nursing Care Guidelines box).

NURSING CARE GUIDELINES

Encouraging Expression of Emotion

Describe the behavior: "You seem angry at everyone."
Give evidence of understanding: "Being angry is only natural."
Give evidence of caring: "It must be difficult to endure so many painful procedures."
Help focus on feelings: "Maybe you wonder why this happened to you."

One of the most important interventions is alleviating the child's feeling of being different and normalizing his or her life as much as possible (see Nursing Care Guidelines box). Whenever possible, the nurse assists the family in assessing the child's daily routine for indications of a need for normalizing practices. For example, the child who remains in a bedroom all day requires a restructured daily routine to provide activities in different parts of the house, such as eating in the kitchen or dining room with the family. Such children may also be deprived of social, recreational, and academic activities that can

[a]Information about self-help groups and books and pamphlets are available from the National Self-Help Clearinghouse, 365 Fifth Ave., Suite 3300, New York, NY 10016; 217-817-1822; http://www.selfhelpweb.org.

be better accommodated by applying normalization practices. For example, home and out-of-home health-related treatments should be planned at times that least interfere with normal daily activities.

NURSING CARE GUIDELINES

Promoting Normalization

Preparation: Prepare child in advance for changes that may occur from the chronic or complex condition.
Example: Tell the child in advance the possible side effects of drug therapy.

Participation: Include child in as many decisions as possible, especially those relating to his or her care regimen.
Example: The child is responsible for taking medications or scheduling home treatments.

Sharing: Allow both family members and child's peers to be a part of the care regimen whenever possible.
Examples: Give the child his or her medication when the other siblings receive their vitamins.
The parent cooks the same menu for the whole family.
If the child is invited to another's home, the parent advises the family of the child's dietary restrictions.

Control: Identify areas where child can be in control so that feelings of uncertainty, passivity, and helplessness are decreased.
Example: The child identifies activities that are appropriate to his or her energy level and chooses to rest when fatigued.

Expectation: Apply the same family rules to the child with a complex chronic illness as to the well siblings or peers.
Example: The child is disciplined, is expected to fulfill household responsibilities, and attends school in accordance with abilities.

Children who are concerned that their condition detracts from their physical attractiveness need attention focused on the normal aspects of appearance and capabilities. Health professionals help strengthen and consolidate the self-image by emphasizing the normal while allowing children to express anger, isolation, fear of rejection, feelings of sadness, and loneliness. The children need positive reinforcement for compliance and any evidence of improvement. Anything that might improve attractiveness and contribute to a positive self-image is used, such as makeup for a teenager with a scar, clothing that disguises a prosthesis, or a hairstyle or wig to cover a deformity or lost hair.

Siblings

The presence of a child with special needs in a family may result in parents paying less attention to the other children. Siblings may respond by developing negative attitudes toward the child or by expressing anger in different forms. The nurse can help by using anticipatory guidance, questioning the parents about what they believe is the best way to have siblings respond to the child, and guiding them through ways to meet their other children's needs for attention. This questioning should take place before serious negative effects occur.

Siblings may also experience embarrassment associated with having a brother or sister with a chronic or complex condition. Parents are then faced with the difficulty of responding to this embarrassment in an understanding and appropriate manner without punishing the siblings for how they feel. Parents are encouraged to talk with the siblings about how they view their affected sibling. For example, siblings of a child with developmental disabilities may express fears about their ability to bear normal children. Adolescents in particular may not be able to discuss these vital issues with their parents and may prefer to consult with the nurse. Many siblings benefit from sharing their concerns with other young people who are experiencing a similar situation. Support groups for siblings can help decrease isolation, promote expression of feelings, and provide examples of effective coping skills.

Many parents express concern about when and how to inform the other children in the family about a sibling's illness or disability. The answer depends on each child's level of sophistication and understanding. However, it is usually best to inform the siblings before a neighbor or other nonfamily member does so. Uninformed siblings may fantasize or develop apprehensions that are out of proportion to the child's actual condition. Furthermore, if parents choose to be silent or deceptive about the issue, they are setting a negative precedent for the siblings to follow rather than encouraging the siblings to cope with the experience in a healthy and nurturing way.

The nurse is sensitive to the reactions of siblings and whenever possible intervenes to promote more positive adjustment. For example, siblings often mention that they are expected to take on additional responsibilities to help the parents care for the child. It is not unusual for them to express a positive reaction to assuming the extra duties but a negative response to feeling unappreciated for doing so. Such feelings can often be minimized by encouraging siblings to discuss this with the parents and by suggesting to parents ways of showing gratitude, such as an increase in allowance, special privileges, and, most significantly, verbal praise.

EDUCATE ABOUT THE DISORDER AND GENERAL HEALTH CARE

Educating the family about the disorder is actually an extension of revealing the diagnosis. Education involves not only supplying technical information but also discussing how the condition will affect the child. Parents may only be able to process limited information at any one time. It may be helpful to provide essential information and then follow by asking, "What else would you like to know about your child's condition?" Responding to parents' questions and concerns ensures that their information needs are met.

Activities of Daily Living

Parents also need guidance in how the condition may interfere with or alter activities of daily living, such as eating, dressing, sleeping, and toileting. One area frequently affected is nutrition. Common problems are undernutrition resulting from food being inappropriately restricted or loss of appetite, vomiting, or motor deficits that interfere with feeding; overnutrition may also occur, usually because of a caloric intake in excess of energy expenditure because of boredom and lack of stimulation in other areas. Although the child requires the same basic nutrients as other children, the daily requirements may differ. Special nutritional considerations are discussed as appropriate throughout the text.

Safe Transportation

Modifications may also be needed regarding car safety. Children with conditions such as low birth weight (see Chapter 8, Discharge Planning and Home Care) or orthopedic, neuromuscular, or respiratory impairments often cannot safely use conventional car restraints. For example, children with hip spica casts cannot sit properly in child safety seats (see Chapter 29, Developmental Dysplasia of the Hip). Modifications can be made to some commercial models, and for older children, a

special vest that secures the child to the back seat in a lying-down position is available.[b]

If a child requires a wheelchair, the family should consult the wheelchair manufacturer for specific instructions regarding safe car transportation. Considerations for wheelchairs used with vehicle transportation must address securing both the wheelchair and the occupant in the wheelchair. Wheelchairs should be secured facing forward with tie-downs at four points. The tie-down system should be dynamically crash tested, as should the occupant securement system that secures the child in the wheelchair. For example, use of trays is not recommended for transportation. For children who must travel with additional medical equipment, this equipment (e.g., oxygen, monitors, ventilators) should be anchored to the floor or underneath the vehicle seat or wheelchair. Soft padding should be added around the equipment to reduce movement. A second adult should be present to monitor the condition of a medically fragile child while traveling.

Primary Health Care

Children with special needs require all of the usual health care recommended for any child. Attention to injury prevention, immunizations, dental health, and regular physical examinations is essential. Nurses can play an important role in reminding parents of these aspects of care that are so often neglected when the concern is focused on the child's chronic condition. Specific discussions of nutrition, sleep and activity, dental health, and injury prevention are presented in the chapters on health promotion for specific age-groups. Immunizations are discussed in Chapter 6.

Parents also need to be aware of the importance of communicating the child's condition in the event of a medical emergency. Young children are unable to give information about their disorders, and although older children may be reliable sources, after an accident they may be physically unable to speak. All children with any type of chronic condition that may affect medical care should wear some type of identification, such as a MedicAlert bracelet,[c] or carry a card in their wallet that lists the medical condition and a phone number for emergency medical records and other personal information.

PROMOTE NORMAL DEVELOPMENT

Aside from knowledge of the condition and its effect on the child's abilities, the family must be guided toward fostering appropriate development in their child. Although each stage may take longer to achieve, parents are guided toward helping the child fully realize his or her potential in preparation for the next developmental stage. Table 17.2 outlines developmental aspects of complex conditions and supportive interventions. With appropriate planning and knowledge of strategies to improve the child's functional abilities, most children can live fulfilling and productive lives.

One important aspect of promoting normal development is to encourage the child's self-care abilities in both activities of daily living and the medical regimen. An assessment of the child's age and physical, emotional, and mental capacities, as well as the support and structure provided by the family, should be considered in determining the appropriate level of self-care in the medical regimen. Even toddlers can be involved in their own care by holding supplies for the parent during a procedure. Over time, children should be encouraged toward greater autonomy in the self-care arena.

BOX 17.7 Characteristics of Parental Overprotection

- Sacrifices self and rest of family for the child
- Continually helps the child even when the child is capable
- Is inconsistent with regard to discipline or uses no discipline; frequently applies different rules to the siblings
- Is dictatorial and arbitrary, making decisions without considering the child's wishes, such as keeping the child from attending school
- Hovers and offers suggestions; calls attention to every activity; overdoes praise
- Protects the child from every possible discomfort
- Restricts play, often because of fear that the child will be injured
- Denies the child opportunities for growing up and assuming responsibility, such as learning to give own medications or perform treatments
- Does not understand the child's capabilities and sets goals too high or too low
- Monopolizes the child's time, such as sleeping with the child, permitting few friends, or refusing participation in social or educational activities

Early Childhood

During infancy, the child is achieving basic trust through a satisfying, intimate, consistent relationship with his or her parents. However, affected children's early existence may be stressful, chaotic, and unsatisfying. Consequently, they may need more parental support and expressions of affection to achieve trust. Likewise, the parents require assistance in finding ways to meet the infant's needs, such as how to hold a rigid or flaccid infant, how to feed a child with tongue thrust or episodes of dyspnea, and how to stimulate a child who seems incapable of achieving any skills. If hospitalizations are frequent or prolonged, every effort is made to preserve the parent-child relationship (see also Chapter 19).

During early childhood, the goal is to adapt to periods of separation from parents, autonomy, and initiative. However, the natural parental response to having a sick child is overprotection (Box 17.7). Parents need help in realizing the importance of brief separations of the child from them and from others involved in the child's care and of providing social experiences outside the home whenever possible. Respite care, which provides temporary relief for family members, can be essential in allowing caregivers time away from the daily burdens.

Young children also need the opportunity to develop independence. Frequently, the child is able to learn self-help skills, such as finger feeding and removing simple articles of clothing, but the parent continues to perform the act. The nurse can provide parents with anticipatory guidance as to the usual milestones expected from the child. When a child is unable to perform a skill independently, functional aids should be used. With innovation, many adaptations can be implemented in children's environments to increase their mobility and independence and allow them to play like other children their age. For example, with slight modifications, a child with physical limitations may be able to ride a tricycle (Fig. 17.4).

Another critical component for normal child development is discipline. Discipline and guidance serve several purposes, such as providing children with boundaries on which to test out their behavior and teaching them socially acceptable behavior. Resentment and hostility can arise among siblings if different standards are applied to each child. The nurse's responsibility is to help parents learn successful methods

[b]Information on car safety restraints for children with special needs is available from the Automotive Safety Program, 1130 West Michigan Street, Fesler Room 207, Indianapolis, IN 46202; 800-543-6227 or 317-274-2997; http://www.preventinjury.org.

Fig. 17.5 Children with disabilities should continue their schooling as soon as their condition permits.

of managing a child's behaviors before they become problems (see Chapter 2, Limit Setting and Discipline).

School Age

For school-age children, the major tasks are entry into school and achieving a sense of industry. Although the importance of school in the life of all children is well known, school absences are significantly higher among children with chronic illnesses than among their healthy peers. The more school absences the child experiences, the more difficult it is to resume attendance, and school phobia may result. The child should return to school as soon as possible after diagnosis or treatments.

Preparation for entry into or resumption of school is best accomplished through a team approach with the parents, child, teacher, school nurse, and primary nurse in the hospital. Ideally, this planning should begin before hospital discharge, provided that the child is well enough to resume usual activities. A structured plan should be developed, with attention to aspects of care that must be continued during school hours, such as administration of medication or other treatments.

Children also need preparation before entering or resuming school. Having a tutor in the hospital or home as soon as children are physically able helps them realize that school will continue and gives them time to consider this prospect (Fig. 17.5). They need to investigate possible answers to the many questions others will ask. One method of anticipatory preparation is to role-play, with the child as the "returned pupil" and the nurse or parent as "other schoolmates." If the child returns to school with some obvious physical change (such as hair loss, amputation, or a visible scar), the nurse might also ask questions about these alterations to prompt preparatory responses from the child.

Classroom peers also need preparation, and a joint plan created by the teacher, nurse, and child is best. At a minimum, classmates should be given a description of the child's condition, prepared for any visible changes in the child, and allowed an opportunity to ask questions. The child should have the option of attending this session. As the child's condition changes, particularly if the illness is potentially fatal, school personnel, including the students, need periodic appraisal of the child's status and preparation for what to expect.

Children with special needs are encouraged to maintain or reestablish relationships with peers and to participate according to their capabilities in any age-appropriate activities. Alternative activities may be substituted for those that are impossible or that place a strain on the child's condition. Programs such as the Special Olympics[d] offer children an opportunity to compete with their peers and to achieve athletic skill. Summer camps[e] allow children to associate with peers and develop a wide variety of skills. Children with special needs can derive enormous benefits from expressive activities, such as art, music, poetry, dance, and drama. With adaptive equipment and imagination, children can participate in a variety of activities. Organizations such as VSA Arts allow children to celebrate and share their accomplishments.[f] Children need the opportunity to interact with healthy peers and to engage in activities with groups or clubs composed of similarly affected age-mates. Organizations such as ostomy clubs, diabetes clubs, and cerebral palsy groups share information and provide support related to the special problems the members face.

Adolescence

Adolescence can be a particularly difficult period for the teenager and family. All of the needs discussed previously apply to this age-group as well. Developing **independence** or **autonomy**, however, is a major task for the adolescent as planning for the future becomes a prominent concern. Although the emphasis in the past has been on

achieving independence from physical assistance, recent developments in the fields of special education, adolescent development, and family systems suggest redefining autonomy in terms of individuals' capacities to take responsibility for their own behavior, to make decisions about their own lives, and to maintain supportive social relationships. Given this understanding, even individuals with severe impairments can be viewed as autonomous if they perceive their own needs and take responsibility for meeting them, either directly or by engaging the assistance of others. As adolescents become more autonomous, the nurse can help them articulate their needs, participate in developing their own care plans, and discover and express how others can be of greatest assistance.

Physical symptoms are high on teenagers' list of health-related concerns. Because adolescence is a time of enormous physical and emotional changes, it is important for the nurse to distinguish between body changes that are related to the child's complex condition and those that are a result of normal body development. It can be a great comfort for teenagers with disabling conditions to know that many of the changes they experience are normal developmental outcomes.

A sense of feeling different from peers can lead to loneliness, isolation, and depression. Participation in groups of teenagers with chronic conditions or disabilities can alleviate feelings of isolation and smooth the transition to a meaningful relationship with one person in adulthood.

ESTABLISH REALISTIC FUTURE GOALS

One of the most difficult adjustments is setting realistic future goals for the child that are based on the child's own goals and values.

Planning for the future should be a gradual process. All along, the parents should cultivate realistic vocations for the child. For example, if children have physical disabilities, they can be directed toward intellectual, artistic, or musical pursuits. Children with developmental disabilities can be taught manual skills. In this way, the child's development proceeds in the direction of self-support through gainful employment.

With prolonged survival, young people with chronic illnesses must deal with new decisions and problems, such as marriage, employment, and insurance coverage. With appropriate guidance, individuals with disabilities can attain gainful employment, marriage, and a family. For those whose conditions are genetic, counseling is needed regarding future offspring. Prospective spouses often benefit from an opportunity to discuss their feelings about marriage to an individual with continued health needs and possibly a limited life span. Health insurance coverage is a critical issue for chronically ill children because of their enormous health care costs over time. The Affordable Care Act allows young adults to remain on their parents' insurance until they are 26 years old and prevents private insurance carriers from denying them coverage. Life insurance is another dilemma, especially when children have serious conditions, such as congenital heart anomalies.

PERSPECTIVES ON THE CARE OF CHILDREN AT THE END OF LIFE

Although most childhood illnesses and many injuries and other trauma respond favorably to treatment, some do not. When a child and family face a prolonged and life-limiting illness, health professionals must confront the challenge of providing the best possible care to meet the physical, psychologic, spiritual, and emotional needs of the child and family during the uncertain course of the illness and at the time of death. When death is sudden and unexpected, nurses are challenged to respond to grief and shock in families and provide comfort and support in the absence of a prior relationship.

Many factors may contribute to how children die. In infants, the leading causes of death are congenital anomalies, respiratory distress syndrome, disorders related to short gestation and low birth weight, and sudden infant death syndrome (Kochanek, Murphy, Xu, et al., 2014) (see Chapter 1). The leading causes of death in children 5 to 9 years old include injuries (accidents), malignant neoplasms, congenital anomalies, assault (nonaccidental trauma), and heart disease. In children 10 to 14 years old, suicide is the third leading cause of death after injuries (accidents) and malignant neoplasms. In youths 15 to 19 years old, assault (nonaccidental trauma), suicide, malignant neoplasms, and heart disease follow accidents as the most prevalent causes of death (Cunningham, Walton, & Carter, 2018).

A child who is diagnosed with a life-limiting illness requires thorough medical and nursing assessments and tailored interventions that address his or her symptom burden. When cure is no longer possible and life-prolonging measures result in pain and suffering to the child, parents need information about care options to assist them in deciding how they want the remaining time with their child to be managed by the health care team. It is important to reassure families that although their child cannot be cured, active care will continue to be provided to maintain the child's comfort. Support is provided to assist the child and family during the dying process. As a result, nurses may care for children and families who are making the difficult transition from curative or restorative treatments to palliative care (Kang, Munson, Hwang, et al., 2014).

PRINCIPLES OF PALLIATIVE CARE

Palliative care involves a multidisciplinary and interdisciplinary approach to the care of children living with or dying from chronic, complex, or potentially life-limiting conditions. Need, not prognosis, is the primary reason to consult with a palliative care provider. Pediatric palliative care focuses on providing optimal symptom management, helping families align medical interventions (i.e., proceeding with a tracheostomy) with their goals for their child, assisting with complex decision making, and supporting the family and health care team caring for a child with a CCC throughout the trajectory of their illness. Pediatric palliative care helps families explore the "what ifs," optimizing quality of life as determined by the family (and child) (Field & Behrman, 2004). The World Health Organization (1998) amended the definition of palliative care for children to include:

- Palliative care for children is the active total care of the child's body, mind, and spirit and involves giving support to the family.
- It begins when illness is diagnosed and continues regardless of whether a child receives treatment directed at the disease.
- Health providers must evaluate and alleviate the child's physical, psychologic, and social distress.
- Effective palliative care requires a broad interprofessional approach that includes the family and makes use of available community resources; it can be successfully implemented even if resources are limited.
- It can be provided in tertiary care facilities, in community health centers, and even in children's homes.

Palliative care interventions do not serve to hasten death but rather to ameliorate pain and suffering by providing optimal pain and symptom management, attending to issues faced by the child and family with regard to prolonged illness and, when appropriate, death and dying. Maximizing a child's quality of life as defined by the parent and child is a key principle in pediatric palliative care (Feudtner, Friebert, & Jewell, 2013; Kang et al., 2014). The implementation of neonatal and pediatric palliative care consulting services within hospitals has led to enhanced quality of life and end-of-life care for children and their families and support for their care providers (Blume, Balkin, Aiyagari, et al., 2014;

O'Quinn & Giambra, 2014). The child and family are considered the unit of care. Several principles are hallmarks of pediatric palliative care (National Consensus Project for Quality Palliative Care, 2018):

- Palliative care can be provided in tandem with curative and life-prolonging treatments.
- It is provided based on a child's and family's need, not prognosis.
- It should be offered in all care settings—inpatient, outpatient, home, and long-term facilities—and include assessing all domains (physical, social, and emotional).
- Determining what is most important to the patient and family provides guidance in establishing goals and preferences.

The death of a child is an extremely stressful event for a family because it is out of the natural order of things. Children represent health, hope, and the future. Their death calls into question the understanding of life. An interprofessional and interdisciplinary team of health care professionals consists of physicians, nurses, social workers, chaplains, personal care aides, child life specialists, music and art therapists, and bereavement counselors skilled in caring for dying patients. The team assists the family by focusing care on the complex interactions among physical, emotional, social, and spiritual issues.

Palliative care seeks to create a therapeutic environment that is as homelike as possible, if not in the child's own home. Through education and support of family members, an atmosphere of open communication is provided regarding the child's dying process and its impact on all members of the family (see Translating Evidence Into Practice box).

TRANSLATING EVIDENCE INTO PRACTICE

Pediatric Pain and Symptom Management at the End of Life

Ask the Question

PICOT Question

In children, what is the pain and symptom experience at the end of life?

Search for the Evidence

Search Strategies

Published studies using the subject terms *child, palliative care, pain,* and *symptoms* were identified and examined. Retrospective descriptive studies dominated the findings, describing infants' and children's end-of-life experiences through the use of medical record reviews and provider and parental surveys.

Databases Used

PubMed, CINAHL

Critically Analyze the Evidence

Children experienced an average of 11 symptoms during their last week of life (Drake, Frost, & Collins, 2003). Pain, dyspnea, fatigue, nausea, vomiting, irritability, and anorexia are the most common distressing symptoms reported by children at the end of life (Miller, Jacob, & Hockenberry, 2011). A variety of motives influence parental decision to withhold or withdraw life support. Pain and suffering have been reported as one of the most important factors (Meert, Thurston, & Sarnaik, 2000). Even when their child's condition is ominous, parents want to ensure that they are making decisions in the best interest of their child and within the framework of being a good parent—for example, putting their child's needs above their own, focusing on quality of life and maintaining comfort, making sure their child feels loved, and being their advocate (October, Fisher, Feudtner, et al., 2014).

Morphine remains the most commonly prescribed medication for pain and dyspnea (Masman, van Dijk, Tibboel, et al., 2015), and these continue to be the most frequently reported symptoms by parents at the end of their child's life. Parents also report that their child continues to experience high levels of pain when death is near. Physicians were more likely than nurses or parents to report that a child's pain and symptoms were well managed at the end of life, but the majority of both provider groups believed that the child's physical management was difficult (Andresen, Seecharan, & Toce, 2004; Wolfe, Grier, Klar, et al., 2000). When a child is diagnosed with a life-limiting condition, early integration of pediatric palliative care, ideally before a crisis, provides time to get to know the child and family in order to best facilitate conversations regarding goals of care. The focus of pediatric palliative care is to support the child and family, address pain and other bothersome symptoms, and help maximize quality of life. Although the core of pediatric palliative care is the child and family, it also aims to support the primary care team.

Barriers to the adequate provision of pediatric palliative care include developmental issues specific to infants and children; symptoms, their causes, how they are related, and effective treatment strategies; lack of education; and reimbursement issues (Harris, 2004).

Apply the Evidence: Nursing Implications

There is **moderate-quality evidence** with a **strong recommendation** (Guyatt, Oxman, Vist, et al., 2008) for better pain management at the end of life. Although the philosophy of palliative care encompasses pain and symptom management for infants and children who may not outlive their disease, the provision of that care to ease suffering and provide comfort to those who will die continues to lag. Studies show that children experience significant pain and other distressing symptoms at the end of life that are not well managed. Discrepancies in perceptions of infants' and children's pain and suffering continue to exist between providers and parents. Barriers to the provision of pediatric palliative care exist. Improvements are needed in the management of pain and symptoms at the end of life for infants and children.

Quality and Safety Competencies: Evidence-Based Practice[a]

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.
Describe common symptoms experienced at the end of life.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.
Integrate evidence into practice by carefully assessing pain and other symptoms in children at the end of life.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.
Appreciate strengths and weakness of evidence for symptom assessment and management at the end of life.

CONCURRENT CARE

The Patient Protection and Affordable Care Act, now known as the Affordable Care Act (ACA), was passed in 2010 to provide affordable, comprehensive health care. A section of the ACA included a provision to improve health care for children, known as "concurrent care for children." Key points of concurrent care include:

- State Medicaid programs or Children's Health Insurance Program (CHIP) is eligible for both curative and hospice care for children under the age of 21 years.
- Children who receive hospice care can also have other services, including disease-directed treatments.
- Families with children who have life-limiting or life-threatening conditions do not have to choose between disease-directed therapies, palliative care, or hospice (Lindley, Edwards, & Bruce, 2014; National Hospice and Palliative Care Organization, 2010).

DECISION MAKING AT THE END OF LIFE

Discussions about the possibility that a child's illness or condition is not curable and that death is an inevitable outcome cause everyone involved a great deal of stress. Physicians, other members of the health care team, and families must consider all information regarding the child's situation and make decisions that all parties agree to and that will have a profound impact on the child and family.

Ethical Considerations in End-of-Life Decision Making

A number of ethical concerns arise when parents and health care professionals are deciding on the best course of care for the dying child. Many parents and health care providers are concerned that not offering treatment that would cause potential pain and suffering but might extend life would be considered euthanasia or assisted suicide. To eliminate such concerns, it is necessary to understand the various terms. **Euthanasia** involves an action carried out by a person other than the patient to end the life of the patient suffering from a terminal condition. The intent of this action is based on the belief that the act is "putting the person out of his or her misery." **Assisted suicide** occurs when someone provides the patient with the means to end his or her life and the patient uses that means to do so. The important distinction between these two actions involves who is acting to end the person's life.

The American Nurses Association's *Code of Ethics for Nurses* does not support the active intent on the part of a nurse to end a person's life. However, it does permit the nurse to provide interventions to relieve symptoms in the dying patient even when the interventions involve a substantial risk of hastening death. When the prognosis for a patient is poor and death is the expected outcome, it is ethically acceptable to withhold or withdraw treatments that may cause pain and suffering and provide interventions that promote comfort and quality of life (American Nurses Association, 2015).

Physician–Health Care Team Decision Making

Decisions by physicians regarding care are often made on the basis of the progression of the disease or amount of trauma, the availability of treatment options that would provide cure from disease or restoration of health, the impact of such treatments on the child, and the child's overall prognosis (Pousset, Bilsen, Cohen, et al., 2010). Often the main determinants prompting physicians to discuss end-of-life issues and options for children with critical illnesses include the child's age, premorbid cognitive condition and functional status, pain or discomfort, probability of survival, and quality of life (Pousset et al., 2010). When the physician discusses this information openly with families, a shared decision-making process can occur regarding **do not attempt resuscitation (DNaR) orders** and care that is focused on the comfort of the child and family during the dying process (Giannini, Messeri, Aprile, et al., 2008).

Unfortunately, many families are not given the option of terminating treatment and pursuing care that is focused on comfort and quality of life when cure is unlikely, and staff may be reluctant to raise the question of DNaR orders. This occurs for a number of reasons, including the belief that not being able to "save" a child is a "failure." Also, the physician and other members of the health care team may lack knowledge of and experience with the principles of palliative care (Baker, Torkildson, Baillargeon, et al., 2007; Price, Dornan, & Quail, 2013).

Parental Decision Making

Rarely are families prepared to cope with the numerous decisions that must be made when a child is dying. When the death is unexpected, parents are challenged to make difficult choices; this can be especially difficult in emergency settings, as seen in cases of accidents or trauma. If the child has either experienced a life-threatening illness (such as cancer) or lived with a chronic illness that has now reached its terminal phase, parents are often unprepared for the reality of their child's impending death (see Family-Centered Care box). Numerous studies have found that families facing the impending death of a child depend on information provided to them by the health care team, particularly an honest appraisal of the child's prognosis, to make difficult decisions regarding care options for their children (Hinds, Oakes, Furman, et al., 2001; Lipstein, Brinkman, & Britto, 2012; Santoro & Bennett, 2018; Wolfe, Friebert, & Hilden, 2002).

FAMILY-CENTERED CARE

Family of the Dying Child

As the group of health professionals that is most involved with families, nurses are in an excellent position to ensure that families are presented with the options available to them. The nurse's first responsibility is to explore the family's wishes. This is best done in concert with the physician but at times may need to be initiated by the nurse. Statements (such as "Tell me about your thoughts for the type of care you want your child to receive when he is dying" or "Have you considered the types of interventions you would like us to use when your child is near death?") can begin discussion of this sensitive but critical aspect of terminal care.

The Dying Child

Children need honest and accurate information about their illness, treatments, and prognosis. This information needs to be given in clear, simple language. In most situations, this best occurs as a gradual process over time that is characterized by increasingly open dialogue among parents, professionals, and the child (Barnes et al., 2012). Providing an atmosphere of open communication early in the course of an illness facilitates answering difficult questions as the child's condition worsens. Providing appropriate literature about the disease, as well as the experience of illness and possible death, is also helpful. Exactly how and when to involve children in decisions regarding care during their dying process and death is an individual matter. The child's age or developmental level is an important consideration in the process (Table 17.4). In general, parents should be asked how they would like their child to be told of his or her prognosis, and they should be included in his or her care. Some parents may request that their child not be told that he or she is dying even if the child asks. This often places health care providers in a difficult situation. Children, even at a young age, are perceptive. Even if they are not told outright that they are dying, they realize that something is seriously wrong and that it involves them. Often, helping parents understand that honesty and shared decision making between them

and their child are important to the child's and family's emotional health will encourage parents to allow discussion of dying with their child. Parents may require professional support and guidance in this process from a nurse, social worker, or child life specialist who has a good relationship with the child and family.

If given the opportunity, children will tell others how much they want to know. Nurses can help children set limits on how much truth they can accept and cope with by asking questions, such as "If the disease came back, would you want to know?" or "Do you want others to tell you everything even if the news isn't good?" or "If someone were not getting better [or more directly, were dying], do you think he would want to know?" Children need time to process feelings and information so that they can assimilate and ideally accept the reality of impending death.

Care of dying adolescents requires the nurse to become knowledgeable about any possible delays or alterations in normal growth and development. Legal and ethical issues also come to the forefront with respect to the age at which an adolescent should have autonomy in decision making with regard to care and treatment. Effective communication among the patient, family, and health care team is an important part of optimal care for dying adolescents (Barnes et al., 2012). See the Next-Generation NCLEX® Examination-Style Unfolding Case Study.

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

Care at the End of Life

Mpho Raletshegwana

Day 1, 8:00 am

1. A 9-year-old boy has paravertebral fibrosarcoma of the right lumbosacral area, complicated by paraplegia, urine retention, constipation, and neuropathic pain. He has a 5-month history of progressive lower back pain and swelling and paralysis of the lower limbs. The patient received and responded well to chemotherapy and radiotherapy, with a 40% regression in his tumor. However, the patient continued to suffer severe "burning/piercing" pain in the lower extremities, especially when the limbs are moved. He continues to require oral analgesics daily and remains bedridden with weakness of the lower extremities. Because of the clinically poor response and poor long-term prognosis, a decision was made by him and his family to focus on comfort and consult palliative care. Plans are for him to be discharged on hospice care once the pain is managed.
   The nursing admission assessment reveals the following results. **Select the assessment findings that need further follow up. Select all that apply.**
   - A. Temperature = 98.6 F (37.0 C)
   - B. Blood pressure = 100/58mmHg
   - C. Heart rate = 124 beats/min
   - D. Respirations = 16 breaths/min
   - E. Visual pain score 8/10
   - F. Persistent localized pain in the vertebrae or lumbar region
   - G. Burning/piercing pain in the lower extremities or neuropathic pain
   - H. Swelling around the lower lumbar area
   - I. Numbness of the lower extremities due to pressure exerted on nerves
   - J. Capillary refill <3 sec in left finger
   - K. Weight = 60 lbs (27.2 kg)

Day 1, 8:30 am

2. Pain is not being controlled by low-dose oral pain medications and opioids, and the plan is to begin intravenous (IV) pain medications to control his pain. Since it is unclear from the history exactly how much morphine has been given and at what intervals throughout the day, the plan is to use a standard starting dose of IV morphine.
   Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided. (Chapter 5 can be used to answer this question if needed).
   An appropriate standard starting dose of IV morphine to administer is____1____. This may be given every 10 minutes for three doses until pain relief is achieved, then scheduled every ____2____hours.

Option 1	Option 2
1–2 mg/kg	4 hours
0.1 to 0.2 mg/kg	15 min
0.5–1.0 mg/kg	2 hours
0.1–1 mg/kg	6 hours
1.0–2.0 mg/kg	10 min

Day 1, 9:15 am

3. IV morphine was started, and the pain assessment revealed a score of 3/10. Because this patient is 9 years old, consideration must be given to the type of pain assessment tool that is most appropriate for a child this age. What specifically would the nurse consider when completing a pain assessment of this 9-year-old? **Select all that apply.**
   - A. Self-report should be used
   - B. Observe the child's behavior
   - C. Evaluate how the patient responds
   - D. Use an infant scale since he is in a great deal of pain
   - E. Use a verbal intensity scale (less, moderate, or severe pain)
   - F. Assess pain once a shift and do not disrupt sleep
   - G. If the child is in a great deal of pain use the Wong-Baker FACES Pain Rating Scale

Day 1, 10:00 am

4. The patient is resting comfortably with both parents at his side. The IV morphine dose is relieving the pain. Further discussion with the mother reveals that the child is also taking gabapentin orally due to the burning/piercing pain in his lower extremities. She states that since starting on this medication the burning sensations have resolved. The nurse reports this to the medical team and oral gabapentin is ordered. What potential complications are prevented by the nursing actions listed below?
   Indicate which nursing action number listed in the far-left column is appropriate for the potential complication listed in the middle column. Place the number in the far-right column. Note that NOT all nursing actions will be used.

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—Cont'd

Care at the End of Life

Nursing Action	Potential Complication	Nursing Action for Complication
1. Administer morphine safely. Observe the patient for excessive sedation and respiratory depression.	To reduce unfounded fears.	
2. Monitor for side effects of morphine: decreased respiratory rate, urinary retention, constipation, and pruritus.	To prevent unwanted side effects that may cause additional discomfort.	
3. Educate parents on the safety and effectiveness of the pain-relieving medications.	To ensure optimal pain relief.	
4. Reassess the pain level after administering pain medication. Assess within 1 hour of oral morphine and 30 minutes after IV administration.	To prevent adverse effects and overdose	
5. Recognize when pain is not well controlled on morphine.	To ensure satisfactory pain relief.	
6. Provide appropriate bowel regimen and monitor urine output.		
7. Provide distraction and counseling to assure parents that everything possible is being done.		

2 days later, 9:00 am

5. The parents and child want to go home and want to manage the pain with oral medications. Since the current dose of morphine provides adequate relief, a plan for pain management on discharge is made to switch to oral morphine. The most recent nursing assessment reveals the following:
   - Temperature = 98.6 F (37C)
   - Blood pressure = 104/60mmHg
   - Heart rate = 76 beats/min
   - Respirations = 16 breaths/min
   - Visual pain score 2/10
   - No burning/piercing pain in the lower extremities or neuropathic pain
   - Swelling remains around the lower lumbar area

   The nurse discusses proper administration of the pain medications at home. His regimen will include both oral morphine and gabapentin.

   For each nursing action, use an X to indicate whether it was Effective (helped to meet expected quality patient outcomes), Ineffective (did not help to meet expected quality patient outcomes), or Unrelated (not related to the quality patient outcomes).

Nursing Action	Effective	Ineffective	Unrelated
Assure parents that the IV morphine dose can be the same dose they administer at home			
Instruct parents to continue around-the-clock medications at home			
Encourage parents to communicate any signs of pain; observe patient for nonverbal signs of pain			
A home bowel regimen should be included in the discharge teaching			
Instruct parents to talk to other family members about their feelings toward pain management			
Stress with the parents that escalating doses will not be needed, and that tolerance to pain medications never occur in children			
Discuss appropriate nonpharmacologic options that can relieve pain			

12:00 noon

6. The nurse while obtaining vital signs notes that the patient looks more withdrawn. He no longer talks to the nursing staff and the parents answer all assessment questions. The mother also notices this and asks the nurse why her son is no longer talking to others. She states he seems to be shutting himself off from the world and wants to know if this is what children do when they are dying. The mother confides to the nurse that she is scared to take him home and asks how the hospice nurse will be of support to her during her son's last days. How would the nurse respond to her question? **Select all that apply.**
   - A. "The hospice nurse will stay with you in your house until your child dies."
   - B. "The hospice nurse will focus on providing comfort for you child."
   - C. "The hospice nurse will keep you informed of what is happening to your child."
   - D. "The hospice nurse will bring your child to the hospital if he gets worse."
   - E. "The hospice nurse will focus on minimizing pain experienced by your child."
   - F. "The hospice nurse will begin antibiotics if your child has fever."
   - G. "The hospice nurse will answer any questions you have."

TABLE 17.4 Children's Understanding of and Reactions to Death

Concepts of Death	Reactions to Death	Nursing Care Management
Infants and Toddlers		
Death has least significance to children younger than 6 months old. After parent-child attachment and trust are established, the loss, even if temporary, of the significant person is profound. Prolonged separation during the first several years is thought to be more significant in terms of future physical, social, and emotional growth than at any subsequent age. Toddlers are egocentric and can only think about events in terms of their own frame of reference—living. Their egocentricity and vague separation of fact and fantasy make it impossible for them to comprehend absence of life. Instead of understanding death, this age-group is affected more by any change in lifestyle.	With the death of someone else, they may continue to act as though the person is alive. As children grow older, they will be increasingly able and willing to let go of the dead person. Ritualism is important; a change in lifestyle could be anxiety producing. This age-group reacts more to the pain and discomfort of a serious illness than to the probable fatal prognosis. This age-group also reacts to parental anxiety and sadness.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Encourage parents to remain as near to child as possible yet be sensitive to parents' needs. Maintain as normal an environment as possible to retain ritualism. If a parent has died, encourage having consistent caregiver for child. Promote primary nursing.
Preschool Children		
Preschoolers believe their thoughts are sufficient to cause death; the consequence is the burden of guilt, shame, and punishment. Their egocentricity implies a tremendous sense of self-power and omnipotence. They usually have some understanding of the meaning of death. Death is seen as a departure, a kind of sleep. They may recognize the fact of physical death but do not separate it from living abilities. Death is seen as temporary and gradual; life and death can change places with one another. They have no understanding of the universality and inevitability of death.	If they become seriously ill, they conceive of the illness as a punishment for their thoughts or actions. They may feel guilty and responsible for the death of a sibling. Greatest fear concerning death is separation from parents. They may engage in activities that seem strange or abnormal to adults. Because they have fewer defense mechanisms to deal with loss, young children may react to a less significant loss with more outward grief than to the loss of a very significant person. The loss is so deep, painful, and threatening that the child must deny it for a time to survive its overwhelming impact. Behavior reactions such as giggling, joking, attracting attention, or regressing to earlier developmental skills indicate children's need to distance themselves from tremendous loss.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Help parents understand behavioral reactions of their children. Encourage parents to remain near the child as much as possible to minimize the child's great fear of separation from parents. If a parent has died, encourage having a consistent caregiver for child. Promote primary nursing.
School-Age Children		
Children still associate misdeeds or bad thoughts with causing death and feel intense guilt and responsibility for the event. Because of their higher cognitive abilities, they respond well to logical explanations and comprehend the figurative meaning of words. They have a deeper understanding of death in a concrete sense. They particularly fear the mutilation and punishment that they associate with death. They personify death as the devil, a monster, or the bogeyman. They may have naturalistic or physiologic explanations of death. By 9 or 10 years old, children have an adult concept of death, realizing that it is inevitable, universal, and irreversible.	Because of their increased ability to comprehend, they may have more fears, for example: • The reason for the illness • Communicability of the disease to themselves or others • Consequences of the disease • The process of dying and death itself Their fear of the unknown is greater than their fear of the known. The realization of impending death is a tremendous threat to their sense of security and ego strength. They are likely to exhibit fear through verbal uncooperativeness rather than actual physical aggression. They are interested in postdeath services. They may be inquisitive about what happens to the body.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Encourage parents to remain near child as much as possible yet be sensitive to parents' needs. Because of children's fear of the unknown, anticipatory preparation is important. Because the developmental task of this age is industry, interventions of helping children maintain control over their bodies and increasing their understanding allow them to achieve independence, self-worth, and self-esteem and avoid a sense of inferiority. Encourage children to talk about their feelings and provide aggressive outlets. Encourage parents to honestly answer questions about dying rather than avoiding the subject or fabricating euphemisms. Encourage parents to share their moments of sorrow with their children. Provide preparation for postdeath services.

TABLE 17.4 Children's Understanding of and Reactions to Death—cont'd

Concepts of Death	Reactions to Death	Nursing Care Management
Adolescents		
Adolescents have a mature understanding of death. They are still influenced by remnants of magical thinking and are subject to guilt and shame. They are likely to see deviations from accepted behavior as reasons for their illness.	Adolescents straddle transition from childhood to adulthood. They have the most difficulty in coping with death. They are least likely to accept cessation of life, particularly if it is their own. Concern is for the present much more than for the past or the future. They may consider themselves alienated from their peers and unable to communicate with their parents for emotional support, feeling alone in their struggle. Adolescents' orientation to the present compels them to worry about physical changes even more than the prognosis. Because of their idealistic view of the world, they may criticize funeral rites as barbaric, money making, and unnecessary.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Avoid alliances with either parent or child. Structure hospital admission to allow for maximum self-control and independence. Answer adolescents' questions honestly, treating them as mature individuals and respecting their needs for privacy, solitude, and personal expressions of emotions. Help parents understand their child's reactions to death and dying, especially that concern for present crises (such as loss of hair) may be much greater than for future ones, including possible death.

Treatment Options for Terminally Ill Children

Based on the child and family's decision regarding their wishes for terminal care, they have several options from which to choose.

Hospital

Families may choose to remain in the hospital to receive care if the child's illness or condition is unstable and home care is not an option or the family is uncomfortable with providing care at home. If a family chooses to remain at the hospital for terminal care, the setting should be made as homelike as possible. Families are encouraged to bring familiar items from the child's room at home. In addition, there should be a consistent and coordinated care plan for the comfort of the child and family.

Home Care

Some families prefer to take their child home and receive services from a home care agency. Generally, these services entail periodic nursing visits to administer a treatment or provide medications, equipment, or supplies. The child's care continues to be directed by the primary physician. Home care is often the option chosen by physicians and families because of the traditional view that a child must be considered to have a life expectancy of less than 6 months to be referred to hospice care. Fortunately, a number of hospice organizations are expanding their services to children based on the presence of a life-limiting disease process for which cure is not possible, rather than on the sole criterion of a limited time-projected prognosis.

Hospice Care

Parents should be offered the option of caring for their child at home during the final phases of an illness with the assistance of a hospice organization. **Hospice**[g] is a community health care organization that specializes in the care of dying patients by combining the hospice philosophy with the principles of palliative care. **Hospice philosophy** regards dying as a natural process and care of dying patients as including management of the physical, psychosocial, and spiritual needs of the patient and family. Care is provided by an interprofessional group in the patient's home or an inpatient facility that uses the hospice philosophy. Hospice care for children was introduced in the 1970s, and a number of community hospice organizations now accept children into their care (Keim-Malpass, Hart, & Miller, 2013; Siden, Chavoshi, Harvey, et al., 2014). However, access to freestanding pediatric hospice services continues to be highly variable (Kassam & Wolfe, 2013). Collaboration between the child's primary treatment team and the hospice care team is essential to the success of hospice care. Families may continue to see their primary care physicians as they choose.

Hospice care is based on a number of important concepts that significantly set it apart from hospital care:

- Family members are usually the principal caregivers and are supported by a team of professional and volunteer staff.
- The priority of care is comfort. The child's physical, psychosocial, and spiritual needs are considered. Pain and symptom control are primary concerns, and no extraordinary efforts are used to attempt a cure or prolong life.
- The family's needs are considered as important as those of the patient.
- Hospice is concerned with the family's postdeath adjustment, and care may continue for a year or more.

The goal of hospice care is for children to live life to the fullest without pain, with choices and dignity, in the familiar environment of their home, and with the support of their family. Hospice care is covered under state Medicaid programs and by most insurance plans. The service provides home visits from nurses, social workers, chaplains, and, in some cases, physicians. Medications, medical equipment, and any necessary medical supplies are all provided by the hospice organization providing care.

With children, the home has been the more common environment for implementing the hospice concept, and this benefits the family in various ways. Children who are dying are allowed to remain with those they love and with whom they feel secure. Many children who were thought to be in imminent danger of death have gone home and lived longer than expected. Siblings can feel more involved

[g]For more information, contact National Hospice and Palliative Care Organization, 1731 King Street, Alexandria, VA 22314; 703-837-1500; fax: 703-837-1233; http://www.nhpco.org; and Children's Hospice International, 1800 Diagonal Road, Suite 600, Alexandria, VA 22314; 703-684-0330; http://www.chionline.org.

in the care and often have more positive perceptions of the death. Parental adaptation is often more favorable, demonstrated by their perceptions of how the experience at home affected their marriage, social reorientation, religious beliefs, and views on the meaning of life and death.

If the home is chosen for hospice care, the child may or may not die in the home. Reasons for final admission to a hospital vary but may be related to the parents' or siblings' wish to have the child die outside the home, exhaustion on the part of the caregivers, and physical problems such as sudden, acute pain or respiratory distress.

BOX 17.8 Ethical Principle of Double Effect

An action that has one good (intended) and one bad (unintended but foreseeable) effect is permissible if the following conditions are met:

- The action itself must be good or indifferent. Only the good consequences of the action must be sincerely intended.
- The good effect must not be produced by the bad effect.
- There must be a compelling or proportionate reason for permitting the foreseeable bad effect to occur.

NURSING CARE OF THE CHILD AND FAMILY AT THE END OF LIFE

Regardless of where the child is cared for during the terminal stage of illness, both the child and the family usually experience fear of (1) pain and suffering, (2) dying alone (child) or not being present when the child dies (parent), and (3) actual death. Nurses can help families by lessening their fears through attention to the care needs of the child and family.

FEAR OF PAIN AND SUFFERING

The presence of unrelieved pain in a terminally ill child can have detrimental effects on the quality of life experienced by the child and family. Parents feel that having their child in pain is unendurable, and this results in feelings of helplessness and a sense that they must be present and vigilant to get the necessary pain medications. Persistent pain also has an impact on the family as a whole. Nurses can alleviate the fear of pain and suffering by providing interventions aimed at treating the pain and symptoms associated with the terminal process in children.

Pain and Symptom Management

Pain control for children in the terminal stages of illness or injury must be given the highest priority. Despite ongoing efforts to educate physicians and nurses on pain management strategies in children, studies have reported that children continue to be undermedicated for their pain (Wolfe, Grier, Klar, et al., 2000). Nearly all children experience some amount of pain in the terminal phase of their illness. The current standard for treating children's pain follows the World Health Organization's analgesic stepladder, which promotes tailoring the pain interventions to the child's level of reported pain. Children's pain should be assessed frequently and medications adjusted as necessary. Pain medications should be given on a regular schedule, and extra doses for breakthrough pain should be available to maintain comfort. Opioid drugs such as morphine should be given for severe pain, and the dose should be increased as necessary to maintain optimal pain relief (World Health Organization, 2012). Techniques such as distraction, relaxation techniques, and guided imagery (Jibb, Nathan, Stevens, et al., 2015) should be combined with drug therapy to provide the child and family with strategies to control pain (see Chapter 5 for further discussion of pain management strategies).

In addition to pain, children experience a variety of symptoms during their terminal course as a result of their disease process or as a side effect of medicines used to manage pain or other symptoms. These symptoms include fatigue, nausea and vomiting, constipation, anorexia, dyspnea, congestion, seizures, anxiety, depression, restlessness, agitation, and confusion (von Lützau, Otto, Hechler, et al., 2012; Wolfe et al., 2002). Each of these symptoms should be aggressively managed with appropriate medications or treatments and with interventions such as repositioning, relaxation, massage, and other measures to maintain the child's comfort and quality of life.

Occasionally, children require very high doses of opioids to control pain. This may occur for several reasons. Children on long-term opioid pain management can become **tolerant** of the drug, meaning that it is necessary to give more drugs to maintain the same level of pain relief. This should not be confused with **addiction**, which is a psychologic dependence on the side effects of opioids. Addiction is not a factor in managing terminal pain in children. Other obvious reasons for requiring increased doses of opioids include progression of disease and other physiologic experiences of pain. It is important to understand that there is no maximum dose that can be given to control pain. However, nurses often express concern that administering doses of opioids that exceed what they are familiar with will hasten the child's death. The **principle of double effect** (Box 17.8) addresses such concerns. It provides an ethical standard that supports the use of interventions intended to relieve pain and suffering even though there is a foreseeable possibility that death may be hastened (Twycross, 2019). In cases in which the child is terminally ill and in severe pain, using large doses of opioids and sedatives to manage pain is justified when no other treatment options that would relieve the pain but make the risk of death less likely are available (DeGraeff & Dean, 2007; Jacobs, 2005). See Chapter 5 for an extensive discussion of pain assessment and management.

Parents' and Siblings' Need for Education and Support

Parents are the primary caregivers when the child is at home, and nurses providing care to the child and family need to teach the family about the medications being given to the child, how to administer them, and the use of nonpharmacologic techniques. This empowers parents and provides a sense of control over the child's comfort and well-being, reducing their fear that the child will be in pain or suffering as he or she is dying. In addition, better bereavement outcomes (e.g., adaptive coping; family cohesion; less anxiety, stress, and depression) have been reported by parents who were actively involved in the care of their child (Goodenough, Drew, Higgins, et al., 2004; Lauer, Mulhern, Schell, et al., 1989). The grief work of fathers in particular seems to be facilitated when their child dies in the home setting. This finding may be related to the increased opportunity of working fathers to provide care to and spend time with their child at home versus the hospital setting.

Siblings may feel isolated and displaced during the time their brother or sister is dying. Parents devote most of their time to the care and comfort of the dying child, causing siblings to feel left out of the parent–sick child relationship. The death of a child affects the entire family, and feelings of loss can also extend into the community.

Fig. 17.6 For a dying child, there is no greater comfort than the security and closeness of a parent.

Immediately after a death, siblings may exhibit changes in behavior, but the long-term psychosocial outcomes of bereaved siblings are not known.

Siblings may become resentful of their sick sibling and begin to feel guilty or ashamed about such feelings (Murray, 1999). Nurses can assist the family by helping the parents identify ways to involve siblings in the caring process, perhaps by bringing some supplies or a favorite toy, game, or food item. Parents should also be encouraged to schedule time focusing on the siblings. Helping parents identify a trusted friend or family member who can sit with the ill child for a short period will allow them to attend to their own needs or those of their other children.

FEAR OF DYING ALONE OR OF NOT BEING PRESENT WHEN THE CHILD DIES

When a child is being cared for at home, the burden of care on parents and family members can be great. Often, as the child's condition declines, family members begin the "death vigil." Rarely is a child left alone for any length of time. This can be exhausting for family members, and nurses can assist the family by helping them arrange shifts so that friends or family members can be present with the child and allow others to rest. If the family has limited resources, community organizations, such as hospice or churches, often have volunteers who are willing to visit and sit with children. It is important that whoever is sitting with the child be aware of when the parent(s) would like to be notified to return to the child's bedside (Fig. 17.6).

When a child is dying in the hospital, the parents should be given full access to the child at all times. If the parents need to leave, they should be provided with a pager or other means of immediate communication and alerted if staff members note any change in the child that may indicate imminent death. Nurses should advocate for parents' presence in intensive care and emergency departments and attend to the parents' needs for food, drinks, comfortable chairs, blankets, and pillows.

BOX 17.9 Physical Signs of Approaching Death

Loss of sensation and movement in the lower extremities, progressing toward the upper body
Sensation of heat, although the body feels cool
Loss of senses:
- Tactile sensation decreasing
- Sensitivity to light
- Hearing the last sense to fail

Confusion, loss of consciousness, slurred speech
Muscle weakness
Loss of bowel and bladder control
Decreased appetite and thirst
Difficulty swallowing
Change in respiratory pattern:
- Cheyne-Stokes respirations (waxing and waning of depth of breathing with regular periods of apnea)
- "Death rattle" (noisy chest sounds from accumulation of pulmonary and pharyngeal secretions)

Weak, slow pulse; decreased blood pressure

FEAR OF ACTUAL DEATH

Home Deaths

Most children receiving hospice care die at home; they often die in their own room with family, pets, and loved possessions around them. The physical process of dying can be distressing to parents because often the child slowly becomes less alert in the days before the actual death. The nurse can assist the family by providing them with information about what changes will occur as the child progresses through the dying process (Box 17.9). During this time, nursing visits often become more frequent and longer in duration to provide the family with additional support as the death nears. The most distressing change for parents to observe is the change in the respiratory pattern. In the final hours of life, the dying patient's respirations may become labored, with deep breaths and long periods of apnea, referred to as *Cheyne-Stokes respirations.* Families should be reassured that this is not distressing to the child and that it is a normal part of the dying process. However, the use of opioids can slow the respirations to make the child breathe more easily, and scopolamine, usually applied as a topical patch, can help reduce noisy respirations known as the "death rattle." Noisy respirations are more likely to occur if the child is overhydrated.

All families have the option of admitting their child to the hospital if they feel unable to deal with the death. The child who dies at home must be pronounced dead. Hospice programs typically have provisions so that this proceeds smoothly. In some circumstances, the police may be notified, with an explanation of the circumstances to prevent unnecessary concern regarding abuse. Providing the police with the number of the responsible practitioner is usually all that is necessary to confirm the cause of death.

Hospital Deaths

Children dying in the hospital who are receiving supportive care interventions experience a similar process. Death resulting from accident or trauma or acute illness in settings such as the emergency department or intensive care unit often requires the active withdrawal of some form of life-supporting intervention, such as a ventilator or

bypass machine. These situations often raise difficult ethical issues (Sullivan, Monagle, & Gillam, 2014), and parents are often less prepared for the actual moment of death. Nurses can assist these parents by providing detailed information about what will happen as supportive equipment is withdrawn, ensuring that appropriate pain medications are administered to prevent pain during the dying process and allowing the parents time before the start of the withdrawal to be with and speak to their child. It is important that the nurse attempt to control the environment around the family at this time by providing privacy, asking if they would like to play music, softening lights and monitor noises, and arranging for any religious or cultural rituals that the family may want performed.

After the child's death, the family should be allowed to remain with the body and hold or rock the child if they desire. After the nurse has removed all tubes and equipment from the body, the parents should be given the option of assisting with the preparation of the body, such as bathing and dressing. It is important for the nurse to determine whether the family has any specific needs because many cultures have adopted specific methods for coping with and mourning death, and impeding these practices may interfere with the grieving process (Clements, Vigil, Manno, et al., 2003).

At some point, the nurse discusses whether the family has made preparations for the burial service and whether the staff can help in any way. Parents often have concerns about the funeral, such as siblings' involvement in the death rituals. Although no absolute answers exist regarding the question of siblings attending the funeral or burial services, the consensus is that the surviving children benefit from being involved in these events. However, children need preparation for post-death services. They should be told what to expect, particularly how the deceased person will look if the coffin is open; allowed private time to say goodbye; and permitted to stay as long as they wish. Ideally, the parents should prepare the siblings. If the parents' grief prevents this communication, a significant family member or friend should substitute.

ORGAN OR TISSUE DONATION AND AUTOPSY

For some families, organ or tissue donation may be a meaningful act—one that benefits another human being despite the loss of their child. Unfortunately, initiating a discussion about tissue donation is often stressful for staff, and there may be confusion regarding whose responsibility this is. In centers in which transplants are performed, a full-time transplant coordinator is usually available to inform the family about organ donation and to take care of details. If such services are not available, the staff needs to determine which members should discuss this topic with the family. Ideally, the person who knows the family best, knows when the death is expected, or has an opportunity to spend time with the family when the death is unexpected takes the role. Often nurses are in an optimal position to suggest tissue donation after consultation with the attending physician. When possible, the topic should be raised before death occurs. The request should be made in a private and quiet area of the hospital and should be simple and direct with questions such as "Are you a donor family?" or "Have you ever considered organ donation?"

Many states have legislated a mandatory request for organ or tissue donation when a child dies, especially if the patient is brain dead. Written consent from the family is required before donation can proceed. When requests for organ donation are made, health care practitioners must address common misunderstandings families have about brain death and organ donation (Franz, DeJong, Wolfe, et al., 1997). Training health care professionals on sensitive approaches to requests for organ donation has been shown to increase families' willingness to consent to organ donation (Workman, Myrick, Meyers, et al., 2013). The option to donate organs should always be separate from the communication of impending or actual death.

Nurses need to be aware of common questions about organ donation to help families make an informed decision. Healthy children who die unexpectedly are excellent candidates for organ donation. Children with cancer, chronic disease, or infection, and those who have suffered prolonged cardiac arrest may not be suitable candidates, although this is individually determined. The nurse should ask whether organ donation was discussed with the child or whether the child ever expressed such a wish. Any number of body tissues or organs can be donated (skin, corneas, bone, kidney, heart, liver, pancreas), and their removal does not mutilate or desecrate the body or cause any suffering. The family may have an open casket, and there is no delay in the funeral. There is no cost to the donor family, but organ donation does not eliminate funeral or cremation responsibilities. With the exception of Orthodox Judaism, most religions permit organ donation as long as the recipient benefits from the transplant. In cases of unexplained death, violent death, or suspected suicide, autopsy is required by law. In other instances, it may be optional, and parents should be informed of this choice. The procedure, as well as forms that require signing, should be explained. The family should know that the child can be in an open casket after an autopsy.

GRIEF AND MOURNING

Grief is a process, not an event, of experiencing physiologic, psychologic, behavioral, social, and spiritual reactions to the loss of a child. Grief is highly individualized, encompassing a broad range of manifestations from person to person. It is a natural and expected reaction to loss. It is neither orderly nor predictable. Grieving in any form is necessary for healing to occur. When death is the expected or a possible outcome of a disorder, the child and family members may experience **anticipatory grief**. Anticipatory grief may be manifested in varying behaviors and intensities and may include denial, anger, depression, and other psychologic and physical symptoms.

Anticipatory guidance may assist grieving family members. Health care professionals should emphasize that grief reactions such as hearing the dead person's voice, feeling distant from others, or seeking reassurance that they did everything possible for the lost person are normal, necessary, and expected. They in no way signify poor coping, insanity, or an approaching mental breakdown. On the contrary, such behaviors signify that the survivor is working through the acute grief. Anticipatory guidance regarding the mourning process may help families recognize the normalcy of their experiences.

It is important to recognize that some family members may experience complicated grief. **Complicated grief reactions** (>1 year after the loss) include such symptoms as intense intrusive thoughts, pangs of severe emotion, distressing yearnings, feelings of excessive loneliness and emptiness, unusual sleep disturbance, and maladaptive levels of loss of interest in personal activities (Meert et al., 2011). Bereaved persons experiencing such prolonged and complicated grief should be referred to an expert in grief and bereavement counseling.

Another important aspect of grief is the individual nature of the grief experience. Each member of the family will experience the grief of the child's death in his or her own way based on the particular relationship with that child. This can create potential conflict for families, because each family member has expectations that the other family members should feel and grieve as they do. Nurses caring for families experiencing grief should be aware of the different grieving styles and help the family learn to recognize and support the uniqueness of each other's grief.

Parental Grief

Parental grief after the death of a child has been found to be the most intense, complex, long-lasting, and fluctuating grief experience compared with that of other bereaved individuals. Although parents experience the primary loss of their child, many secondary losses are felt, such as the loss of part of one's self, hopes and dreams for the child's future, the family unit, prior social and emotional community supports, and often spousal support. It is common for parents of the same child to experience different grief reactions.

Studies with bereaved parents have shown that grieving does not end with the severing of the bond with the deceased child but rather involves a continuing bond between the parent and the deceased child (Klass, 2001). Parental resolution of grief is a process of integrating the dead child into daily life in which the pain of losing a child is never completely gone but lessens. There are occasions of brief relapse but not to the degree experienced when the loss initially occurred. Thus parental grief work is never completed and is a timeless process of accommodating the new reality of being without a child as it changes over time (Davies, 2004). A child's death can also challenge the marital relationship in several ways. Maternal and paternal reactions often differ (Hendrickson, 2009; Moriarty, Carroll, & Cotroneo, 1996; Scholtes & Browne, 2015; Vance, Najman, Thearle, et al., 1995). Different grieving styles between the couple may hinder communication and support for each other. Differing needs and expectations can place a strain on the marriage.

Sibling Grief

Each child grieves in his or her own way and on his or her own timeline. Children, even adolescents, grieve differently than adults. Adults and children differ more widely in their reactions to death than in their reactions to any other phenomenon. Children of all ages grieve the loss of a loved one, and their understanding and reactions to death depend on their age and developmental level. Children grieve for a longer duration, revisiting their grief as they grow and develop new understandings of death. However, they do not grieve 100% of the time. They grieve in spurts and can be emotional and sad in one instance and then, just as quickly, off and playing. Children express their grief through play and behavior. Children can be exquisitely attuned to their parents' grief and will try to protect them by not asking questions or by trying not to upset them. This can set the stage for the sibling to try to become the "perfect child." Children exhibit many of the grief reactions of adults, including physical sensations and illnesses, anger, guilt, sadness, loneliness, withdrawal, acting out, sleep disturbances, isolation, and search for meaning. Again, nurses should be attentive for signs that siblings are struggling with their grief and provide guidance to parents when possible.

At times, family members may need assistance in their grieving (see Nursing Care Guidelines box). Communication with the bereaved family is essential, but often nurses do not know what to say and feel helpless in offering words of comfort. The most supportive approach is to avoid judging the family's reactions or offering advice or rationalizations and to focus on feelings. Perhaps the most valuable supportive measure the nurse can perform for families is to listen. Families understand that no words will relieve their pain; all they want is acceptance, understanding, and respect for their grief.

It is important for families to understand that mourning takes a long time. Whereas acute grief may last only weeks or months, resolving the loss is measured in years. Holidays and anniversaries can be particularly difficult, and people who previously had been supportive may now expect the family to have "adjusted." Consequently, prolonged mourning is often silent and lonely.

Many families never receive the support and guidance that could help them resolve the loss. A plan for regular follow-up with bereaved families can be beneficial. At minimum, one follow-up phone call or meeting with the family should be arranged. Families can also be referred to self-help groups. When such groups are not available, nurses can be instrumental in bringing families together or facilitating parent and sibling groups. Formal bereavement programs or bereavement counseling can be helpful as well.

NURSING CARE GUIDELINES

Supporting Grieving Families[a]

General

Stay with the family; sit quietly if they prefer not to talk; cry with them if desired.
Accept the family's grief reactions; avoid judgmental statements (e.g., "You should be feeling better by now").
Avoid offering rationalizations for the child's death (e.g., "Your child isn't suffering anymore").
Avoid artificial consolation (e.g., "I know how you feel," "You are still young enough to have another baby").
Deal openly with feelings such as guilt, anger, and loss of self-esteem.
Focus on feelings by using a feeling word in the statement (e.g., "You're still feeling all the pain of losing a child").
Refer the family to an appropriate self-help group or for professional help if needed.

At the Time of Death

Reassure the family that everything possible is being done for the child if they want life-saving interventions.
Do everything possible to ensure the child's comfort, especially relieving pain.
Provide the child and family with the opportunity to review special experiences or memories in their lives.
Express personal feelings of loss or frustrations (e.g., "We will miss him so much," "We tried everything; we feel so sorry that we couldn't save her").
Provide information that the family requests and be honest.
Respect the emotional needs of family members, such as siblings, who may need brief respites from the dying child.
Make every effort to arrange for family members, especially the parents, to be with the child at the moment of death if they want to be present.
Allow the family to stay with the dead child for as long as they wish and to rock, hold, or bathe the child.
Provide practical help when possible, such as collecting the child's belongings.
Arrange for spiritual support based on the family's religious beliefs; pray with the family if no one else can stay with them.

Post Death

Attend the funeral or visitation if there was a special closeness with the family.
Initiate and maintain contact (e.g., sending cards, telephoning, inviting them back to the unit, making a home visit).
Refer to the dead child by name; discuss shared memories with the family.
Discourage the use of drugs and alcohol as a method of escaping grief.
Encourage all family members to communicate their feelings rather than to remain silent to avoid upsetting another family member.
Emphasize that grieving is a painful process that often takes years to resolve.

[a] "Family" refers to all significant persons involved in the child's life, such as parents, siblings, grandparents, and other close relatives or friends.

NURSES' REACTIONS TO CARING FOR DYING CHILDREN

The caring for a dying child can be one of the most stressful aspects of nursing, it can also be incredibly rewarding. Even when a child is not expected to live, his or her death seems unnatural. Nurses experience reactions to the death of a patient that are very similar to the responses of family members, including denial, anger, depression, guilt, and ambivalent feelings

Strategies that can assist nurses in maintaining the ability to work effectively in these settings include maintaining good general health, developing well-rounded interests, using distancing techniques such as taking time off when needed, developing and using professional and personal support systems, cultivating the capacity for empathy, focusing on the positive aspects of the caregiver role, and basing nursing interventions on sound theory and empiric observations. Attending shared-remembrance rituals, sharing stories about their patient and experiences, can also help some nurses resolve their grief (Rice, Bennett, & Billingsley, 2014). Similarly, attending the funeral services can be a supportive act for both the family and the nurse and in no way detracts from the professionalism of care.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. When caring for a 4-year-old with a chronic disability, the nurse notes that while encouraging the child to take part in his own care, the mother constantly gives in to the child, allowing him to have his own way. While in the exam room, the child refused to get on the table and the mother allowed him to remain on the floor making it impossible for the nurse to obtain a blood pressure. What anticipatory guidance can the nurse give to promote normalization in this relationship? **Use an X for the health teaching statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
"'Giving in' is not a detriment to your child when he or she has a disability and limitations."			
"When parents establish reasonable limits, children are likely to develop independence that is appropriate for their age and achievement equal to their limitations."			
"It is best to wait to explain any procedure to the child until they are at the health care setting or just before the procedure to avoid unduly upsetting your child."			
"I recommend talking to other mothers in your neighborhood about how they parent their children."			
"It is important to realize that it would be unfair to the siblings to expect similar rules to apply to all children in the family."			

2. A 5-year-old boy with cystic fibrosis is hospitalized with pneumonia. His mother remains by his side and confides in the nurses that she is having difficulty coping with her child's chronic illness. She is a single mother and the father is not around. It is important for the nurse to realize that children with disabilities or chronic illness and their families may have different methods of coping than those of healthy children. Often, they have a resilience that is to be admired. Which of these statements reflect ways in which this mother can foster resilience in her young boy? **Select all that apply.**
   - **A.** Accept that chronic illness is part of living.
   - **B.** Home school the child until he is in high school.
   - **C.** Focus on the child's strengths and encourage independence.
   - **D.** The parents should set long-term goals to create a sense of hope.
   - **E.** Protect the child from having to learn about his or her disability or illness on a repeated basis.
   - **F.** Develop relationships with other children and their families who have similar circumstances to build support.

3. A 10-year-old girl is admitted to the hospital with pneumonia. She has acute lymphocytic leukemia and is in relapse. The nurse admitting her is reviewing her pain medications since she has been on oral morphine at home for the past month. Which of the following factors would the nurse consider when managing the pain of a terminally ill child? **Select all that apply.**
   - **A.** Pain medications are given on an as-needed schedule, and extra doses for breakthrough pain are available to maintain comfort.
   - **B.** Opioid drugs, such as morphine, are given for severe pain, and the dosage is increased as necessary to maintain optimum pain relief.
   - **C.** The same dose of morphine should be maintained throughout this hospitalization so she does not become addicted and need a higher dose when discharged.
   - **D.** Addiction is a factor in managing terminal pain in a child, and the nurse plays an important role in educating parents that their child may become addicted.
   - **E.** Nurses often express concern that administering dosages of opioids that exceed those with which they are familiar will hasten the child's death (principle of double effect).
   - **F.** In addition to pain medication, techniques such as music therapy, distraction, and guided imagery should be combined with medications to provide the child and family with strategies to control pain.

4. As the nurse caring for a culturally diverse population, it is important to understand the cultural health beliefs of families. A nurse caring for a child with congenital heart disease whose family is from China has a difficult time communicating with the mother, even though she speaks some English. **Indicate which nursing action number listed in the far-left column is most appropriate for each potential complication that could result from poor communication listed in the middle column. Place the number in the far right column. Note that not all actions will be used.**

Nursing Action	Potential communication problems	Appropriate nursing action for potential communication problem
1. Listen to the mother's perception of the seriousness or severity of the illness.	Lack of support from family and friends	
2. Provide an opportunity for the mother to discuss her concerns and worries.	Nurse unaware of the mother's understanding of the child'	
3. Acknowledge language constraints may make it necessary for the health care team to make some decisions.	Lack of support from health care providers	
4. Ask the mother how her extended family feels about the child's illness.		
5. Tell the mother not to talk to anyone else about her		
6. Explore alternative medicines and therapies.		
7. Explore the mother's support network to find others that can help.

Impact of Cognitive or Sensory Impairment on the Child and Family

CONCEPTS

- Cognition
- Sensory Perception

COGNITIVE IMPAIRMENT

GENERAL CONCEPTS

Cognitive impairment (CI) is a general term that encompasses any type of intellectual disability. The term *intellectual disability* (formerly **mental retardation**) has become the most commonly used term internationally (American Association on Intellectual and Developmental Disabilities, 2013; American Psychiatric Association, 2013). In this chapter, the term *CI* is used synonymously with *intellectual disability.*

Intellectual disability, as defined by the American Association on Intellectual and Developmental Disabilities, in children consists of three components: (1) intellectual functioning, (2) adaptive functioning, and (3) the onset of disabilities during childhood or age younger than 18 years. Intellectual functioning is measured by the intelligence quotient (IQ) test, and intellectual disability exists where there is an IQ score of 70 or below or sometimes as high as 75. CI is an umbrella term characterized by significant limitations in intellectual functioning and impairment in a number of different adaptive areas: communication, self-care, home living, social skills, health and safety, self-direction, functional academics, community use, work, and lifelong learning (American Association on Intellectual and Developmental Disabilities, 2013; National Academies of Sciences, Engineering, and Medicine, 2015). The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders,* Fifth edition (DSM-5) criteria recommend moving away from exclusively relying on IQ testing toward using additional measures of adaptive functioning (American Psychiatric Association, 2013; Moran, 2013). The DSM-5 is the diagnostic standard and states that a child with CI must demonstrate deficits in adaptive functioning that result in failure to meet developmental and sociocultural standards for personal independence and social responsibility (Moran, 2013).

The DSM-5 terminology and diagnostic criteria are consistent with those terms established by the American Association on Intellectual and Developmental Disabilities (Tassé, Luckasson, & Nygren, 2013). Careful evaluation to identify the needs of individuals with CI focuses on promoting habilitation for each person. It is anticipated that the functional capabilities of children with CI will improve over time when appropriate supports are provided.

Diagnosis and Classification

The diagnosis of CI is usually made after professionals or the family suspects that the child's developmental progress is delayed. In some cases, it is confirmed at birth because of recognition of distinct syndromes, such as Down syndrome and fetal alcohol syndrome. At the other extreme, the diagnosis is made when problems such as speech delays or school problems arouse concern. In all cases, a high index of suspicion for developmental delay and behavioral signs are necessary for early diagnosis (Box 18.1), and routine developmental screening can assist in early identification. Delays are typically seen in gross and fine motor and speech development, although the latter is most predictive. **Developmental disability** can be described as any significant lag or delay in a child's physical, cognitive, behavioral, emotional, or social development when compared to developmental norms. CI is an impairment encompassing intellectual ability and adaptive behavior that are functioning significantly below average (see Box 18.1). In the absence of clear-cut evidence of CI, it is more appropriate to use a diagnosis of developmental disability.

Results of standardized tests are helpful in contributing to the diagnosis of CI. Tests for assessing adaptive behaviors include the Vineland Adaptive Behavior Scales (Vineland-3) and the Adaptive Behavior Assessment System (ABS-3). Informal appraisal of adaptive behavior may be made by those fully acquainted with the child (e.g., teachers, parents, other care providers). Usually these behavioral observations lead parents to seek evaluation of the child's development. The Wechsler Intelligence Scale for Children (WISC-V) provides an overall IQ score and aids in the diagnoses of learning disabilities (Na & Burns, 2016).

A more useful approach for clinical application is classification based on educational potential or symptom severity. For educational purposes, the mildly impaired group constitutes about 85% of all people with CI, and the group with moderate levels of CI accounts for about 10% of the intellectually disabled population (Shea, 2012) (Table 18.1).

Etiology

The causes of severe CI are primarily genetic, biochemical, and infectious. Although the etiology is unknown in the majority of cases, familial, social, environmental, and organic causes may predominate. Among individuals with CI, a sizable proportion of the cases are linked to Down syndrome, fragile X syndrome (FXS), or fetal alcohol syndrome. General categories of events that may lead to CI include the

BOX 18.1 Early Signs Suggestive of Cognitive Impairment

Dysmorphic syndromes (e.g., Down syndrome, fragile X syndrome FXS)
Irritability or nonresponsiveness to environment
Major organ system dysfunction (e.g., feeding or breathing difficulties)
Gross motor delay
Fine motor delay
Language difficulties or delay
Behavior difficulties

following (Casanova, Gerstner, Sharp, et al., 2018; Gilissen, Hehir-Kwa, Thung, et al., 2014; Hoyme, Kalberg, Elliot, et al., 2016; Katz & Lazcano-Ponce, 2008; Mefford, Batshaw, & Hoffman, 2012):

- Infection and intoxication, such as congenital rubella, syphilis, maternal drug consumption (e.g., fetal alcohol syndrome), chronic lead ingestion, or kernicterus
- Trauma or physical agent (e.g., injury to the brain experienced during the prenatal, perinatal, or postnatal period)
- Inadequate nutrition and metabolic disorders, such as phenylketonuria or congenital hypothyroidism
- Gross postnatal brain disease, such as neurofibromatosis and tuberous sclerosis
- Unknown prenatal influence, including cerebral and cranial malformations, such as microcephaly and hydrocephalus
- Chromosomal abnormalities resulting from radiation; viruses; chemicals; parental age; and genetic mutations, such as Down syndrome and FXS
- Gestational disorders, including preterm birth, low birth weight, and postterm birth
- Psychiatric disorders with onset during the child's developmental period up to age 18 years, such as autism spectrum disorders (ASDs)
- Environmental influences, including evidence of a deprived environment associated with a history of intellectual disability among parents and siblings

NURSING CARE OF CHILDREN WITH IMPAIRED COGNITIVE FUNCTION

Nurses play a major role in identifying children with CI. In the newborn and early infancy periods, few signs are present, except in such disorders as Down syndrome (discussed later in the chapter). However, delayed developmental milestones are the major clues to CI. In addition, nurses must have a high index of suspicion for early behavior patterns that may suggest CI (see Box 18.1). Parental concerns, such as delayed development compared with siblings, need to be taken seriously. All children should receive regular developmental assessment, and the nurse is often the person responsible for performing such assessments. When delays are found, the nurse must use sensitivity and discretion in revealing this finding to parents.

Fig. 18.1 A push panel allows a child with cognitive impairment (CI) to turn a computer on and off.

Educate Child and Family

To teach children with CI, one must investigate their learning abilities and deficits. This is important for the nurse who may be involved in a home care program or who may be caring for the child in a school or health care setting. The nurse who understands how these children learn can effectively teach them basic skills or prepare them for various health-related procedures.

Children with CI have a marked deficit in their ability to discriminate between two or more stimuli because of difficulty in recognizing the relevance of specific cues. However, these children can learn to discriminate if the cues are presented in an exaggerated, concrete form and if all extraneous stimuli are eliminated. For example, the use of colors to emphasize visual cues or the use of singing or rhymes to stress auditory cues can help them learn. Their deficit in discrimination also implies that concrete ideas are learned much more effectively than abstract ideas. Therefore demonstration is preferable to verbal explanation, and learning should be directed toward mastering a skill rather than understanding the scientific principles underlying a procedure.

Another cognitive deficit is in short-term memory. Whereas children of average intelligence can remember several words, numbers, or directions at one time, children with CI are less able to do so. Therefore they need simple, one-step directions. Learning through a step-by-step process requires a **task analysis** in which each task is separated into its necessary components and each step is taught completely before proceeding to the next activity.

One critical area of learning that has had a tremendous impact on education for cognitively impaired individuals is **motivation** or the use of positive reinforcement to encourage the accomplishment of specific tasks or behaviors. Advances in technology have greatly aided in providing reinforcement, especially in children with severe disabilities who may have physical disabilities that limit their range of capabilities. For example, with the use of specially designed switches, children are given control of some event in the environment, such as turning on a computer (Fig. 18.1). Activation of the computer becomes the reinforcement for pushing the switch. Repetitive use of these switches

provides an early, simplistic association with a technical device that may progress to increasingly complex aids.

Early intervention program is a systematic program of therapy, exercises, and activities designed to address developmental delays in disabled children to help achieve their full potentials (Bull & Committee on Genetics, 2011; Crnic, Neece, McIntyre, et al., 2017; Guralnick, 2017; National Down Syndrome Society, 2019a). Considerable evidence indicates that these programs are valuable for children with CI. Nurses working with these families need to be aware of the types of programs in their community. Under the Individuals with Disabilities Education Act (IDEA) of 1990 (Public Law 101-476), states are encouraged to provide full early intervention services and are required to provide educational opportunities for all children with disabilities from birth to 21 years of age. Services may be provided under state programs for Children with Special Health Care Needs (CSHCN) or Head Start or by private organizations such as the National Down Syndrome Society,[a] Easter Seals,[b] or The Arc of the United States.[c] Parents should inquire about these programs by contacting the appropriate agencies. The child's education should begin as soon as possible, because it has been shown that early intervention exposure tends to be associated with more positive developmental and behavioral outcomes in children with CI (Crnic et al., 2017; Guralnick, 2017; Wallander, Biasini, Thorsten, et al., 2014). As children grow older, their education should be directed toward vocational training that prepares them for as independent a lifestyle as possible within their scope of abilities.

Teach Child Self-Care Skills

When a child with CI is born, parents often need assistance in promoting normal developmental skills that other children learn easily. There is no way to predict when a child should be able to master self-care skills, such as feeding, toileting, dressing, and grooming, because a wide age variability exists in the child with CI who is able to accomplish such functions.

Teaching self-care skills also necessitates a working knowledge of the individual steps needed to master a skill. For example, before beginning a self-feeding program, the nurse performs a task analysis. After a task analysis, the child is observed in a particular situation, such as eating, to determine what skills are possessed and the child's developmental readiness to learn the task. Family members are included in this process because their "readiness" is as important as the child's. Numerous self-help aids are available to facilitate independence, and these can help eliminate some of the difficulties of learning, such as using a plate with suction cups to prevent accidental spills.

Promote Child's Optimal Development

Optimal development involves more than achieving independence. It requires appropriate guidance for establishing acceptable social behavior and personal feelings of self-esteem, worth, and security. These attributes are not simply learned through a stimulation program. Rather, they must arise from the genuine love and caring that exist among family members. However, families need guidance in providing an environment that fosters optimal development. Often the nurse can provide assistance in these areas of childrearing.

Fig. 18.2 Placing an attractive object outside the child's reach encourages crawling movements. (Courtesy James DeLeon, Texas Children's Hospital, Houston, TX.)

Another important area for promoting optimal development and self-esteem is ensuring the child's physical well-being. Any congenital defects, such as cardiac, gastrointestinal, or orthopedic anomalies, should be repaired. Plastic surgery may be considered when the child's appearance can be substantially improved. Dental health is significant, and orthodontic and restorative procedures can improve facial appearance immensely.

Encourage Play and Exercise

Children who are cognitively impaired have the same need for play and exercise as any other child. However, because of the children's slower development, parents may be less aware of the need to provide such activities. Therefore the nurse will need to guide parents toward selection of suitable play and exercise activities. Because play has been discussed for children in each age-group in earlier chapters, only the exceptions are presented here (Fig. 18.2).

The type of play is based on the child's developmental age, although the need for sensorimotor play may be prolonged. Parents should use every opportunity to expose the child to as many different sounds, sights, and sensations as possible. Appropriate toys include musical mobiles, stuffed toys, floating toys, a rocking chair or horse, a swing, bells, and rattles. The child should be taken on outings, such as trips to the grocery store or shopping center. Other people should be encouraged to visit in the home, and individuals should relate directly to the child through means such as cuddling, holding, rocking, and talking to the child face to face.

Toys are selected for their recreational and educational value. For example, a large inflatable beach ball is a good water toy; it encourages interactive play and can be used to learn motor skills, such as balance, rocking, kicking, and throwing. Attractive toys encourage a child to reach, therefore assisting in the development of motor skills (see Fig. 18.2). Musical toys that mimic animal sounds or respond with social phrases are excellent ways to encourage speech. A doll with removable clothes and different types of closures can help the child learn dressing skills. Toys should be simple in design so that the child can learn to manipulate them without help. For children with severe cognitive and physical impairment, electronic switches can be used to allow them to operate toys (Figs. 18.3 and 18.4).

Fig. 18.3 A manual switch allows a child with cognitive impairment (CI) to play with a battery-operated toy.

Fig. 18.5 A child with cognitive and physical impairments can activate electronic and communication equipment by moving a device near her head.

Fig. 18.4 A favorite toy provides stimulation for a young child.

Suitable physical activities are based on the child's size, coordination, physical fitness and maturity, motivation, and health (see Fig. 18.4). Some children may have physical problems that prevent participation in certain sports. These children often have greater success in individual and dual sports than in team sports and enjoy themselves most with children who are at the same developmental level. The Special Olympics[d] provides these children with a unique competitive opportunity.

Safety is a major consideration in selecting recreational and exercise activities. For example, toys that may be appropriate developmentally may present dangers to a child who is strong enough to break them or use them incorrectly.

Provide Means of Communication

Verbal skills are typically delayed more than other physical skills. Speech requires adequate hearing and interpretation (**receptive skills**) and facial muscle coordination (**expressive skills**). Because both receptive and expressive skills may be impaired, these children need frequent audiometric testing and should be fitted with hearing aids if indicated. In addition, they may need help in learning to control their facial muscles. For example, some children may need tongue exercises to correct the tongue thrust or gentle reminders to keep the lips closed.

Nonverbal communication may be appropriate for some of these children, and various devices are available. For children with physical limitations, several adaptations or types of communication devices are available to facilitate selection of the appropriate picture or word (Fig. 18.5). Some children may be taught sign language or **Blissymbols**—a highly stylized system of graphic symbols representing words, ideas, and concepts. Although the symbols require education to learn their meaning, no reading skill is required. The symbols are typically arranged on a board, and the person points or uses some type of selector to convey a message.

Establish Discipline

Discipline must begin early. Limit-setting measures need to be simple, consistently applied, and appropriate for the child's mental age. Control measures are based primarily on teaching a specific behavior rather than on understanding the reasons behind it. Stressing moral lessons is of little value to a child who lacks the cognitive skills to learn from self-criticism or evaluation of previous mistakes. Behavior modification, especially reinforcement of desired actions, and use of time-out procedures are appropriate forms of behavior control.

Encourage Socialization

Acquiring social skills is a complex task, as is learning self-care procedures. Active rehearsals with role-playing, practice sessions, and positive reinforcement for desired behavior have been the most successful approaches. Parents should be encouraged early to teach their child socially acceptable behavior: waving goodbye, saying "hello" and "thank you," responding to his or her name, greeting visitors, and sitting modestly. The teaching of socially acceptable sexual behavior is especially important to minimize sexual exploitation. Parents also need to expose the child to strangers so that he or she can practice manners, because there is no automatic transfer of learning from one situation to another.

Dressing and grooming are also important aspects of self-esteem and social acceptance. Clothes should be clean, age appropriate, and well fitted with self-adhering fasteners and elastic openings to facilitate self-dressing.

[d]1133 19th St. NW, Washington, DC 20036; 800-700-8585 or 202-628-3630; fax: 202-824-0200; http://www.specialolympics.org (website includes listing of state offices); info@specialolympics.org; https://www.facebook.com/SpecialOlympics/; https://twitter.com/SpecialOlympics. In Canada: Special Olympics Canada, 21 St. Clair Ave. E, Suite 600, Toronto, ON M4T 1N5; 416-927-9050; 888-888-0608; fax: 416-927-8475; http://www.specialolympics.ca.

Opportunities for social interaction and infant stimulation programs should began at an early age. As soon as possible, parents should enroll their child in early intervention or other appropriate preschool programs. Not only do these programs provide education and training, but they also offer an opportunity for social interaction with other children and adults. As children grow older, they should have peer experiences similar to those of other children, including group outings, sports, and organized activities, such as scouts and Special Olympics. Nurses should assess the child's abilities and encourage others (e.g., parents, teachers) to promote developmentally appropriate peer interaction, such as classroom and school activities, dance classes, clubs, vacations, and family outings (Bull & Committee on Genetics, 2011; National Down Syndrome Society, 2019b; Sanchack & Thomas, 2016; Shapiro & O'Neill, 2020).

Provide Information on Sexuality

Adolescence may be a particularly difficult time for parents, especially in terms of the child's sexual behavior, possibility of pregnancy, future plans to marry, and ability to be independent. Frequently, minimal anticipatory guidance has been offered to parents to prepare the child for physical and sexual maturation. The nurse should help in this area by providing parents with information about sexuality education that is appropriate to the child's developmental level. For example, adolescent girls need a *simple* explanation of menstruation and instructions on personal hygiene during the menstrual cycle.

These adolescents also need practical sexual information on anatomy, physical development, and conception.[e] Because they are easy to persuade and lack judgment, they need a well-defined, concrete code of conduct with specific instructions for handling certain situations. The subtleties of social sexual behavior are less beneficial than specific instructions for handling certain situations. For example, an adolescent should be firmly told never to go alone anywhere with any person that he or she does not know well. To protect the child or adolescent from sexual abuse, parents must closely observe their child's or adolescent's activities and associates. The question of contraceptive protection for these adolescents is often a parental concern.

Parents of these adolescents are often concerned about the advisability of marriage between two individuals with significant CI. There is no conclusive answer; each situation must be judged individually. In some instances, marriage is possible. The nurse should discuss this topic with parents and with the prospective couple, stressing suitable living accommodations and contraceptive methods. If children are conceived, these parents require specialized assistance in learning to meet the needs of their offspring (Brown, Potvin, Lunsky, et al., 2018; Bull & Committee on Genetics, 2011; Homeyard, Montgomery, Chinn, et al., 2016).

Help Family Adjust to Future Care

Not all families are able to cope with home care of children who are cognitively impaired, especially those who have severe or profound CI or multiple disabilities. Older parents may not be able to continue care responsibilities after they reach retirement or older age. The decision regarding residential placement is a difficult one for families, and the availability of such facilities varies widely. The nurse's role includes assisting parents in investigating and evaluating programs and helping parents adjust to the decision for placement.

[e]Sources of information on sexuality and conception include Planned Parenthood Federation of America, 434 W. 33rd St., Floor 12, New York, NY 10001; 212-541-7800 or 800-230-7526; http://www.plannedparenthood.org; https://www.facebook.com/PlannedParenthood/ and also The ARC of the United States (see footnote earlier in this chapter).

Care for Child During Hospitalization

Caring for the child during hospitalization can be a special challenge. Frequently, nurses are unfamiliar with children who are cognitively impaired, and they may cope with their feelings of insecurity and fear by ignoring or isolating the child. Not only is this approach nonsupportive, it may also be destructive to the child's sense of self-esteem and optimum development, and it may impair the parents' ability to cope with the stress of the experience. To prevent engaging in this nontherapeutic approach, nurses should use the mutual participation model in planning the child's care. Parents should stay with their child but not be made to feel as if the responsibility is totally theirs.

When the child is admitted, a detailed history is taken (see Chapter 4), with special focus on all self-care abilities. Questions about the child's abilities are approached positively. For example, rather than asking, "Is your child toilet trained yet?" the nurse may state, "Tell me about your child's toileting habits." The assessment should also focus on any special devices the child uses, effective measures of limit setting, unusual or favorite routines, and any behaviors that may require intervention. If the parent states that the child engages in repetitive behaviors (e.g., overactivity, impulsivity) and self-stimulatory or self-injurious activities (e.g., head banging, self-biting), the nurse should inquire about events that precipitate them and techniques (e.g., distraction, medication) that the parents use to manage them (Davies & Oliver, 2016; Morano, Ruiz, Hwang, et al., 2017).

The nurse also assesses the child's functional level of eating and playing; ability to express needs verbally; progress in toilet training; and relationship with objects, toys, and other children. The child is encouraged to be as independent as possible in the hospital.

Realizing that the child may be lonely in the hospital, the nurse makes certain that toys and other activities are provided. The child is placed in a room with other children of approximately the same developmental age, preferably a room with only two beds to avoid overstimulation. The nurse should treat the child with dignity and respect in a manner that promotes acceptance and understanding by other children, parents, and those with whom the child comes in contact in the hospital.

Explain procedures to the child using methods of communication that are at the appropriate cognitive level. Generally, explanations should be simple, short, and concrete, emphasizing what the child will experience physically. Demonstration either through actual practice or with visual aids is always preferable to verbal explanation. Include parents in preprocedural teaching to aid in the child's learning and to help the nurse learn effective methods of communicating with the child.

During hospitalization, the nurse should also focus on growth-promoting experiences for the child. For example, hospitalization may be an excellent opportunity to emphasize to parents the abilities that the child does have but has not had the opportunity to practice, such as self-dressing. It may also be an opportunity for social experiences with peers, group play, or new educational and recreational activities. For example, one child who had the habit of screaming and kicking demonstrated a definite decrease in those behaviors after he learned to pound pegs and use a punching bag. Through social services, the parents may become aware of specialized programs for the child. Hospitalization may also offer parents a respite from everyday care responsibilities and an opportunity to discuss their feelings with a concerned professional.

Assist in Measures to Prevent Cognitive Impairment

Besides having a responsibility to families with a child with CI, nurses also need to be involved in programs aimed at preventing CI.

Many of the familial, social, and environmental factors known to cause mild impairment are preventable. Counseling and education can reduce or eliminate such factors (e.g., poor nutrition, cigarette smoking, chemical abuse), which increase the risk of prematurity and intrauterine growth restriction. Interventions are directed toward improving maternal health by educating women on the dangers of chemicals, including prenatal alcohol exposure, which affects organogenesis, craniofacial development, and cognitive ability. Other preventive strategies that play an important role include adequate prenatal care; optimal medical care of high-risk newborns; rubella immunization; genetic counseling; and prenatal screening, especially for Down syndrome or FXS. The use of folic acid supplements prevents neural tube defects during pregnancy and during the childbearing years; the use of newborn screening for treatable inborn errors of metabolism (such as congenital hypothyroidism, phenylketonuria, and galactosemia) is appropriate to prevent developmental disabilities in children.

DOWN SYNDROME

Down syndrome is the most common chromosomal abnormality of a generalized syndrome, occurring in 1 in 700 to 733 live births in the United States, with approximately 6000 births annually (Lee, 2020). It occurs in people of all races and economic levels.

Etiology

The cause of Down syndrome is not known, but evidence from cytogenetic and epidemiologic studies supports the concept of multiple causality. Although the cause is unclear, the cytogenetics of the disorder is well established. Approximately 95% of all cases of Down syndrome are attributable to an extra chromosome 21 (group G), hence the name **nonfamilial trisomy 21**. Although children with trisomy 21 are born to parents of all ages, there is a statistically greater risk in older women, particularly those older than 35 years of age. For example, in women 35 years old, the chance of conceiving a child with Down syndrome is about 1 in 350 live births, but in women 40 years old, it is about 1 in 100. However, the majority (≈80%) of infants with Down syndrome are born to women younger than 35 years of age because younger women have higher fertility rates (Arumugam, Raja, Venugopalan, et al., 2016; Lee, 2020). About 4% of cases may be caused by **translocation** of chromosomes 15 and 21 or 22. This type of genetic aberration is usually hereditary and is not associated with advanced parental age. About 1% to 4% of affected persons demonstrate **mosaicism**, which refers to a mixture of normal and abnormal chromosomes in the cells. The degree of cognitive and physical impairment is related to the percentage of cells with the abnormal chromosome makeup.

Diagnostic Evaluation

Down syndrome usually can be diagnosed by the clinical manifestations alone (Box 18.2 and Fig. 18.6), but a chromosome analysis should be done to confirm the genetic abnormality.

Several physical problems are associated with Down syndrome. Many of these children have congenital heart malformations, the most common being septal defects. Respiratory tract infections are prevalent and, when combined with cardiac anomalies, are the chief causes of death, particularly during the first year of life. Hypotonicity of chest and abdominal muscles and dysfunction of the immune system probably predispose the child to the development of respiratory tract infection. Other physical problems include thyroid dysfunction, especially congenital hypothyroidism, and an increased incidence of leukemia.

BOX 18.2 Clinical Manifestations of Down Syndrome

Head and Eyes
- Separated sagittal suture
- Brachycephaly
- Rounded and small skull
- Flat occiput
- Enlarged anterior fontanel
- Oblique palpebral fissures (upward, outward slant)[a]
- Inner epicanthal folds
- Speckling of iris (Brushfield spots)

Nose and Ears
- Small nose[a]
- Depressed nasal bridge (saddle nose)[a]
- Small ears and narrow canals
- Short pinna (vertical ear length)
- Overlapping upper helices
- Conductive hearing loss

Mouth and Neck
- High, arched, narrow palate[a]
- Protruding tongue
- Hypoplastic mandible
- Delayed teeth eruption and microdontia
- Alignment teeth abnormalities common
- Periodontal disease
- Neck skin excess and laxity[a]
- Short and broad neck

Chest and Heart
- Shortened rib cage
- Twelfth rib anomalies
- Pectus excavatum or carinatum
- Congenital heart defects common (e.g., atrial septal defect, ventricular septal defect)

Abdomen and Genitalia
- Protruding, lax, and flabby abdominal muscles
- Rectus abdominus diastasis.
- Umbilical hernia
- Small penis
- Cryptorchidism
- Bulbous vulva

Hands and Feet
- Broad, short hands and stubby fingers
- Incurved little finger (clinodactyly)
- Transverse palmar crease
- Wide space between big and second toes[a]
- Plantar crease between big and second toes[a]
- Broad, short feet and stubby toes

Musculoskeletal and Skin
- Short stature
- Hyperflexibility and muscle weakness[a]
- Hypotonia
- Atlantoaxial instability
- Dry, cracked, and frequent fissuring
- Cutis marmorata (mottling)

Other
- Reduced birth weight
- Learning difficulty (average intelligence quotient [IQ] of 50)
- Hypothyroidism common
- Impaired immune function
- Increased risk of leukemia
- Early-onset dementia (in one-third)

[a] Most common findings in modified chart (Arumugam, Raja, Venugopalan, et al., 2016; Pueschel, 1999).

Therapeutic Management

Although no cure exists for Down syndrome, a number of therapies are advocated, such as surgery to correct serious congenital anomalies (e.g., heart defects, strabismus). These children also benefit from evaluative echocardiography soon after birth and regular medical care. Evaluation of sight and hearing is essential, and treatment of otitis media is required to prevent auditory loss, which can influence cognitive function. Periodic testing of thyroid function is recommended, especially if growth is severely delayed.

About 15% of children with Down syndrome have **atlantoaxial instability**; almost all of these children are asymptomatic. The American Academy of Pediatrics no longer recommends screening asymptomatic children with Down syndrome for atlantoaxial instability with cervical spine x-rays due to the unproven value of detecting patients at risk of developing spinal cord compression injury (Bull & Committee on Genetics, 2011; National Down Syndrome Society,

Fig. 18.6 A young child with Down syndrome holds a doll with Down syndrome.

2019d). However, the Special Olympics requires that all athletes with Down syndrome receive neck x-rays and neurologic examination prior to sports participation (Leas, Goldstein, Kellan, et al., 2017; National Down Syndrome Society, 2019d).

! NURSING ALERT

Immediately report any child with the following signs of spinal cord compression:

- Persistent neck pain
- Loss of established motor skills and bladder or bowel control
- Changes in sensation

Prognosis

Life expectancy for those with Down syndrome has improved but remains lower than for the general population. Most individuals with Down syndrome survive to 60 years old and beyond (Englund, Jonsson, Zander, et al., 2013; Weijerman & de Winter, 2010). As the prognosis continues to improve for these individuals, it will be important to provide for their long-term health care and social and leisure needs.

Nursing Care Management

Support the Family at the Time of Diagnosis

Because of the unique physical characteristics, infants with Down syndrome are usually diagnosed at birth, and parents should be informed of the diagnosis at this time. Most parents usually prefer that both of them be present during the informing interview so that they can support one another emotionally. Parents appreciate receiving reading material about the syndrome[f] and being referred to parent groups and/or professional counseling.

Parental responses to the child may greatly influence decisions regarding future care. Whereas some families willingly take the child home, others consider foster care or adoption. The nurse must answer questions about developmental potential carefully, because the responses may influence the parents' decisions. The nurse should share the available informative sources (such as parent groups, professional counseling, and literature) to help the family learn about Down syndrome.

Assist the Family in Preventing Physical Problems

Many of the physical characteristics of infants with Down syndrome present challenges and nursing problems. The hypotonicity of muscles and hyperextensibility of joints complicate positioning. The limp, flaccid extremities resemble the posture of a rag doll; as a result, holding the infant is difficult and cumbersome. Sometimes parents perceive this lack of molding to their bodies as evidence of inadequate parenting. The extended body position promotes heat loss, because more surface area is exposed to the environment. Encourage the parents to swaddle or wrap the infant snugly in a blanket before picking up the child to provide security and warmth. The nurse also discusses with parents their feelings concerning attachment to the child, emphasizing that the child's lack of clinging or molding is a physical characteristic and not a sign of detachment or rejection.

Decreased muscle tone compromises respiratory expansion. In addition, the underdeveloped nasal bone causes a chronic problem of inadequate drainage of mucus. The constant stuffy nose forces the child to breathe by mouth, which dries the oropharyngeal membranes, increasing the susceptibility to upper respiratory tract infections. Measures to lessen these problems include clearing the nose with a bulb-type syringe, rinsing the mouth with water after feedings, increasing fluid intake, and using a cool-mist vaporizer to keep the mucous membranes moist and the secretions liquefied. Other helpful measures include changing the child's position frequently, practicing good hand washing, and properly disposing of soiled articles, such as tissues. If antibiotics are ordered, the nurse stresses the importance of completing the full course of therapy for successful eradication of the infection and prevention of growth of resistant organisms.

Inadequate drainage resulting in pooling of mucus in the nose also interferes with feeding. Because the child breathes by mouth, sucking for any length of time is difficult. When eating solids, the child may gag on the food because of mucus in the oropharynx. Parents are advised to clear the nose before each feeding; give small, frequent feedings; and allow opportunities for rest during mealtime.

The protruding tongue also interferes with feeding, especially of solid foods. Parents need to know that the tongue thrust is not an indication of refusal to feed but a physiologic response. Parents are advised to use a small but long, straight-handled spoon to push the food toward the back and side of the mouth. If food is thrust out, it should be refed.

Dietary intake needs supervision. Decreased muscle tone affects gastric motility, predisposing the child to constipation. Dietary measures, such as increased fiber and fluid, promote evacuation. The child's eating habits may need scrutiny to prevent obesity. Height and weight measurements should be obtained on a serial basis. Because the previously used Down syndrome–specific growth charts no longer reflected the current population styles and body proportions, updated growth charts were developed to provide indications of how growth of an individual child compares with peers of the same age and sex with Down syndrome (Centers for Disease Control and Prevention, 2017; Zemel, Pipan, Stallings, et al., 2015).

During infancy, the child's skin is pliable and soft. However, it gradually becomes rough and dry and is prone to cracking and infection. Skin care involves the use of minimum soap and application of lubricants. Lip balm is applied to the lips, especially when the child is outdoors, to prevent excessive chapping.

Assist in Prenatal Diagnosis and Genetic Counseling

Prenatal diagnosis of Down syndrome through chorionic villus sampling and amniocentesis can detect the presence of trisomy or

[f]For The ARC and National Down Syndrome Society contact information, see the footnotes earlier in the chapter.

translocation in the chromosomal analysis of fetal cells. Advances in development of noninvasive prenatal testing (NIPT) as a measurement of cell-free deoxyribonucleic acid (DNA) from the plasma of pregnant women detects nearly all cases of Down syndrome (Curnow, Sanderson, & Beruti, 2019; Gil, Accurti, Santacruz, et al., 2017; Hui, 2019; Iwarsson, Jacobsson, Dagerhamn, et al., 2017; Lee, 2020; Palomaki & Kloza, 2018). However, invasive fetal karyotyping is still the required diagnostic approach to confirm the presence of a chromosomal abnormality prior to making irreversible decisions relative to the pregnancy outcome (Badeau, Lindsay, Blais, et al., 2017; Gray & Wilkins-Haug, 2018; Iwarsson et al., 2017).

Prenatal testing and genetic counseling should be offered to all women, including those of advanced maternal age, those with a family history of the disorder, and those of younger age because most children with Down syndrome are born to younger mothers due to their higher overall birth rate (Lee, 2020; National Down Syndrome Society, 2019a). If prenatal testing indicates that the fetus is affected, the nurse must allow the parents to express their feelings about whether to proceed with the pregnancy or an elective abortion and support their decision. It is important for nurses to be aware of their own attitudes regarding testing and related decisions.

FRAGILE X SYNDROME

FXS is the most common inherited cause of CI and the second most common genetic cause of CI or intellectual disability after Down syndrome. It has been described in all ethnic groups and races; the incidence of affected boys is 1 in 3600 to 4000, the incidence of affected girls is 1 in 4000 to 6000, the incidence of carrier girls is 1 in 151, and the incidence of carrier boys is 1 in 468 worldwide (Mink, 2016; National Fragile X Foundation, 2019).

The syndrome is caused by an abnormal gene on the lower end of the long arm of the X chromosome. Chromosome analysis may demonstrate a **fragile site** (a region that fails to condense during mitosis and is characterized by a nonstaining gap or narrowing) in the cells of affected males and females and in carrier females. This fragile site has been determined to be caused by a gene mutation that results in excessive repeats of nucleotide in a specific DNA segment of the X chromosome. The number of repeats in a normal individual is between 6 and 50. An individual with 50 to 200 base-pair repeats is said to have a **permutation** and is therefore a carrier. When passed from a parent to a child, these base-pair repeats can expand from 200 or more, which is called a **full mutation**. This expansion occurs only when a carrier mother passes the mutation to her offspring; it does not occur when a carrier father passes the mutation to his daughters.

The inheritance pattern has been termed **X-linked dominant with reduced penetrance**. This is in distinct contrast to the classic X-linked recessive pattern in which all carrier females are normal, all affected males have symptoms of the disorder, and no males are carriers. Consequently, genetic counseling of affected families is more complex than that for families with a classic X-linked disorder, such as hemophilia. Both affected sexes are capable of transmitting the fragile X disorder. Prenatal diagnosis of the fragile X gene mutation is possible with direct DNA testing in a family with an established history using amniocentesis or chorionic villus sampling (Finucane, Lincoln, Bailey, et al., 2017; National Fragile X Foundation, 2019). The FMR1 mutation testing is highly accurate and is being researched for incorporation into the newborn universal screening program (Bailey, Berry-Kravis, Gane, et al., 2017; Riley, Mailick, Berry-Kravis, et al., 2017; Riley & Wheeler, 2017; Tassone, 2014).

BOX 18.3 Clinical Manifestations of Fragile X Syndrome

Physical Features

Increased head circumference
Long, wide, or protruding ears
Long, narrow face with prominent jaw
Strabismus
Mitral valve prolapse, aortic root dilation
Hypotonia
In postpubertal males, enlarged testicles

Behavioral Features

Mild to severe cognitive impairment (CI)
Speech delay; may be rapid speech with stuttering and word repetition
Short attention span, hyperactivity
Hypersensitivity to taste, sounds, and touch
Intolerance to change in routine
Autistic-like behaviors, such as social anxiety and gaze aversion
Possible aggressive behavior

Clinical Manifestations

The classic trend of physical findings in adult men with FXS consists of a long face with a prominent jaw (prognathism); large, protruding ears; and large testes (macroorchidism). In prepubertal children, however, these features may be less obvious, and behavioral manifestations may initially suggest the diagnosis (Box 18.3). In carrier females, the clinical manifestations are extremely varied.

Therapeutic Management

FXS has no cure. Medical treatment may include the use of serotonin agents, such as carbamazepine (Tegretol) or fluoxetine (Prozac), to control violent temper outbursts and the use of central nervous system stimulants or clonidine (Catapres) to improve attention span and decrease hyperactivity and melatonin for sleep difficulties. Treatments of FXS are being investigated in clinical trials; these include targeted therapies as in protein replacement and the identification of blood and tissue biomarkers that quantify brain function (Bagni, Tassone, Neri, et al., 2012; Budimirovic, Berry-Kravis, Erickson, et al., 2017; Hagerman, Berry-Kravis, Hazlett, et al., 2017; Lee, Ventola, Budimirovic, et al., 2018).

All affected children require referral to early intervention programs (speech and language therapy, occupational therapy, and special education assistance) and multidisciplinary assessment, including cardiology, neurology, and orthopedic anomalies.

Prognosis

Individuals with FXS are expected to live a normal life span. Their CI may be improved by behavioral and educational interventions that usually begin in preschool-age children.

Nursing Care Management

Because CI is a fairly consistent finding in individuals with FXS, the care given to these families is the same as for any child with intellectual disability. Because the disorder is hereditary, genetic counseling is important to inform parents and siblings of the risks of transmission. In addition, any male or female with unexplained or nonspecific mental impairment should be referred for genetic testing and, if needed,

counseling. Families with a member affected by the disorder should be referred to the National Fragile X Foundation.[g]

SENSORY IMPAIRMENT

HEARING IMPAIRMENT

Hearing impairment is one of the most common disabilities in the United States. An estimated 3 to 6 per 1000 well infants have hearing loss of varying degrees (American Academy of Pediatrics, 2019; Dedhia, Graham, & Park, 2018; Grindle, 2014). For infants admitted to neonatal intensive care units, the incidence rises sharply to approximately 2 to 4 per 100 neonates (Almadhoob & Ohlsson, 2015; American Academy of Pediatrics, Joint Committee on Infant Hearing, 2007; Colella-Santos, Hein, de Souza, et al., 2014). In the United States, there are about 1 million children with hearing impairment ranging in age from birth to 21 years old, and almost one-third of these children have other disabilities, such as visual or cognitive deficits.

Definition and Classification

Hearing impairment is a general term indicating disability that may range in severity from slight to profound hearing loss. *Slight to moderately severe hearing loss* describes a person who has residual hearing sufficient to enable successful processing of linguistic information through audition, generally with the use of a hearing aid. *Severe to profound hearing loss* describes a person whose hearing disability precludes successful processing of linguistic information through audition with or without a hearing aid. Hearing-impaired persons who are speech impaired tend not to have a physical speech defect other than that caused by the inability to hear.

Hearing defects may be classified according to etiology, pathology, or symptom severity. Each is important in terms of treatment, possible prevention, and rehabilitation.

Etiology

Hearing loss may be caused by a number of prenatal and postnatal conditions. These may include a family history of childhood hearing impairment, anatomic malformations of the head or neck, low birth weight, severe perinatal asphyxia, perinatal infection (cytomegalovirus, rubella, herpes, syphilis, toxoplasmosis, bacterial meningitis), maternal prenatal substance abuse, chronic ear infection, cerebral palsy, Down syndrome, prolonged neonatal oxygen supplementation, or administration of ototoxic drugs (Colella-Santos et al., 2014; Gan, Rowe, Benton, et al., 2016; Haddad, Dodhia, & Spitzer, 2020; Neumann, Chadha, & Tavartkiladze, 2019; Singh, 2015).

In addition, high-risk neonates who survive the once fatal prenatal or perinatal conditions may be susceptible to hearing loss from the disorder or its treatment. For example, sensorineural hearing loss may result from continuous humming noises or high noise levels associated with incubators, oxygen hoods, or intensive care units, especially when combined with the use of potentially ototoxic antibiotics.

Environmental noise is a special concern. Sounds loud enough to damage sensitive hair cells of the inner ear can produce irreversible hearing loss. Very loud, brief noise (such as gunfire) can cause immediate, severe, and permanent loss of hearing. Longer exposure to less intense but still hazardous sounds (such as loud, persistent music via headphones, sound systems, concerts, or industrial noises) may also produce hearing loss (Carroll, Eichwald, Scinicariello, et al., 2017; Centers for Disease Control and Prevention, 2018a; Guest, Munro, Prendergast, et al., 2017; Pawlaczyk-Luszczynska, Zamojska-Daniszewska, Dudarewicz, et al., 2017; Sliwinska-Kowalska & Zaborowski, 2017; World Health Organization, 2019). Loud noises combined with toxic substances (such as smoking or secondhand smoke) produce a synergistic effect on hearing that causes hearing loss (Chang, Ryou, Jun, et al., 2016; Fabry, Davila, Arheart, et al., 2011; Hu, Sasaki, & Ogasawara, 2019; Talaat, Metwaly, Khafagy, et al., 2014).

Pathology

Disorders of hearing are divided according to the location of the defect. **Conductive** or **middle-ear hearing loss** results from interference of transmission of sound to the middle ear. It is the most common of all types of hearing loss and most frequently a result of recurrent serous otitis media. Conductive hearing impairment involves mainly interference with loudness of sound.

Sensorineural hearing loss involves damage to the inner ear structures or the auditory nerve. The most common causes are congenital defects of inner ear structures or consequences of acquired conditions, such as kernicterus, infection, administration of ototoxic drugs, or exposure to excessive noise. Sensorineural hearing loss results in distortion of sound and problems in discrimination. Although the child hears some of everything going on around him or her, the sounds are distorted, severely affecting discrimination and comprehension.

Mixed conductive-sensorineural hearing loss results from interference with transmission of sound in the middle ear and along neural pathways. It frequently results from recurrent otitis media and its complications.

Central auditory imperception includes all hearing losses that are not linked to defects in the conductive or sensorineural structures. They are usually divided into organic or functional losses. In the **organic** type of central auditory imperception, the defect involves the reception of auditory stimuli along the central pathways and the expression of the message into meaningful communication. Examples are **aphasia**, the inability to express ideas in any form, either written or verbal; **agnosia**, the inability to interpret sound correctly; and **dysacusis**, difficulty in processing details or discriminating among sounds. In the **functional** type of hearing loss, no organic lesion exists to explain a central auditory loss. Examples of functional hearing loss are conversion hysteria (an unconscious withdrawal from hearing to block remembrance of a traumatic event), infantile autism, and childhood schizophrenia.

Symptom Severity

Hearing impairment is expressed in terms of a **decibel (dB)**, a unit of loudness. Hearing is measured at various frequencies, such as 500, 1000, and 2000 cycles per second, the critical listening speech range. Hearing impairment can be classified according to **hearing threshold level** (the measurement of an individual's hearing threshold by means of an audiometer) and the degree of symptom severity as it affects speech (Table 18.2). These classifications offer only general guidelines regarding the effect of the impairment on any individual child, because children differ greatly in their ability to use residual hearing.

Therapeutic Management

Conductive Hearing Loss

Treatment of hearing loss depends on the cause and type of hearing impairment. Many conductive hearing defects respond to medical or surgical treatment, such as antibiotic therapy for acute otitis media or insertion of tympanostomy tubes for chronic otitis media. When the conductive hearing loss is permanent, hearing can be improved with the use of a hearing aid to amplify sound.

[g]1861 International Drive, Suite 200, McLean, VA 22102; 800-688-8765; email: natlfx@fragilex.org

TABLE 18.2 Classification of Hearing Impairment Based on Symptom Severity

Hearing Level (dB)	Effect
Slight: 16 to 25	Has difficulty hearing faint or distant speech Usually is unaware of hearing difficulty Likely to achieve in school but may have problems No speech defects
Mild to moderate: 26 to 55	May have speech difficulties Understands face-to-face conversational speech at 0.9 to 1.5 m (3 to 5 ft)
Moderately severe: 56 to 70	Unable to understand conversational speech unless loud Considerable difficulty with group or classroom discussion Requires special speech training
Severe: 71 to 90	May hear a loud voice if nearby May be able to identify loud environmental noises Can distinguish vowels but not most consonants Requires speech training
Profound: 91	May hear only loud sounds Requires extensive speech training

dB, Decibels.

The nurse should be familiar with the types, basic care, and handling of hearing aids, especially when the child is hospitalized.[h] Types of hearing aids include those worn in or behind the ear, models incorporated into an eyeglass frame, and types worn on the body with a wire connection to the ear (Fig. 18.7). One of the most common problems with a hearing aid is **acoustic feedback**, an annoying whistling sound usually caused by improper fit of the ear mold. Sometimes the whistling may be at a frequency that the child cannot hear but that is annoying to others. In this case, if children are old enough, they are told of the noise and asked to readjust the aid.

NURSING TIP To reduce or eliminate whistling from a hearing aid, try removing and reinserting the aid, making certain that no hair is caught between the ear mold and the ear canal, cleaning the ear mold or ear, or lowering the volume of the aid.

As children grow older, they may be self-conscious about the device. Efforts may be made to make the aid inconspicuous, such as styling the hair to cover behind-the-ear or in-the-ear models and using attractive frames for glasses with connected hearing aids. Give children responsibility for the care of the device as soon as they are able, because fostering independence is a primary goal of rehabilitation.

! NURSING ALERT

Stress to parents the importance of storing batteries for hearing aids in a safe location out of reach of children and of teaching children not to remove the battery from the hearing aid (or supervising young children when they do so). Battery ingestion requires immediate emergency management.

[h]Information about hearing aids is available from the International Hearing Society, 16880 Middlebelt Road, Suite 4, Livonia, MI 48154; 800-521-5247 (hearing help line) or 734-522-7200; fax: 734-522-0200; http://www.ihsinfo.org; http://www.facebook.com/ihsinfo; http://twitter.com/IHSinfo.

Fig. 18.7 On-the-body hearing aids are convenient for young children, such as this child with severe bilateral hearing loss. Note eye patching for strabismus.

Sensorineural Hearing Loss

Treatment for sensorineural hearing loss is much less satisfactory. Because the defect is not one of intensity of sound, hearing aids are of less value in this type of defect. The use of **cochlear implants**[i] (a surgically implanted prosthetic device) provides a sensation of hearing for individuals who have severe or profound hearing loss (Centers for Disease Control and Prevention, 2018a; Health Quality Ontario, 2018; Korver, Smith, & Van Camp, 2017; Pettinato, De Clerck, Verhoeven, et al., 2017). Children with sensorineural hearing loss have lost or damaged some or all of their hair cells or auditory nerve fibers. Often these children cannot benefit from conventional hearing aids because they only amplify sound that cannot be processed by a damaged inner ear. A cochlear implant bypasses the hair cells to directly stimulate surviving auditory nerve fibers so that they can send signals to the brain. These signals can be interpreted by the brain to produce sound and sensations (Easwar, Yamazaki, Deighton, et al., 2017; Gan et al., 2016; Grindle, 2014; Pettinato et al., 2017).

Multichanneled implants are sophisticated devices that stimulate the auditory nerve at a number of locations with differently processed signals. This type of stimulation allows a person to use the pitch information present in speech signals, leading to better understanding of speech. The trend is toward early use of cochlear implants, usually by 12 months old, to give the child maximum opportunity to develop listening, language, and speaking skills.

Nursing Care Management

Assessment of children for hearing impairment is a critical nursing responsibility. Identification of hearing loss before 3 months of age with intervention no later than 6 months of age is essential to improve the language and educational development of children with hearing impairments (American Academy of Pediatrics, 2019; Centers for

[i]Hearing Enrichment Language Program of the Hough Ear Institute as part INTEGRIS Baptist Medical Center Cochlear Implant Clinic, 3300 N.W. Expressway, Oklahoma City, OK 73112; 405-949-3011 or 888-951-2277; http://integrisok.com/baptist-medical-center-oklahoma-city-ok-services-hearing; http://www.facebook.com/integrishealthOK.

BOX 18.4 Clinical Manifestations of Hearing Impairment

Infants

Lack of startle or blink reflex to a loud sound
Failure to be awakened by loud environmental noises
Failure to localize a source of sound by 6 months old
Absence of babble or voice inflections by 7 months old
General indifference to sound
Lack of response to the spoken word; failure to follow verbal directions
Response to loud noises as opposed to the voice

Children

Use of gestures rather than verbalization to express desires, especially after 15 months old
Failure to develop intelligible speech by 24 months old
Monotone and unintelligible speech; lessened laughter
Vocal play, head banging, or foot stamping for vibratory sensation
Yelling or screeching to express pleasure, needs, or annoyance
Asking to have statements repeated or answering them incorrectly
Greater response to facial expression and gestures than to verbal explanation
Avoidance of social interaction; prefer to play alone
Inquiring, sometimes confused facial expression
Suspicious alertness alternating with cooperation
Frequent stubbornness because of lack of comprehension
Irritability at not making themselves understood
Shy, timid, and withdrawn behavior
Frequent appearance of being "in a world of their own" or markedly inattentive

Disease Control and Prevention, 2018a; Grindle, 2014; Lammers, Jansen, Grolman, et al., 2015; World Health Organization, 2012). The Joint Committee on Infant Hearing issued guidelines on auditory screening of newborns and infants to detect early hearing loss and implement intervention programs (American Academy of Pediatrics, 2019; American Academy of Pediatrics, Joint Committee on Infant Hearing, 2007; Centers for Disease Control and Prevention, 2018a; Joint Committee on Infant Hearing of the American Academy of Pediatrics, Muse, Harrison, et al., 2013). Auditory testing is presented in Chapter 4.

At birth, the nurse should observe the neonate's response to auditory stimuli, as evidenced by the startle reflex, head turning, eye blinking, and cessation of body movement. The infant may vary in the intensity of the response, depending on the state of alertness. However, consistent absence of a reaction should lead to suspicion of hearing loss. Box 18.4 summarizes other clinical manifestations of hearing impairment in infants.

Children who are profoundly hearing impaired are much more likely to be diagnosed during infancy than are children who are less severely affected. If the defect is not detected during early childhood, it likely will become evident on entry into school, when the child has difficulty learning. Unfortunately, some of these children are erroneously placed in special classes for students with learning disabilities or CI. Therefore it is essential that the nurse suspect a hearing impairment in any child who demonstrates the behaviors listed in Box 18.4.

! NURSING ALERT

When parents express concern about their child's hearing and speech development, refer the child for a hearing evaluation. Absence of well-formed syllables *(da, na, yaya)* by 11 months old should result in immediate referral.

During early childhood, the primary importance of hearing impairment is the effect on speech development. A child with a mild conductive hearing loss may speak fairly clearly but in a loud, monotone voice. A child with a sensorineural defect usually has difficulty in articulation. Communication may be difficult, leading to frustration when words are not understood. For example, an inability to hear higher frequencies may result in the word "spoon" being pronounced "poon." Children with articulation problems need to have their hearing tested.

Lipreading

Although the child may become an expert at lipreading, only about 40% of the spoken word is understood, or less if the speaker has an accent, mustache, or beard. Exaggerating pronunciation or speaking in an altered rhythm further lessens comprehension. Parents can help the child understand the spoken word by using the suggestions in the Nursing Care Guidelines box. The child learns to supplement the spoken word with sensitivity to visual cues, primarily body language and facial expression (e.g., tightening the lips, muscle tension, eye contact).

NURSING CARE GUIDELINES

Facilitating Lipreading

Attract child's attention before speaking; use light touch to signal speaker's presence.
Stand close to child.
Face child directly or move to a 45-degree angle.
Stand still; do not walk back and forth or turn away to point or look elsewhere.
Establish eye contact and show interest.
Speak at eye level and with good lighting on speaker's face.
Be certain nothing interferes with speech patterns, such as chewing food or gum.
Speak clearly and at a slow and even rate.
Use facial expression to assist in conveying messages.
Keep sentences short.
Rephrase message if child does not understand the words.

Cued Speech

The cued speech method of communication is an adjunct to straight lipreading. It uses hand signals to help the child with hearing impairment to distinguish between words that look alike when formed by the lips (e.g., mat, bat). It is most commonly used by children with hearing impairment who are using speech rather than by those who are nonverbal.

Sign Language

Sign language, such as **American Sign Language (ASL)** or **British Sign Language (BSL)**, is a visual-gestural language that uses hand signals that roughly correspond to specific words and concepts in the English language. Encourage family members to learn signing, because using or watching hands requires much less concentration than lipreading or talking. Also, a symbol method enables some children with hearing impairment to learn more and to learn faster.

Speech Language Therapy

The most formidable task in the education of a child who is profoundly hearing impaired is learning to speak. Speech is learned through a multisensory approach using visual, tactile, kinesthetic, and auditory stimulation. Encourage parents to participate fully in the learning process.

Additional Aids

Everyday activities present problems for older children with hearing impairment. For example, they may not be able to hear the telephone, doorbell, or alarm clock. Several commercial devices are available to help them adjust to these dilemmas. Flashing lights can be attached to a telephone or doorbell to signal its ringing. Trained hearing ear dogs can provide great assistance because they alert the person to sounds, such as someone approaching, a moving car, a signal to wake up, or a child's cry. Special teletypewriters or telecommunications devices for the deaf (TDD or TTY) help those who are hearing impaired to communicate with each other over the telephone; the typed message is conveyed via the telephone lines and displayed on a small screen.[j]

Any audiovisual medium presents dilemmas for these children, who can see the picture but cannot hear the message. However, with **closed captioning** a special decoding device is attached to the television, and the audio portion of a program is translated into subtitles that appear on the screen.[k]

Socialization

Socialization is extremely important to children's development. If children attend a special school for the hearing impaired, they are able to socialize with peers in that setting. Classmates become a potential source of close friendships because they communicate more easily among themselves. Encourage parents to promote these relationships whenever possible.

Children with a hearing impairment may need special help with school or social activities. For children wearing hearing aids, keep background noise to a minimum. Because many of these children are able to attend regular classes, the teacher may need assistance in adapting methods of teaching for the child's benefit. The school nurse is often in an optimal position to emphasize methods of facilitated communication, such as lipreading (see Nursing Care Guidelines box). Because group projects and audiovisual teaching aids may hinder the hearing-impaired child's learning, carefully evaluate the use of these educational methods.

In a group setting, it is helpful for the other members to sit in a semicircle in front of the child with a hearing impairment. Because one of the difficulties in following a group discussion is that the child is unaware of who will speak next, someone should point out each speaker. Speakers can also be given numbers, or their names can be written down as each person talks. If one person writes down the main topic of the discussion, the child is able to follow lipreading more closely. Such practices can increase the child's ability to participate in sports, organizations such as Scouts, and group projects.

Support Child and Family

Once the diagnosis of hearing impairment is made, parents need extensive support to adjust to the shock of learning about their child's disability and an opportunity to realize the extent of the hearing loss. If the hearing loss occurs during childhood, the child also requires sensitive, supportive care during the long and often difficult adjustment to this sensory loss. Early rehabilitation is one of the best strategies for fostering adjustment. Progress in learning communication, however, may not always coincide with emotional adjustment. Depression or anger is common, and such feelings are a normal part of the grieving process.

Care for the Child During Hospitalization

The needs of the hospitalized child with impaired hearing are the same as those of any other child, but the disability presents special challenges to the nurse. For example, verbal explanations must be supplemented by tactile and visual aids, such as books or actual demonstration and practice. Children's understanding of the explanation needs to be constantly reassessed. If their verbal skills are poorly developed, they can answer questions through drawing, writing, or gesturing. For example, if the nurse is attempting to clarify where a spinal tap is done, ask the child to point to where the procedure will be done on the body. Because children with hearing impairments often need more time to grasp the full meaning of an explanation, the nurse needs to be patient and allow ample time for understanding.

When communicating with the child, the nurse should use the same principles as those outlined for facilitating lipreading. The child's hearing aid should be checked to ensure that it is working properly. If it is necessary to awaken the child at night, the nurse should gently shake the child or turn on the hearing aid before arousing the child. The nurse should always make certain that the child can see him or her before any procedures, even routine ones such as changing a diaper or regulating an infusion. It is important to remember that the child may not be aware of the nurse's presence until alerted through visual or tactile cues.

Ideally, parents are encouraged to room with the child. However, the nurse must convey to them that this is not to serve as a convenience to the nurse but as a benefit to the child. Although the parents' aid can be enlisted in familiarizing the child with the hospital and explaining procedures, the nurse should also talk directly to the youngster, encouraging expression of feelings about the experience. If the child's speech is difficult to understand, try to become familiar with his or her pronunciation of words. Parents often can be helpful by explaining the child's usual speech habits. Nonverbal communication devices that use pictures or words that the child can point to are also available. The nurse can make boards by drawing pictures or writing words on cardboard that represent common needs, such as *parent, food, water,* or *toilet.*

The nurse has a special role as child advocate and is in a strategic position to alert other health team members and other patients to the child's special needs regarding communication. For example, the nurse should accompany other practitioners on visits to the child's room to ensure that they speak to the child and that the child understands what is said. Caregivers may forget that the child can perceive and learn despite a hearing loss, and consequently they communicate only with the parents. As a result, the child's needs and feelings remain unrecognized and unaddressed.

Because children with impaired hearing may have difficulty forming social relationships with other children, introduce the child to roommates and encourage them to engage in play activities. The hospital setting can provide growth-promoting opportunities for social relationships. With the assistance of a child life specialist, the child can learn new recreational activities, experiment with group games, and engage in therapeutic play. Playing with puppets or dollhouses, role-playing with dress-up clothes, building with a hammer and nails, finger painting, and water play can help the child express feelings that previously were suppressed.

Assist in Measures to Prevent Hearing Impairment

A primary nursing role is prevention of hearing loss. Because the most common cause of impaired hearing is chronic otitis media, it is essential that appropriate measures be instituted to treat existing infections and prevent recurrences (see Chapter 21. Children with a history of ear or respiratory infections or any other condition known to increase the risk of hearing impairment should receive periodic auditory testing.

To prevent the causes of hearing loss that begin prenatally and perinatally, pregnant women need counseling on the need for early prenatal care, including genetic counseling for known familial disorders; avoidance of all ototoxic drugs, especially during the first trimester; tests to rule out syphilis, rubella, or blood incompatibility; medical management of maternal diabetes; strict control of alcohol intake; adequate dietary intake; and avoidance of smoke exposure. Stress the need for routine immunization during childhood to eliminate the possibility of acquired sensorineural hearing loss from rubella, mumps, or measles (encephalitis).

Exposure to excessive noise pollution is a well-established cause of sensorineural hearing loss. The nurse should routinely assess the possibility of environmental noise pollution and advise children and parents of the potential danger. When individuals engage in activities associated with high-intensity noise (e.g., flying model airplanes, loud music, target shooting, snowmobiling), they should protect their hearing by wearing ear protection devices, decreasing music volume, and limiting or avoiding exposure to loud sounds (Centers for Disease Control and Prevention, 2018a). Even common household equipment, such as lawn mowers, vacuum cleaners, and telephones, can be harmful.

! NURSING ALERT

Suspect hazardous noise if the listener experiences (1) difficulty in communication while hearing the sound, (2) ringing in the ears (tinnitus) after exposure to the sound, or (3) muffled hearing after leaving the sound.

VISUAL IMPAIRMENT

Visual impairment is a common problem during childhood. In the United States, the prevalence of serious visual impairment in the pediatric population is estimated to be between 30 and 64 children per 100,000 population. Visual impairment such as refractive error, strabismus, and amblyopia occur in 5% to 10% of all preschoolers, who are usually identified through vision screening programs (American Academy of Pediatrics, Committee on Practice and Ambulatory Medicine, 2016; O'Hara, 2016; US Department of Health and Human Services, Office of Disease Prevention and Health Promotion, 2015; US Preventive Services Task Force, 2017; Ying, Maguire, Cyert, et al., 2014). The nurse's role is one of assessment, detection, prevention, referral, and (in some instances) rehabilitation.

Definition and Classification

Visual impairment is a general term that encompasses both partial sight and legal blindness. **Partial sight** or **partial visual impairment** is defined as a visual acuity between 20/70 and 20/200. The child can generally use normal-size print, because near vision is almost always better than distance vision. **Legal blindness** or **severe permanent visual impairment** is defined as a visual acuity of 20/200 or lower or a visual field of 20 degrees or less in the better eye. It is important to keep in mind that legal blindness is not a medical diagnosis but a legal definition. Educational and governmental agencies in the United States use the legal definition of blindness to determine tax status, eligibility for entrance into special schools, eligibility for financial aid, and other benefits.

Etiology

Visual impairment can be caused by a number of genetic and prenatal or postnatal conditions. These include perinatal infections (herpes, chlamydia, gonococci, rubella, syphilis, toxoplasmosis); retinopathy of prematurity; trauma; postnatal infections (meningitis); and disorders such as sickle cell disease, juvenile rheumatoid arthritis, Tay-Sachs disease, albinism, and retinoblastoma. In many instances, such as with refractive errors, the cause of the defect is unknown.

Refractive errors are the most common types of visual disorders in children. The term **refraction** means bending and refers to the bending of light rays as they pass through the lens of the eye. Normally, light rays enter the lens and fall directly on the retina. However, in refractive disorders, the light rays fall either in front of the retina (**myopia**) or beyond it (**hyperopia**). Other eye problems, such as strabismus, may or may not include refractive errors, but they are important because, if untreated, they result in severe permanent visual impairment from amblyopia.

Trauma

Trauma is a common cause of visual impairment in children. Injuries to the eyeball and adnexa (supporting or accessory structures, such as eyelids, conjunctiva, or lacrimal glands) can be classified as penetrating or nonpenetrating. **Penetrating wounds** are most often a result of sharp instruments (such as sticks, knives, or scissors) or propulsive objects (such as firecrackers, guns, arrows, or slingshots). **Nonpenetrating injuries** may be a result of foreign objects in the eyes, lacerations, a blow from a blunt object such as a ball (baseball, softball, basketball, racquet sports) or fist, or thermal or chemical burns.

Treatment is aimed at preventing further ocular damage and is primarily the responsibility of the ophthalmologist. It involves adequate examination of the injured eye (with the child sedated or anesthetized in severe injuries); appropriate immediate intervention, such as removal of the foreign body or suturing of the laceration; and prevention of complications, such as administration of antibiotics or steroids and complete bed rest to allow the eye to heal and blood to reabsorb (see Emergency Treatment box). The prognosis varies according to the type of injury. It is usually guarded in all cases of penetrating wounds because of the high risk of serious complications.

Infections

Infections of the adnexa and structures of the eyeball or globe may occur in children. The most common eye infection is **conjunctivitis** (see Chapter 6. Treatment is usually with ophthalmic antibiotics. Severe infections may require systemic antibiotic therapy. Steroids are used cautiously because they exacerbate viral infections such as herpes simplex, increasing the risk of damage to the involved structures.

Nursing Care Management

Nursing care of the visually impaired child is a critical nursing responsibility. Discovery of a visual impairment as early as possible is essential to prevent social, physical, and psychologic damage to the child. Assessment involves (1) identifying those children who by virtue of their history are at risk, (2) observing for behaviors that indicate a vision loss, and (3) screening all children for visual acuity and signs of other ocular disorders such as strabismus. This discussion focuses on clinical manifestations of various types of visual problems. Vision testing is discussed in Chapter 6.

EMERGENCY TREATMENT

Eye Injuries

Foreign Object

Examine eye for presence of a foreign body (evert upper eyelid to examine upper eye).
Remove a freely movable object with pointed corner of gauze pad lightly moistened with water.
Do not irrigate eye or attempt to remove a penetrating object (see Penetrating Injuries).
Caution child against rubbing eye.

Chemical Burns

Irrigate eye copiously with tap water for 15 to 20 minutes.
Evert upper eyelid to flush thoroughly.
Hold child's head with eye under a tap of running lukewarm water.
Take child to emergency department.
Have child rest with eyes closed.
Keep room darkened.

Ultraviolet Burns

If skin is burned, patch both eyes (make certain eyelids are completely closed); secure dressing with Kling bandages wrapped around head rather than with tape.
Have child rest with eyes closed.
Refer to an ophthalmologist.

Hematoma ("Black Eye")

Use a flashlight to check for gross hyphema (hemorrhage into anterior chamber; visible fluid meniscus across iris; more easily seen in light-colored than in brown eyes).
Apply ice for first 24 hours to reduce swelling if no hyphema is present.
Refer to an ophthalmologist immediately if hyphema is present.
Have child rest with eyes closed.

Penetrating Injuries

Take child to emergency department.
Never remove an object that has penetrated eye.
Follow strict aseptic technique in examining eye.
Observe for:

- Aqueous or vitreous leaks (fluid leaking from point of penetration)
- Hyphema
- Shape and equality of pupils, reaction to light, prolapsed iris (not perfectly circular)

Apply a Fox shield if available (not a regular eye patch) and apply patch over unaffected eye to prevent bilateral movement.
Maintain bed rest with child in a 30-degree Fowler position.
Caution child against rubbing eye.
Refer to an ophthalmologist.

Infancy

At birth, the nurse should observe the neonate's response to visual stimuli, such as following a light or object and cessation of body movement. The infant may vary in the intensity of the response, depending on the state of alertness.

Of special importance in detecting visual impairment during infancy are the parents' concerns regarding visual responsiveness in their child. Their concerns, such as lack of eye contact from the infant, must be taken seriously. During infancy, the child should be tested for strabismus. Lack of binocularity after 2 to 4 months of age is considered abnormal and must be treated to prevent amblyopia (American Academy of Pediatrics, Committee on Practice and Ambulatory Medicine, 2016; Rogers & Jordan, 2013).

NURSING ALERT

Suspect visual impairment in an infant who does not react to light and in a child of any age if the parents express concern.

Childhood

Because the most common visual impairment during childhood is refractive error, testing for visual acuity is essential. The school nurse usually assumes major responsibility for vision testing in schoolchildren. In addition to assessing for refractive errors, the nurse should be aware of signs and symptoms that indicate other ocular problems. If the family is given a referral requesting further eye testing, the nurse is responsible for follow-up concerning the recommendation.

Learning that their child is visually impaired precipitates an immense crisis for families. Encourage the family to investigate appropriate early intervention and educational programs for their child as soon as possible. Sources of information include state commissions for the visually impaired, local schools for children with visual impairments, the American Foundation for the Blind,[l] the National Federation of the Blind,[m] the National Association for Parents of Children with Visual Impairments,[n] the National Association for Visually Handicapped,[o] the American Council of the Blind,[p] and CNIB.[q]

Promote Parent-Child Attachment

A crucial time in the life of visually impaired infants is when the infant and the parents are getting acquainted with each other. Pleasurable patterns of interaction between the infant and parents may be lacking if there is not enough reciprocity. For example, if the parent gazes fondly at the infant's face and seeks eye contact but the infant fails to respond because he or she cannot see the parent, a troubled cycle of responses may occur. The nurse can help parents learn to look for other cues that indicate the infant is responding to them, such as whether the eyelids blink; whether the activity level accelerates or slows; whether respiratory patterns change, such as faster or slower breathing, when the parents come near; and whether the infant makes throaty sounds when the parents speak to the infant. In time, parents learn that the infant has unique ways of relating to them. Encourage the parents to show affection using nonvisual methods, such as talking or reading, cuddling, and walking the child.

Promote the Child's Optimal Development

Promoting the child's optimum development requires rehabilitation in a number of important areas. These include learning self-help skills and appropriate communication techniques to become independent. Although nurses may not be directly involved in such programs, they can provide direction and guidance to families regarding the availability of programs and the need to promote these activities in their child.

Development and Independence

Motor development depends on sight almost as much as verbal communication depends on hearing. From earliest infancy, parents are encouraged to expose the infant to as many visual-motor experiences as possible, such as sitting supported in an infant seat or swing and being given opportunities for holding up the head, sitting unsupported, reaching for objects, and crawling.

Despite visual impairment, the child can become independent in all aspects of self-care. The same principles used for promoting independence in sighted children apply, with additional emphasis on nonvisual cues. For example, the child may need help in dressing, such as special arrangement of clothing for style coordination and braille tags to distinguish colors and prints.

The child with permanent visual impairments also must learn to become independent in navigational skills. The two main techniques are the **tapping method** (use of a cane to survey the environment for direction and to avoid obstacles) and **guides**, such as a sighted human guide or a dog guide, such as a seeing eye dog. Children who are partially sighted may benefit from ocular aids, such as a monocular telescope.

Play and Socialization

Children with severe permanent visual impairments do not learn to play automatically. Because they cannot imitate others or actively explore the environment as sighted children do, they depend much more on others to stimulate and teach them how to play. Parents need help in selecting appropriate play materials, especially those that encourage fine and gross motor development and stimulate the senses of hearing, touch, and smell. Toys with educational value are especially useful, such as dolls with various clothing closures.

Children with severe permanent visual impairments have the same needs for socialization as sighted children. Because they have little difficulty in learning verbal skills, they are able to communicate with agemates and participate in suitable activities. The nurse should discuss with parents opportunities for socialization outside the home, especially regular preschools. The trend is to include these children with sighted children to help them adjust to the outside world for eventual independence.

To compensate for inadequate stimulation, these children may develop self-stimulatory activities, such as body rocking, finger flicking, or arm twirling. Discourage such habits because they delay the child's social acceptance. Behavior modification is often successful in reducing or eliminating self-stimulatory activities.

Education

The main obstacle to learning is the child's total dependence on nonvisual cues. Although the child can learn via verbal lecturing, he or she is unable to read the written word or to write without special education. Therefore the child must rely on **braille**, a system that uses raised dots to represent letters and numbers. The child can then read braille with the fingers and can write messages using a braille writer. However, this system is not useful for communicating with others unless others read braille. A more portable system for written communication is the use of a braille slate and stylus or a microcassette tape recorder. A recorder is especially helpful for leaving messages for others and taking notes during classroom lectures. For mathematic calculations, portable calculators with voice synthesizers are available.[r]

Books on CDs and cassette tapes are significant sources of reading material in addition to braille books, which are large and cumbersome. The Library of Congress[s] has talking books and braille books, which are available at many local and state libraries and directly from the Library of Congress. Currently, there are two types of talking books and book players: digital and cassette, though new books are made only in the digital format with the recorded cassettes being phased out (The New York Public Library, 2019). The talking book machine and cassette tape player are provided at no cost to families, and there is no postage fee for returning the materials. Learning Ally (formally known as Recording for the Blind and Dyslexic)[t] also provides texts and CDs and cassette tapes of books, which are helpful for secondary and college students who are visually impaired. A means of writing is learning to use a home computer with a voice synthesizer that can be adapted to speak each letter or word typed.

Children with partial sight benefit from specialized visual aids that produce a magnified retinal image. The basic methods are accommodative techniques, such as bringing the object closer; devices such as special plus lenses, handheld and stand magnifiers, telescopes, video projection systems, and large print materials are used. Special equipment is available to enlarge print. Information about services for the partially sighted is available from the National Association for Visually Handicapped and American Foundation for the Blind. Children with diminished vision often prefer to do close work without their glasses and compensate by bringing the object very near to their eyes. This should be allowed. The exception is children with vision in only one eye, who should always wear glasses for protection.

Care for the Child During Hospitalization

Because nurses are more likely to care for children who are hospitalized for procedures that involve temporary loss of vision than for children who have severe permanent visual impairments, the following discussion concentrates primarily on the needs of such children. The nursing care objectives in either situation are to (1) reassure the child and family throughout every phase of treatment, (2) orient the child to the surroundings, (3) provide a safe environment, and (4) encourage independence. Whenever possible, the same nurse should care for the child to ensure consistency in the approach.

When sighted children temporarily lose their vision, almost every aspect of the environment becomes bewildering and frightening. They are forced to rely on nonvisual senses for help in adjusting to the visual impairment without the benefit of any special training. Nurses have a major role in minimizing the effects of temporary loss of vision. They need to talk to the child about everything that is occurring, emphasizing aspects of procedures that are felt or heard. They should always identify themselves as soon as they enter the room and before they approach the child. Because unfamiliar sounds are especially frightening, these are explained. Encourage the parents to room with their child and participate in the care. Familiar objects, such as a teddy bear or doll, should be brought from home to help lessen the strangeness of the hospital. As soon as the child is able to be out of bed, orient the child to the immediate surroundings. If the child is able to see on admission, this opportunity is taken to point out significant aspects of the room. Encourage the child to practice ambulating with the eyes closed to become accustomed to this experience.

[r]A catalog of numerous products for people with vision problems is available from Lighthouse International. For contact information, see footnote earlier in the chapter.

(State listings of libraries for readers who are visually impaired or physically handicapped, as well as other reference circulars, are available from this office.)

[t]20 Roszel Road, Princeton, NJ 08540; 800-221-4792 or 866-RFBD-585; http://learningally.org; email: info@learningally.org; http://www.facebook.com/LearningAlly.org.

The room is arranged with safety in mind. For example, a stool is placed next to the bed to help the child climb in and out of bed. The furniture is always placed in the same position to prevent collisions. Remind cleaning personnel to keep the room in order. If the child has difficulty navigating by feeling the walls, a rope can be attached from the bed to the point of destination, such as the bathroom. Attention to details (such as well-fitting slippers and robes that do not drag on the floor) is important in preventing tripping. Unlike the child who is visually impaired, these children are not familiar with navigating with a cane.

The child is encouraged to be independent in self-care activities, especially if the visual loss may be prolonged or potentially permanent. For example, during bathing, the nurse sets up all of the equipment and encourages the child to participate. At mealtimes, the nurse explains where each food item is on the tray, opens any special containers, prepares cereal or toast, and encourages the child in self-feeding. Favorite finger foods (such as sandwiches, hamburgers, hot dogs, or pizza) may be good selections. Praise the child for efforts at being cooperative and independent. Any improvements made in self-care, no matter how small, are stressed.

Appropriate recreational activities are provided, and if a child life specialist is available, such planning is done jointly. Because children with temporary visual impairment have a wide variety of play experiences to draw on, they are encouraged to select activities. For example, if they like to read, they may enjoy listening to books on CD or having someone to read to them. If they prefer manual activity, they may appreciate playing with clay or building blocks or feeling different textures and naming them. If they need an outlet for aggression, activities such as pounding or banging on a drum can be helpful. Simple board and card games can be played with a "seeing partner" or an opponent who helps with the game. They should have familiar toys from home to play with because familiar items are more easily manipulated than new ones. If parents want to bring presents, they should be objects that stimulate hearing and touch, such as a radio, music box, or stuffed animal.

Occasionally, children who are visually impaired come to the hospital for procedures to restore their vision. Although this is an extremely happy time, it also requires intervention to help them adjust to sight. They need an opportunity to take in all that they see. They should not be bombarded with visual stimuli. They may need to concentrate on people's faces or their own to become accustomed to this experience. They often need to talk about what they see and to compare the visual images with their mental ones. The children may also go through a period of depression, which must be respected and supported. Encourage the children to discuss how it feels to see, especially in terms of seeing themselves.

Newly sighted children also need time to adjust and engage in activities that were impossible before. For example, they may prefer to use braille to read rather than learning a new "visual approach" because of familiarity with the touch system. Eventually, as they learn to recognize letters and numbers, they will integrate these new skills into reading and writing. However, parents and teachers must be careful not to push them before they are ready. This applies to social relationships and physical activities as well as to learning situations.

Assist in Measures to Prevent Visual Impairment

An essential nursing goal is to prevent visual impairment. This involves many of the same interventions discussed for hearing impairments:

- Prenatal screening for pregnant women at risk, such as those with rubella or syphilis infection and family histories of genetic disorders associated with visual loss
- Adequate prenatal and perinatal care to prevent prematurity
- Periodic screening of all children, especially newborns through preschoolers, for congenital and acquired visual impairments caused by refractive errors, strabismus, and other disorders
- Rubella immunization of all children
- Safety counseling regarding the common causes of ocular trauma, including safe practices when working with, playing with, and carrying objects such as scissors, knives, and balls

! NURSING ALERT

A helmet with a face mask should be required for children playing football, hockey, fencing and baseball (catcher).

After detection of eye problems, the nurse should encourage the family to prevent further ocular damage by undertaking corrective treatment. For the child with strabismus, this often necessitates occlusion patching of the stronger eye. Compliance with the procedure is greatest during the early preschool years. It is more difficult to encourage school-age children to wear the occlusive patch because the poor visual acuity of the uncovered weaker eye interferes with school work and the patch sets them apart from their peers. In school, they benefit from being positioned favorably (closer to the white board or other visual media) and allowed extra time to read or complete an assignment. If treatment of the eye disorder requires instillation of ophthalmic medication, the family is taught the correct procedure (see Chapter 20).

Children who need glasses to correct refractive errors need time to adjust to wearing glasses. Young children who often pull off glasses benefit from temporal pieces that wrap around the ears or an elastic strap attached to the frames and around the back of the head to hold the glasses on securely. Once children appreciate the value of clear vision, they are more likely to wear the corrective lenses.

Glasses should not interfere with any activity. Special protective guards are available during contact sports to prevent accidental injury, and all corrective lenses should be made from safety glass, which is shatterproof. Often, corrective lenses improve visual acuity so dramatically that children are able to compete more effectively in sports. This in itself is a tremendous inducement to continue wearing glasses.

Contact lenses are a popular alternative to conventional glasses, especially for adolescents. Several types are available, such as hard lenses, including gas-permeable ones, and soft lenses, which may be designed for daily or extended wear. Contact lenses offer several advantages over glasses, such as greater visual acuity, total corrected field of vision, convenience (especially with the extended-wear type), and optimal cosmetic benefit. Unfortunately, they are usually more expensive and require much more care than glasses, including considerable practice to learn techniques for insertion and removal. If they are prescribed, the nurse can be helpful in teaching parents or older children how to care for the lenses.

Because trauma is the leading cause of visual impairment, the nurse has the major responsibility of preventing further eye injury until specific treatment is instituted. The major principles to follow when caring for an eye injury are outlined in the Emergency Treatment box earlier in the chapter. Because patients with a serious eye injury fear visual impairment, the nurse should provide the child and family with support and reassurance.

HEARING–VISUAL IMPAIRMENT

The most traumatic sensory impairment is loss of both vision and hearing, which may have profound effects on the child's development. These losses interfere with the normal sequence of physical, intellectual, and psychosocial growth. Although such children often achieve the usual motor milestones, their rate of development is slower. These children learn communication only with specialized training. **Finger spelling** is one desirable method often taught to these children. Words are spelled letter

by letter into the hearing–visually impaired child's hand, and the child spells into the other person's hand. Some children with residual hearing or visual impairment can learn to speak. Whenever possible, encourage speech because it allows communication with other individuals.

The future prospects for hearing–visually impaired children are, at best, unpredictable. Congenital hearing and visual impairment are accompanied by other physical or neurologic problems, which further diminish the child's learning potential. The most favorable prognosis is for children who have acquired hearing and visual impairments with few, if any, associated disabilities. Their learning capacity is greatly potentiated by their developmental progress before the sensory impairments. Although total independence, including gainful vocational training, is the goal, some children with hearing–visual impairment are unable to develop to this level. They may require lifelong parental or residential care. The nurse working with such families helps them deal with future goals for the child, including possible alternatives to home care during the parents' advancing years.

COMMUNICATION IMPAIRMENT

AUTISM SPECTRUM DISORDERS

ASDs are complex neurodevelopmental disorders of unknown etiology. The DSM-5 revised the definition of ASD based on two behavior domains: difficulties in social communication and social interaction and unusually restricted, repetitive behavior, interest, or activities (American Psychiatric Association, 2013; Brentani, Paula, Bordini, et al., 2013; Lai, Lombardo, & Baron-Cohen, 2014).

ASD is frequently diagnosed in toddlers because their atypical development is being recognized early (Lai et al., 2014; Sanchack & Thomas, 2016; Zwaigenbaum, Bauman, Stone, et al., 2015). It occurs in 1 in 59 to 68 children in the United States; is about four times more common in boys than in girls; and is not related to race, region, or socioeconomic level (Baio, Wiggins, Christensen, et al., 2018; Centers for Disease Control and Prevention, 2018b; Christensen, Baio, Braun, et al., 2016; National Autism Association, 2017).

Etiology

The cause of ASD is unknown. Researchers are investigating a number of theories, including a link between hereditary, genetic, medical, immune dysregulation or neuroinflammation, oxidative stress (damage to cellular tissue), and environmental factors (Andrews, Sheppard, & Windham, 2018; Feinberg, Bakulski, Jaffe, et al., 2015; Gilbert & Man, 2017: Ng, de Montigny, Ofner, et al., 2017; Posar & Visconti, 2016; Willfors, Carlsson, Anderlid, et al., 2017; Wong, Napoli, Krakowiak, et al., 2016). Individuals with ASD have been associated with early medical events (cerebral hemorrhage, hyperbilirubinemia), abnormal electroencephalograms, epileptic seizures, delayed development of hand dominance, persistence of primitive reflexes, metabolic abnormalities (elevated blood serotonin), cerebellar vermis hypoplasia (part of the brain involved in regulating motion and some aspects of memory), and infantile abnormal head enlargement (Bridgemohan 2020; Gilbert & Man, 2017; Willfors et al., 2017).

The strong evidence for a genetic basis in twins is consistent with an autosomal recessive pattern of inheritance. Twin studies demonstrate a high concordance (60% to 96%) for monozygotic (identical) twins and less than 5% concordance for dizygotic (nonidentical) twins (Tick, Bolton, Happe, et al., 2016).

There is a relatively high risk of recurrence of ASD in families with one affected child (Chawarska, Shic, Macari, et al., 2014; Sandin, Lichtenstein, Kuja-Holkola, et al., 2014; Zwaigenbaum et al., 2015). Several genes have been suggested as possible causative factors in ASD (Gilbert & Man, 2017; Talkowski, Minikel, & Gusella, 2014; Willsey & State, 2015; Wong et al., 2016).

The scientific evidence to date shows no link between measles, mumps, and rubella (MMR); prenatal tetanus, diphtheria, and acellular pertussis (Tdap); and thimerosal-containing vaccines and ASDs (Barile, Kuperminc, Weintraub, et al., 2012; Becerra-Culqui, Getahun, Chiu, et al., 2018; Centers for Disease Control and Prevention, 2017; Goin-Kochel, Mire, Dempsey, et al., 2016; Price, Thompson, Goodson, et al., 2010; Taylor, Swerdfeger, & Eslick, 2014; Uno, Uchiyama, Kurosawa, et al., 2015; US Food and Drug Administration, 2018; Zerbo, Qian, Yoshida, et al., 2017) (see Translating Evidence Into Practice box). ASD has been reported in association with a number of conditions, such as FXS, tuberous sclerosis, Prader-Willie syndrome, metabolic disorders, fetal rubella syndrome, *Haemophilus influenzae* meningitis, and structural brain anomalies (Kaufmann, Kidd, Andrews, et al., 2017; National Autism Association, 2017; Niu, Han, Dy, et al., 2017). Reports have retrospectively tied ASD to prenatal and perinatal events, such as maternal and paternal ages over 40 years old, uterine bleeding during pregnancy, low Apgar score, fetal distress, and neonatal hyperbilirubinemia (Amin, Smith, & Wang, 2011; Hadjkacem,

TRANSLATING EVIDENCE INTO PRACTICE

Thimerosal-Containing Vaccines and Autism Spectrum Disorders

Ask the Question

Is the incidence of autism spectrum disorders (ASDs) increased in children who receive vaccines containing thimerosal?

Search for the Evidence

Search Strategies

Published studies from 2003 to 2018 focused on the pediatric population and restricted to the English language.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, Vaccine Adverse Events Reporting System (VAERS) database, American Academy of Pediatrics, Autism Research Institute.

Critically Analyze the Evidence

Grade criteria: Moderate evidence with strong recommendations for practice (Balshem, Helfand, Schünemann, et al., 2011). Evidence does not support an association between the increased incidence of autism and mercury exposure from the pharmaceutical preservative thimerosal.

- A Cochrane systematic review of 64 studies assessing the effectiveness and adverse effects associated with the trivalent measles, mumps, and rubella (MMR) vaccine on healthy patients up to 15 years old found no significant association between MMR and either autism or other conditions (Demicheli, Rivetti, Debalini, et al., 2012). Previously done studies supported the same conclusion because the studies found no association between thimerosal-containing vaccines and ASD (Demicheli, Jefferson, Rivetti, et al., 2005; Hurley, Tadrous, & Miller, 2010; Parker, Schwartz, Todd, et al., 2004; Schultz, 2010; World Health Organization, 2012).
- Two large studies in Europe found no evidence that childhood vaccination with thimerosal-containing vaccines was associated with the development of ASDs. One longitudinal study evaluated more than 14,000 children in the United Kingdom. The mercury exposure from thimerosal-containing vaccines was recorded and calculated at ages 3, 4, and 6 months and compared with

TRANSLATING EVIDENCE INTO PRACTICE—cont'd

Thimerosal-Containing Vaccines and Autism Spectrum Disorders

cognitive and behavioral-developmental assessments performed from 6 to 91 months old (Heron, Golding, & ALSPAC Study Team, 2004). The second study, a cohort of 467,450 children in Denmark, compared the incidence of ASDs in children vaccinated with thimerosal-containing vaccines with the incidence of ASDs in children vaccinated with a thimerosal-free formulation of the same vaccine (Hvid, Stellfeld, & Wohlfahrt, 2003).

- Another study that evaluated 1047 children from early life to 7 to 10 years old and their biologic mothers found no statistically significant associations between thimerosal exposure from vaccines early in life. It noted a small but statistically significant association between early thimerosal exposure and the presence of tics in boys and recommended that there be further research in this area (Barile, Kuperminc, Weintraub, et al., 2012). A cohort study that evaluated 196,929 children suggested a possible increased risk of ASD among children whose mothers received an influenza vaccination during their first trimester of pregnancy, although this association was not statistically significant after a post hoc analysis adjusting for multiple comparisons, and there was no association between ASD and influenza vaccination received during any trimester (Zerbo, Qian, Yoshida, et al., 2017).
- Case-control studies have also found no relationships between MMR vaccination and the increased risk of ASDs (Price, Thompson, Goodson, et al., 2010; Uno, Uchiyama, Kurosawa, et al., 2015). Another small case control study investigated the mercury level in maternal prenatal serum and early postnatal newborn serum of children with ASD (n = 84) compared to children with intellectual disability or developmental delay (n = 49) and the general population (n = 159) and found no significant association with the risk of ASD (Yau, Green, Alaimo, et al., 2014). A similar finding was concluded in a meta-analysis of evidence on the impact of prenatal and early infancy exposures to mercury on autism and attention-deficit/hyperactivity disorder (ADHD) with the recommendation of further study to be conducted on the effects of environmental perinatal mercury exposures and increased risk of developmental disorders (Yoshimasu, Kiyohara, Takemura, et al., 2014).
- Review studies by the same first author reported epidemiologic evidence of a suggestive and/or significant relationship between increasing organic mercury exposure from thimerosal-containing vaccines and subsequent risk of neurodevelopmental disorders. The case-controlled studies examined automated records updated through the year 2000 in the Vaccine Safety Datalink (VSD) for organic exposure to hepatitis B vaccine administered in the first 6 months of life with a significant increased risk of neurodevelopmental disorder (Geier, Hooker, Kern, et al., 2014) and also examined organic exposure from *Haemophilus influenzae* type b with suggestive neurodevelopmental outcomes (Geier, Kern, Homme, et al., 2018; Geier, Kern, King, et al., 2015). Conversely, the Global Advisory Committee on Vaccine Safety reviewed both animal and human toxicity studies in which the blood and brain did not attain toxic levels, making it biologically implausible for any relationship between thimerosal in vaccines and neurologic toxicity to exist (World Health Organization, 2012). Another evidence-based meta-analysis of case-controlled studies and cohort studies supported the same conclusion; the findings suggested that vaccinations are not associated with the development of autism or ASD (Taylor, Swerdfeger, & Eslick, 2014).
- In 2004 the Institute of Medicine completed a review and concluded that the epidemiologic evidence supports the rejection of a causal relationship between thimerosal exposure from childhood vaccines and the onset of autism (Institute of Medicine, 2004). In 2013 the Institute of Medicine completed an update to the review of the evidence reported from January 1990 to May 2013 and concluded that the review did not reveal an evidence base, suggesting that the US childhood immunization schedule is linked to learning or developmental disorders or attention-deficit or disruptive disorders. This review was also supported by the Institute of Medicine (2011) in a report on adverse effects of vaccines. The Institute of Medicine, now called the National Academy of Medicine, concluded that the body of evidence favors rejection of a causal relationship between autism and the MMR vaccine and thimerosal-containing vaccines (Institute of Medicine, 2011, 2013) as reported by the US Food and Drug Administration (2018). Based on guidelines established by the US Food and Drug Administration (2018), Centers for Disease Control and Prevention (2017), and other government monitoring agencies, no children will be exposed to excessive mercury from childhood vaccines.

Apply the Evidence: Nursing Implications

There is moderate-quality evidence with a strong recommendation that there is no link between vaccines containing thimerosal and ASDs.

Quality and Safety Competencies: Evidence-Based Practice[a]

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Compare research summaries that provide evidence of the lack of association between vaccines containing thimerosal and autism or other neurodevelopmental disorders.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by sharing results with parents regarding the benefits of vaccinating their children and the evidence regarding lack of association between immunizations and autism disorders.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate strengths and weaknesses of the evidence that confirms the lack of a link between vaccines containing thimerosal and autism or other neurodevelopmental disorders.

[a]Based on the Quality and Safety Education for Nurses website at http://www.qsen.org.

Ayadi, Turki, et al., 2016; Wang, Hua, Weidong, et al., 2017). These same researchers, however, urge caution in interpreting these findings.

Clinical Manifestations and Diagnostic Evaluation

Children with ASD demonstrate core deficits primarily in social interactions, communication, and behavior. Failure of social interaction and communication development is one of the hallmarks of ASD. Parents of autistic children have reported that their child showed less interest in social interaction (e.g., abnormal eye contact, decreased response to own name, decreased imitation, usual repetitive behavior) and had verbal and motor delay (Bolton, Golding, Emond, et al., 2012; Kirchner, Hatri, Heekeren, et al., 2011; National Autism Association, 2017; Sanchack & Thomas, 2016). Children with ASD may have significant gastrointestinal symptoms. Constipation is a common symptom and can be associated with acquired megarectum in children with ASD (National Autism Association, 2017; Neumeyer, Anixt, Chan, et al., 2018).

Children with autism do not always have the same manifestations, from mild forms requiring minimal supervision to severe forms in which self-abusive behavior is common. The majority of children with autism have some degree of CI, with scores typically in the moderate to severe range. Despite their relatively moderate to severe disability, some children with autism (known as **savants**) excel in particular areas, such as art, music, memory, mathematics, or perceptual skills, such as puzzle building.

[a]Additional information on secretin may be found by contacting the Autism Society, 4340 East-West Hwy., Suite 350, Bethesda, MD 20814-3067; 800-3AUTISM or 301-657-0881; http://www.autism-society.org.

NURSING TIP Claims of beneficial results from the use of secretin, a peptide hormone that stimulates pancreatic secretion, have been studied extensively in multiple randomized control trials, denoting clear evidence that it lacks any benefit (Krishnaswami, McPheeters, & Veenstra-Vanderweele, 2011; Lee, Oh, Park, et al., 2014; Lyra, Rizzo, Sunahara, et al., 2017; Williams, Wray, & Wheeler, 2012).[a]

Communication impairments are a common sign in children with ASD that may range from absent to delayed speech. Any child who does not display language skills such as babbling or gesturing by 12 months old, single words by 16 months old, and two-word phrases by 24 months old is recommended for immediate hearing and language evaluation. Autism regression occurs when the child seems to develop normally, then regresses suddenly; this is a red-flag event that has been frequently displayed in expressive language (Fernell, Eriksson, & Gillberg, 2013; National Autism Association, 2017; Pearson, Charman, Happe, et al., 2018).

Early recognition, referral, diagnosis, and intensive early intervention tend to improve outcomes for children with ASD (Adelman & Kubiszyn, 2016; Christensen, Maenner, Bilder, et al., 2019; National Autism Association, 2017; Reichow, Hume, Barton, et al., 2018; Zwaigenbaum et al., 2015). Unfortunately, diagnosis is often not made until 2 to 3 years after symptoms are first recognized. However, in a retrospective study, the majority of parents observed atypical development in their children with ASD before 24 months of age (Lemcke, Juul, Parner, et al., 2013).

The American Academy of Pediatrics has recommended that pediatric health care providers administer two ASD screenings at ages 18 and 24 months using a valid screening tool. Children whose screening results are concerning subsequently should receive a comprehensive developmental evaluation from a developmental pediatrician, child neurologist, child psychiatrist, or child psychologist (Baio et al., 2018; National Autism Association, 2017).

Prognosis

ASD is usually a lifelong condition with often devastating comorbidities. However, with early and intensive interventions, the symptoms associated with autism can be greatly improved, and in some cases reported symptoms were completely overcome (Kerub, Haas, Menashe, et al., 2018; National Autism Association, 2017; Sanchack & Thomas, 2016; Wodka, Mathy, & Kalb, 2013). Some ultimately achieve independence, but most require lifelong adult supervision. Aggravation of psychiatric symptoms occurs in about half of children with ASD during adolescence, with girls having a tendency for continued deterioration.

Early recognition of behaviors associated with ASD is critical to implement appropriate interventions and family involvement. There is a growing body of evidence that parent-delivered interventions are associated with some improved outcomes, yet further research

incorporating consistent measures is needed in this area (Bearss, Burrell, Stewart, et al., 2015; Brentani et al., 2013; Oono, Honey, & McConachie, 2013). The prognosis is most favorable for children with higher intelligence, functional speech, and less behavioral impairment (Bridgemohan 2020; Orinstein, Helt, Troyb, et al., 2014; Solomon, Buaminger, & Rogers, 2011).

Nursing Care Management

Therapeutic intervention for children with ASD is a specialized area involving professionals with advanced training. Although there is no cure for ASD, numerous therapies have been used. The most promising results have been through highly structured and intensive behavior modification programs. In general, the objective in treatment is to promote positive reinforcement, increase social awareness of others, teach verbal communication skills, and decrease unacceptable behavior. Providing a structured routine for the child to follow is key in the management of ASD.

ASD is associated with comorbidities (e.g., aggression, explosive outburst, self-injury, asthma, epilepsy, gastrointestinal or digestive disorders, immune disorders, feeding disorders, anxiety disorder, bipolar disorder, sleeping disorders) that have been treated with not only early behavioral modification programs but also medical management (e.g., aripiprazole [Abilify] and risperidone [Risperdal]) and complementary and alternative medicine (Goel, Hong, Findling, et al., 2018; National Autism Association, 2017; Sanchack & Thomas, 2016). Complementary and alternative medicine has emerged as a treatment of ASD ranging from massage and therapeutic horseback riding to the implementation of elimination diets (e.g., gluten-free diet and casein-free diet); vitamin and omega-3 supplementation; and high-fat, low-carbohydrate ketogenic diet. However, there is a need for further research to validate these therapeutic approaches (Adams, Audhya, Geis, et al., 2018; Cheng, Rho, & Masino, 2017; Hopf, Madren, & Santianni, 2016; Ly, Bottelier, Hoekstra, et al., 2017; Nath, 2017; Trzmiel, Purandare, Michalak, et al., 2019).

When these children are hospitalized, the parents are essential to planning care and ideally should stay with the child as much as possible. Nurses should recognize that not all children with ASD are the same and that they require individual assessment and treatment. Decreasing stimulation by using a private room, avoiding extraneous auditory and visual distractions, and encouraging the parents to bring in possessions the child is attached to may lessen the disruptiveness of hospitalization. Because physical contact often upsets these children, minimal holding and eye contact may be necessary to avoid behavioral outbursts. Take care when performing procedures on, administering medicine to, and feeding these children because they may be either fussy eaters who willfully starve themselves or gag to prevent eating or indiscriminate hoarders who swallow any available edible or inedible items, such as a thermometer. The eating habits of children with ASD may be particularly problematic for families and may involve food refusal accompanied by mineral deficiencies, mouthing objects, eating nonedibles, and smelling and throwing food (Herndon, DiGuiseppi, Johnson, et al., 2009; Lazaro & Ponde, 2017; Panerai, Suraniti, Cantania, et al., 2018).

Children with ASD need to be introduced slowly to new situations, with visits with staff caregivers kept short whenever possible. Because these children have difficulty organizing their behavior and redirecting their energy, they need to be told directly what to do. Communication should be at the child's developmental level, brief, and concrete.

Family Support

ASD, as with so many other chronic conditions, involves the entire family and often becomes "a family disease." Nurses can help alleviate the guilt and shame often associated with this disorder by stressing what is known from a biologic standpoint and by providing family support. It is imperative to help parents understand that they are not the cause of the child's condition.

Parents need expert counseling early in the course of the disorder and should be referred to the Autism Society website. The society provides information about education, treatment programs and techniques, and facilities such as camps and group homes. Other helpful resources for parents of children with ASD are the local and state departments of mental health and developmental disabilities; these organizations provide important programs and in-school programs throughout the United States for children with ASD.

As much as possible, the family is encouraged to care for the child in the home. With the help of family support programs in many states, families are often able to provide home care and assist with the educational services the child needs. As the child approaches adulthood and the parents become older, the family may require assistance in locating a long-term placement facility.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A mother comments to a nurse working on the pediatric unit, "My second child just does not seem to be acting like or responding the same way as my first child. She is 2 years old and she does not speak." The nurse performs a complete history and assessment and the findings are listed below. **Select the assessment findings that require follow-up by the nurse. Select all that apply.**
   - **A.** Unable to speak
   - **B.** The mother is a single mom
   - **C.** Unable to follow instructions
   - **D.** Sibling was delayed a year in school
   - **E.** History of urinary tract infection at 1year of age
   - **F.** The child was premature; born at 36 weeks' gestation
   - **G.** History of maternal drug consumption during pregnancy
   - **H.** History of irritability and crying without being able to be consoled.

2. When interacting with a parent at a 3-year-old during the child's well visit, which information below provided by the parent would be an indication for a speech referral? **Select all that apply.**
   - **A.** Frequent omission of final consonants
   - **B.** Stuttering or any other type of dysfluency
   - **C.** Failure to use sentences of three or more words
   - **D.** Failure to speak any meaningful words spontaneously
   - **E.** Using different words or nicknames for certain people
   - **F.** Omission of word endings (e.g., plurals, tenses of verbs)

3. A mother of a child with Down syndrome is overwhelmed by thoughts of the future and asks many questions. She is 35 years old and blames herself for waiting so long to get pregnant. She is not sure how to care for the child now that she is turning 1 year of age. The nurse providing teaching would discuss which of the following with the mother? **Use an X for the health teaching statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
"It is unfortunate that you waited so long to have children, most children with Down syndrome are born to older women."			
"When feeding your infant use a small, straight-handled spoon to push food to the side and back of the mouth."			
"Parents like you believe that the experience of having this special child makes them stronger and more accepting of others."			
"As your child gets older it has been found that school is detrimental to the child with Down syndrome due to lack of one-on-one teaching."			
"I am going to listen closely to your child's heart because congenital heart problems can occur in a child with Down syndrome."			

4. The nurse is caring for a 4-year-old boy who has been diagnosed with Autism Spectrum Disorder (ASD). The mother is convinced that the childhood immunizations he has received have caused his ASD. The child has difficulty making eye contact and has verbal and motor delays. Understanding autism spectrum disorders (ASDs) is very important for those who care for children. What would be the nurse's response to the mother's concerns? **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**

Research studies have found that there is no link between ___1___ containing ___2___ and the development of ASD in children.

Options for 1	Options for 2
antibiotics	thimerosal
vitamins	arsenic
vaccines	penicillin
milk	hormones
fruit juices	amoxicillin

- Family-Centered Care

STRESSORS OF HOSPITALIZATION AND CHILDREN'S REACTIONS

Often illness and hospitalization are the first crises children must face. Especially during the early years, children are particularly vulnerable to these stressors because stress represents a change from the usual state of health and environmental routine, and children have a limited number of coping mechanisms to resolve **stressors**. Major stressors of hospitalization include separation, loss of control, bodily injury, and pain. Children's reactions to these crises are influenced by their developmental age; their previous experience with illness, separation, or hospitalization; their innate and acquired coping skills; the seriousness of the diagnosis; and the support system available. Children also expressed fears caused by the unfamiliar environment or lack of information; child-staff relations; and the physical, social, and symbolic environment (Samela, Salanterä, & Aronen, 2009).

SEPARATION ANXIETY

The major stress from middle infancy throughout the preschool years, especially for children ages 6 to 30 months, is separation anxiety, also called **anaclitic depression**. The principal behavioral responses to this stressor during early childhood are summarized in Box 19.1. During the stage of **protest**, children react aggressively to the separation from the parent. They cry and scream for their parents, refuse the attention of anyone else, and are inconsolable in their grief (Fig. 19.1). In contrast, through the stage of **despair**, the crying stops, and depression is evident. The child is much less active, is uninterested in play or food, and withdraws from others (Fig. 19.2).

The third stage is **detachment**, also called **denial**. Superficially, it appears that the child has finally adjusted to the loss. The child becomes more interested in the surroundings, plays with others, and seems to form new relationships. However, this behavior is the result of resignation and is not a sign of contentment. The child detaches from the parent in an effort to escape the emotional pain of desiring the parent's presence and copes by forming shallow relationships with others, becoming increasingly self-centered, and attaching primary importance to material objects. This is the most serious stage in that reversal of the potential adverse effects is less likely to occur after detachment is established. In most situations, the temporary separations imposed by hospitalization do not cause such prolonged parental absences that the child enters the detachment stage. In addition, considerable evidence suggests that even with stressors (such as separation) children are remarkably adaptable, and permanent ill effects are rare.

Although progression to the stage of detachment is uncommon, the initial stages are frequently observed even with brief separations from either parent. Unless health team members understand the meaning of each stage of behavior, they may erroneously label the behaviors as positive or negative. For example, they may see the loud crying of the protest phase as "bad" behavior. Because the protests increase when a stranger approaches the child, they may interpret that reaction as meaning that they should stay away. During the quiet, withdrawn phase of despair, health team members may think that the child is finally "settling in" to the new surroundings, and they may see the detachment behaviors as proof of a "good adjustment." The faster this stage is reached, the more likely it is that the child will be regarded as the "ideal patient."

Because children seem to react "negatively" to visits by their parents, uninformed observers feel justified in restricting parental visiting privileges. For example, during the protest stage, children outwardly do not appear happy to see their parents (Fig. 19.3). In fact, they may even cry louder. If they are depressed, they may reject their parents or begin to protest again. Often they cling to their parents in an effort to ensure their continued presence. Consequently, such reactions may be regarded as "disturbing" the child's adjustment to the new surroundings. If the separation has progressed to the phase of detachment, children will respond no differently to their parents than they would to any other person.

Such reactions are distressing to parents, who are unaware of their meaning. If parents are regarded as intruders, they will see their absence as "beneficial" to the child's adjustment and recovery. They may respond to the child's behavior by staying for only short periods, visiting less frequently, or deceiving the child when it is time to leave. The result is a destructive cycle of misunderstanding and unmet needs.

BOX 19.1 Manifestations of Separation Anxiety in Young Children

Stage of Protest

Behaviors observed during later infancy include:

- Cries
- Screams
- Searches for parent with eyes
- Clings to parent
- Avoids and rejects contact with strangers

Additional behaviors observed during toddlerhood include:

- Verbally attacks strangers (e.g., "Go away")
- Physically attacks strangers (e.g., kicks, bites, hits, pinches)
- Attempts to escape to find parent
- Attempts to physically force parent to stay

Behaviors may last from hours to days.

Protest, such as crying, may be continuous, ceasing only with physical exhaustion.

Approach of a stranger may precipitate increased protest.

Stage of Despair

Observed behaviors include:

- Is inactive
- Withdraws from others
- Is depressed, sad
- Lacks interest in environment
- Is uncommunicative
- Regresses to earlier behavior (e.g., thumb sucking, bedwetting, use of pacifier, use of bottle)

Behaviors may last for variable length of time.

Child's physical condition may deteriorate from refusal to eat, drink, or move.

Stage of Detachment

Observed behaviors include:

- Shows increased interest in surroundings
- Interacts with strangers or familiar caregivers
- Forms new but superficial relationships
- Appears happy

Detachment usually occurs after prolonged separation from parent; it is rarely seen in hospitalized children.

Behaviors represent a superficial adjustment to loss.

Fig. 19.1 In the protest phase of separation anxiety, children cry loudly and are inconsolable in their grief for the parent. (© 2015 iStock.com.)

Fig. 19.2 During the despair phase of separation anxiety, children are sad, lonely, and uninterested in food and play.

Fig. 19.3 Young children may appear withdrawn and sad even in the presence of a parent. (Courtesy E. Jacob, Texas Children's Hospital, Houston, TX.)

Early Childhood

Separation anxiety is the greatest stress imposed by hospitalization during early childhood. If separation is avoided, young children have a tremendous capacity to withstand any other stress. During this age period, the typical reactions just described are seen. Children in the toddler stage demonstrate more goal-directed behaviors. For example, they may plead with the parents to stay and physically try to keep the parents with them or try to find parents who have left. The child may demonstrate displeasure on the parents' return or departure by having temper tantrums; refusing to comply with the usual routines of mealtime, bedtime, or toileting; or regressing to more primitive levels of development. Temper tantrums, bedwetting, or other behaviors exhibited by children may also be expressions of anger, a physiologic response to stress, or symptoms of illness.

Because preschoolers are more secure interpersonally than toddlers, they can tolerate brief periods of separation from their parents and are more inclined to develop substitute trust in other significant adults. The stress of illness usually renders preschoolers less able to cope with

separation; as a result, they manifest many of the stage behaviors of separation anxiety. In general, the protest behaviors are more subtle and passive than those seen in younger children. Preschoolers may demonstrate separation anxiety by refusing to eat, having trouble sleeping, crying quietly for their parents, continually asking when the parents will visit, or withdrawing from others. They may express anger indirectly by breaking toys, hitting other children, or refusing to cooperate during usual self-care activities. Nurses need to be sensitive to these less obvious signs of separation anxiety in order to intervene appropriately.

Later Childhood and Adolescence

Previous research has indicated that the family does not play as important a role for school-age children as it does during the toddler and preschool years. In a prior study, children were asked about their fears when hospitalized, and children listed their greatest fears regarding hospitalization as being separated from family and friends, being in an unfamiliar environment, receiving investigations or treatments, and losing self-determination or choices (Coyne, 2006). In a qualitative study of children 5 to 9 years old, children described hospitalization in stories that focused on being alone and feeling scared, angry, or sad. These children also described the need for protection and companionship while hospitalized (Wilson, Megel, Enenbach, et al., 2010).

Although school-age children are better able to cope with separation in general, the stress and often accompanying regression imposed by illness or hospitalization may increase their need for parental security and guidance. This is particularly true for young school-age children who have only recently left the safety of the home and are struggling with the crisis of school adjustment. School-age children may react more to the separation from their usual activities and peers than to the absence of their parents. These children have a high level of physical and mental activity that frequently finds no suitable outlets in the hospital environment, and even when they dislike school, they admit to missing its routine and worry that they will not be able to compete or "fit in" with their classmates when they return. Feelings of loneliness, boredom, isolation, and depression are common. Such reactions may occur more as a result of separation than of concern over the illness, treatment, or hospital setting.

School-age children may need and desire parental guidance or support from other adult figures but may be unable or unwilling to ask for it. Because the goal of attaining independence is so important to them, they are reluctant to seek help directly, fearing that they will appear weak, childish, or dependent. Cultural expectations to "act like a man" or to "be brave and strong" weigh heavily on these children, especially boys, who tend to react to stress with stoicism, withdrawal, or passive acceptance. Often the need to express hostile, angry, or other negative feelings finds outlets in alternate ways, such as irritability and aggression toward parents, withdrawal from hospital personnel, inability to relate to peers, rejection of siblings, or subsequent behavioral problems in school.

For adolescents, separation from home and parents may produce varied emotions, ranging from difficulty coping to welcoming the event. Loss of peer-group contact may pose a severe emotional threat because of loss of group status, inability to exert group control or leadership, and loss of group acceptance. Deviations within peer groups are poorly tolerated, and although group members may express concern for the adolescent's illness or need for hospitalization, they continue their group activities, quickly filling the gap of the absent member. During the temporary separation from their usual group, ill adolescents may benefit from group associations with other hospitalized teens.

LOSS OF CONTROL

One of the factors influencing the amount of stress imposed by hospitalization is the amount of control a person perceives he or she possesses. Lack of control increases the perception of threat and can affect children's coping skills. Many hospital situations decrease the amount of control a child feels. Although the usual sensory stimulations are lacking, the additional hospital stimuli of sight, sound, and smell may be overwhelming. Without an insight into the type of environment conducive to children's optimal growth, the hospital experience can at best temporarily slow development and at worst permanently restrict it. Because children's needs vary greatly depending on their age, the major areas of loss of control in terms of physical restriction, altered routine or rituals, and dependency are discussed for each age-group.

EFFECTS OF HOSPITALIZATION ON THE CHILD

Children may react to the stressors of hospitalization before admission, during hospitalization, and after discharge. A child's concept of illness is even more important than age and intellectual maturity in predicting the level of anxiety before hospitalization (Clatworthy, Simon, & Tiedeman, 1999). This may or may not be affected by the duration of the condition or prior hospitalizations; therefore nurses should avoid overestimating the illness concepts of children with prior medical experience (Box 19.2).

Individual Risk Factors

A number of risk factors make certain children more vulnerable than others to the stresses of hospitalization (Box 19.3). Rural children

BOX 19.2 Post-Hospital Behaviors in Children

Young Children

They show initial aloofness toward parents; this may last from a few minutes (most common) to a few days.

This is frequently followed by dependency behaviors:

- Tendency to cling to parents
- Demands for parents' attention
- Vigorous opposition to any separation (e.g., staying at preschool or with a babysitter)

Other negative behaviors include:

- New fears (e.g., nightmares)
- Resistance to going to bed, night waking
- Withdrawal and shyness
- Hyperactivity
- Temper tantrums
- Food peculiarities
- Attachment to blanket or toy
- Regression in newly learned skills (e.g., self-toileting)

Older Children

Negative behaviors include:

- Emotional coldness followed by intense, demanding dependence on parents
- Anger toward parents
- Jealousy toward others (e.g., siblings)

BOX 19.3 Risk Factors That Increase Children's Vulnerability to the Stressors of Hospitalization

"Difficult" temperament
Lack of fit between child and parent
Age (especially between 6 months old and 5 years old)
Male gender
Below-average intelligence
Multiple and continuing stresses (e.g., frequent hospitalizations)

may exhibit significantly greater degrees of psychologic upset than urban children, possibly because urban children have opportunities to become familiar with a local hospital. Because separation is such an important issue surrounding hospitalization for young children, children who are active and strong willed tend to fare better when hospitalized than youngsters who are passive. Consequently, nurses should be alert to children who passively accept all changes and requests; these children may need more support than "oppositional" children.

The stressors of hospitalization may cause young children to experience short- and long-term negative outcomes. Adverse outcomes may be related to the length and number of admissions, multiple invasive procedures, and the parents' anxiety. Common responses include regression, separation anxiety, apathy, fears, and sleeping disturbances, especially for children younger than 7 years old (Melnyk, 2000). Supportive practices, such as family-centered care and frequent family visiting, may lessen the detrimental effects of such admissions. Nurses should attempt to identify children at risk for poor coping strategies (Small, 2002).

Changes in the Pediatric Population

The pediatric population in hospitals has changed dramatically over the past 2 decades. With a growing trend toward shortened hospital stays and outpatient surgery, a greater percentage of the children hospitalized today have more serious and complex problems than those hospitalized in the past. Many of these children are fragile newborns and children with severe injuries or disabilities who have survived because of major technologic advances and have been left with chronic or disabling conditions that require frequent and lengthy hospital stays. The nature of their conditions increases the likelihood that they will experience more invasive and traumatic procedures while they are hospitalized. These factors make them more vulnerable to the emotional consequences of hospitalization and result in their needs being significantly different from those of the short-term patients of the past (see Chapter 18 for further discussion on children with special needs). Most of these children are infants and toddlers, which is the age-group most vulnerable to the effects of hospitalization.

Concern in recent years has focused on the increasing length of hospitalization because of complex medical and nursing care, elusive diagnoses, and complicated psychosocial issues. Without special attention devoted to meeting children's psychosocial and developmental needs in the hospital environment, the detrimental consequences of prolonged hospitalization may be severe.

Beneficial Effects of Hospitalization

Although hospitalization can be and usually is stressful for children, it can also be beneficial. The most obvious benefit is the recovery from illness, but hospitalization also can present an opportunity for children to master stress and feel competent in their coping abilities. The hospital environment can provide children with new socialization experiences that can broaden their interpersonal relationships. The psychologic benefits need to be considered and maximized during hospitalization. Appropriate nursing strategies to achieve this goal are presented later in the chapter.

STRESSORS AND REACTIONS OF THE FAMILY OF THE CHILD WHO IS HOSPITALIZED

PARENTAL REACTIONS

The crisis of childhood illness and hospitalization affects every member of the family. Parents' reactions to illness in their child depend on a variety of factors. Although one cannot predict which factors are most likely to influence their response, several variables have been identified (Box 19.4). (See also Chapter 17.)

BOX 19.4 Factors Affecting Parents' Reactions to Their Child's Illness

- Seriousness of the threat to the child
- Previous experience with illness or hospitalization
- Medical procedures involved in diagnosis and treatment
- Available support systems
- Personal ego strengths
- Previous coping abilities
- Additional stresses on the family system
- Cultural and religious beliefs
- Communication patterns among family members

Recent research has identified common themes among parents whose children were hospitalized. These include feelings of an overall sense of helplessness, questioning the skills of staff, accepting the reality of hospitalization, needing to have information explained in simple language, dealing with fear, coping with uncertainty, and seeking reassurance from caregivers. Reassurance from the health care team can be in the form of collaboration, information sharing, preparation for procedures, ensuring formal and informal support for the family, and providing information in an unbiased and culturally sensitive manner (Eichner & Johnson, 2012).

SIBLING REACTIONS

Siblings' reactions to a sister's or brother's illness or hospitalization are discussed in Chapter 17 and differ little when a child becomes temporarily ill. Siblings experience loneliness, fear, and worry, as well as anger, resentment, jealousy, and guilt. Illness may also result in children's loss of status within either their family or their social group. Various factors that influence the effects of the child's hospitalization on siblings have been identified. Recently, it has been found that parents of siblings of children with chronic illness tended to rate sibling health-related quality of life better than the siblings' self-reports, and greater disease severity of the affected child and older sibling age may be risk factors for impaired well sibling quality of life (Limbers & Skipper, 2014). Although these factors are similar to those seen when a child has a chronic illness, Craft (1993) reported that the following factors regarding siblings are related specifically to the hospital experience and increase the effects on the sibling:

- Being younger and experiencing many changes
- Being cared for outside the home by care providers who are not relatives
- Receiving little information about their ill brother or sister
- Perceiving that their parents treat them differently compared with before their sibling's hospitalization

Parents are often unaware of the number of effects that siblings experience during the sick child's hospitalization and the benefit of simple interventions to minimize such effects, such as explicit explanations about the illness and provisions for the siblings to remain at home. Sibling visitation is usually beneficial to the patient, sibling, and parent but should be evaluated on an individual basis. Siblings should be prepared for the visit with developmentally appropriate information and be given the opportunity to ask questions.

NURSING CARE OF THE CHILD WHO IS HOSPITALIZED

PREPARATION FOR HOSPITALIZATION

Children and families require individualized care to minimize the potential negative effects of hospitalization. One method that can decrease negative feelings and fear in children is preparation for hospitalization. The rationale for preparing children for the hospital experience and related procedures is based on the principle that fear of the unknown exceeds fear of the known. When children do not have paralyzing fear to cope with, they are able to direct their energies toward dealing with the other, unavoidable stresses of hospitalization.

Although preparation for hospitalization is a common practice, there is no universal standard or program for all settings. The preparation process may be elaborate, with tours, puppet shows, and playtime with miniature hospital equipment; it may involve the use of books, videos, or films; or it may be limited to a brief description of the major aspects of any hospital stay. No consensus exists on the timing of preparation. Some authorities recommend preparing children 4 to 7 years old about 1 week in advance so that they can assimilate the information and ask questions. For older children, the time may be longer. For young children, who may be unsure about what they observed, 1 or 2 days before admission is sufficient for anticipatory preparation. The length of the session should be tailored to the children's attention span—the younger the child, the shorter the program. The optimal approach is one that is individualized for each child and family.

Regardless of the specific type of program, all children, even those who have been hospitalized previously, benefit from an introduction to the environment and routine of the unit. Sometimes it is not possible to prepare children and families for hospitalization, such as in the event of sudden, acute illness. Care should be taken to orient the child and family to hospital routines, establish expectations, and allow for questions (Abraham & Moretz, 2012).

NURSING TIP: In many hospitals, child life specialists—health care professionals with extensive knowledge of child growth and development and of the special psychosocial needs of children who are hospitalized and their families—help prepare children for hospitalization, surgery, and procedures. Although the structure of a program may vary depending on the size of the pediatric facility, the patient population, and the availability of ancillary services, the two primary program objectives for child life specialists are consistent: (1) to reduce the stress and anxiety related to the hospitalization or health care–related experiences and (2) to promote normal growth and development in the health care setting and at home (Thompson, 2009).

A collaborative effort between the nurse, child life specialist, and other members of the child's health care team helps ensure the best possible hospital experience for the child and family.

Admission Assessment

The nursing admission history refers to a systematic collection of data about the child and family that allows the nurse to plan individualized care. The nursing admission history presented in Box 19.5

BOX 19.5 Nursing Admission History According to Functional Health Patterns[a]

Health Perception/Health Management Pattern

Why has your child been admitted?
How has your child's general health been?
What does your child know about this hospitalization?
- Ask the child why he or she came to the hospital.
- If the answer is "For an operation or for tests," ask the child to tell you about what will happen before, during, and after the operation or tests.

Has your child ever been in the hospital before?
- How was that hospital experience?
- What things were important to you and your child during that hospitalization? How can we be most helpful now?

What medications does your child take at home?
- Why are they given?
- When are they given?
- How are they given (if a liquid, with a spoon; if a tablet, swallowed with water; or other)?
- Does your child have any trouble taking medication? If so, what helps?
- Is your child allergic to any medications?

What, if any, forms of complementary medicine practices are being used?

Nutrition/Metabolic Pattern

What is the family's usual mealtime?
Do family members eat together or at separate times?
What are your child's favorite foods, beverages, and snacks?
- Average amounts consumed or usual size of portions
- Special cultural practices, such as family eats only ethnic food

What foods and beverages does your child dislike?
What are your child's feeding habits (bottle, cup, spoon, eats by self, needs assistance, any special devices)?
How does your child like the food served (warmed, cold, one item at a time)?
How would you describe your child's usual appetite (hearty eater, picky eater)?
- Has being sick affected your child's appetite? In what ways?

Are there any known or suspected food allergies?
Is your child on a special diet?
Are there any feeding problems (excessive fussiness, spitting up, colic); any dental or gum problems that affect feeding?
- What do you do for these problems?

Elimination Pattern

What are your child's toileting habits (diaper, toilet trained—day only or day and night, use of word to communicate urination or defecation, potty chair, regular toilet, other routines)?
What is your child's usual pattern of elimination (bowel movements)?
Do you have any concerns about elimination (bedwetting, constipation, diarrhea)?
- What do you do for these problems?

Have you ever noticed that your child sweats a lot?

Sleep/Rest Pattern

What is your child's usual hour of sleep and awakening?
What is your child's schedule for naps; length of naps?
Is there a special routine before sleeping (bottle, drink of water, bedtime story, night-light, favorite blanket or toy, prayers)?
Is there a special routine during sleep time, such as waking to go to the bathroom?
What type of bed does your child sleep in?
Does your child have a separate room or share a room; if shares, with whom?
Does your child sleep with someone or alone (e.g., sibling, parent, other person)?
What is your child's favorite sleeping position?
Are there any sleeping problems (falling asleep, waking during night, nightmares, sleep walking)?
Are there any problems in awakening and getting ready in the morning?
- What do you do for these problems?

BOX 19.5 Nursing Admission History According to Functional Health Patterns—cont'd

Activity/Exercise Pattern

What is your child's schedule during the day (preschool, daycare center, regular school, extracurricular activities)?
What are your child's favorite activities or toys (both active and quiet interests)?
What is your child's usual television-viewing schedule at home?
What are your child's favorite programs?
Are there any television restrictions?
Does your child have any illness or disabilities that limit activity? If so, how?
What are your child's usual habits and schedule for bathing (bath in tub or shower, sponge bath, shampoo)?
What are your child's dental habits (brushing, flossing, fluoride supplements or rinses, favorite toothpaste); schedule of daily dental care?
Does your child need help with dressing or grooming, such as hair combing?
Are there any problems with these patterns (dislike of or refusal to bathe, shampoo hair, or brush teeth)?
- What do you do for these problems?

Are there special devices that your child requires help in managing (eyeglasses, contact lenses, hearing aid, orthodontic appliances, artificial elimination appliances, orthopedic devices)?
Note: Use the following code to assess functional self-care level for feeding, bathing and hygiene, dressing and grooming, toileting:
0: Full self-care
I: Requires use of equipment or device
II: Requires assistance or supervision from another person
III: Requires assistance or supervision from another person and equipment or device
IV: Is totally dependent and does not participate

Cognitive/Perceptual Pattern

Does your child have any hearing difficulty?
- Does the child use a hearing aid?
- Have "tubes" been placed in your child's ears?

Does your child have any vision problems?
- Does the child wear glasses or contact lenses?

Does your child have any learning difficulties?
What is the child's grade in school?
For information on pain, see Chapter 5.

Self-Perception/Self-Concept Pattern

How would you describe your child (e.g., takes time to adjust, settles in easily, shy, friendly, quiet, talkative, serious, playful, stubborn, easygoing)?
What makes your child angry, annoyed, anxious, or sad? What helps?
How does your child act when annoyed or upset?
What have been your child's experiences with and reactions to temporary separation from you (parent)?
Does your child have any fears (places, objects, animals, people, situations)?
- How do you handle them?

Do you think your child's illness has changed the way he or she thinks about himself or herself (e.g., more shy, embarrassed about appearance, less competitive with friends, stays at home more)?

Role/Relationship Pattern

Does your child have a favorite nickname?
What are the names of other family members or others who live in the home (relatives, friends, pets)?
Who usually takes care of your child during the day and night (especially if other than parent, such as babysitter, relative)?
What are the parents' occupations and work schedules?
Are there any special family considerations (adoption, foster child, stepparent, divorce, single parent)?
Have any major changes in the family occurred lately (death, divorce, separation, birth of a sibling, loss of a job, financial strain, mother beginning a career, other)? Describe child's reaction.
Who are your child's play companions or social groups (peers, younger or older children, adults, or prefers to be alone)?
Do things generally go well for your child in school or with friends?
Does your child have "security" objects at home (pacifier, bottle, blanket, stuffed animal or doll)? Did you bring any of these to the hospital?
How do you handle discipline problems at home? Are these methods always effective?
Does your child have any condition that interferes with communication? If so, what are your suggestions for communicating with your child?
Will your child's hospitalization affect the family's financial support or care of other family members (e.g., other children)?
What concerns do you have about your child's illness and hospitalization?
Who will be staying with your child while hospitalized?
How can we contact you or another close family member outside of the hospital?

Sexuality/Reproductive Pattern

(Answer questions that apply to your child's age-group.)
Has your child begun puberty (developing physical sexual characteristics, menstruation)? Have you or your child had any concerns?
Does your daughter know how to do breast self-examination?
Does your son know how to do testicular self-examination?
How have you approached topics of sexuality with your child?
Do you think you might need some help with some topics?
Has your child's illness affected the way he or she feels about being a boy or a girl? If so, how?
Do you have any concerns with behaviors in your child, such as masturbation, asking many questions or talking about sex, not respecting others' privacy, or wanting too much privacy?
Initiate a conversation about an adolescent's sexual concerns with open-ended to more direct questions and using the terms *friends* or *partners* rather than *girlfriend* or *boyfriend:*
- Tell me about your social life.
- Who are your closest friends? (If one friend is identified, could ask more about that relationship, such as how much time they spend together, how serious they are about each other, if the relationship is going the way the teenager hoped.)
- Might ask about dating and sexual issues, such as the teenager's views on sexuality education, "going steady," "living together," or premarital sex.
- Which friends would you like to have visit in the hospital?

Coping/Stress Tolerance Pattern

(Answer questions that apply to your child's age-group.)
What does your child do when tired or upset?
- If upset, does your child want a special person or object?
- If so, explain.

If your child has temper tantrums, what causes them, and how do you handle them?
Whom does your child talk to when worried about something?
How does your child usually handle problems or disappointments?
Have there been any big changes or problems in your family recently? If so, how have you handled them?
Has your child ever had a problem with drugs or alcohol or tried to commit suicide?
Do you think your child is "accident prone?" If so, explain.

Value/Belief Pattern

What is your religion?
How is religion or faith important in your child's life?
What religious practices would you like continued in the hospital (e.g., prayers before meals or bedtime; visit by minister, priest, or rabbi; prayer group)?

[a]The focus of the admission history is the child's psychosocial environment. Most of the questions are worded in terms of parental responses. Depending on the child's age, they should be addressed directly to the child when appropriate.

BOX 19.6 Complementary Medicine Practices and Examples

Nutrition, diet, and lifestyle or behavioral health changes: Macrobiotics, megavitamins, diets, lifestyle modification, health risk reduction and health education, wellness

Mind-body control therapies: Biofeedback, relaxation, prayer therapy, guided imagery, hypnotherapy, music or sound therapy, massage, aromatherapy, education therapy

Traditional and ethnomedicine therapies: Acupuncture, Ayurvedic medicine, herbal medicine, homeopathic medicine, American Indian medicine, natural products, traditional Asian medicine

Structural manipulation and energetic therapies: Acupressure, chiropractic medicine, massage, reflexology, therapeutic touch, Qigong

Pharmacologic and biologic therapies: Antioxidants, cell treatment, chelation therapy, metabolic therapy, oxidizing agents

Bioelectromagnetic therapies: Diagnostic and therapeutic application of electromagnetic fields (e.g., transcranial electrostimulation, neuromagnetic stimulation, electroacupuncture)

is organized according to the functional health patterns outlined by Gordon (2002) (see Chapter 1, Diagnosis). This assessment framework is a guideline for formulating nursing diagnoses. One of the main purposes of the history is to assess the child's usual health habits at home to promote a more normal environment in the hospital. Questions related to activities of daily living in the nutritional/metabolic, elimination, sleep/rest, and activity/exercise patterns are a major part of the assessment. The questions found under the health perception/health management pattern are directed toward evaluation of the child's preparation for hospitalization and are key factors in determining whether additional preparation is needed. The questions included in the self-perception/self-concept and role/relationship patterns offer insight into the child's potential reaction to hospitalization, especially in terms of separation.

The nurse should also inquire about the use of any medications at home, including complementary medicine practices (Box 19.6). In a study of children with cancer, 42% had used alternative or complementary therapies simultaneously with or after conventional treatments (Fernandez, Pyesmany, & Stutzer, 1999). It is important that the use of any herbal or complementary therapy be noted in a preoperative assessment because of possible anesthesia or surgical complications related to herbal products (Flanagan, 2001) (see Critical Thinking Case Study box).

In addition to completing the nursing admission history, nurses should also perform a physical assessment (see Chapter 4) before planning care. At the very least, the nurse's physical assessment of the child should include observation of the body for any bruises, rashes, signs of neglect, deformities, or physical limitations. The nurse should also listen to the heart and lungs to assess overall physical status. For example, it is impossible to evaluate improvement in respiratory function in a child admitted with pulmonary disease unless there are baseline data with which to compare subsequent findings.

Preparing the Child for Admission

The preparation that children require on the day of admission depends on the kind of pre-hospital counseling they have received. If they have been prepared in a formalized program, they usually know what to expect in terms of initial medical procedures, inpatient facilities, and nursing staff. Pre-hospital counseling does not preclude the need for support during procedures, such as obtaining blood specimens, x-ray tests, or physical examination. For example, undressing young children before they feel comfortable in their new surroundings can be upsetting. Causing needless anxiety and fear during admission may adversely affect the nurse's establishment of trust with these children. Nursing assistance during the admission procedure is vital regardless of how well prepared any child is for the experience of hospitalization. In addition, spending this time with the child gives the nurse an opportunity to evaluate the child's understanding of subsequent procedures (Fig. 19.4). Ideally, a primary nurse is assigned whenever possible to allow for individualized care and to provide a substitute support person for the child.

When a child is admitted, nurses follow several universal admission procedures (Box 19.7). The minimum considerations for room assignment are age, sex, and nature of the illness. No absolute rules govern room selection, but in general, placing children of the same age-group and with similar types of illness in the same unit is both psychologically and medically advantageous. There may be exceptions; for example, a child in traction may be therapeutic for another child confined to bed because of a serious illness. A child who is independent despite physical disabilities may help another child with similar or different limitations, and the parents of the child with disabilities may achieve deeper insight into and acceptance of their child's disorder.

Age grouping is especially important for adolescents. Many hospitals try to place teenagers on their own unit or in a separate designated section of the pediatric or general unit whenever possible.

CRITICAL THINKING CASE STUDY

Complementary and Alternative Medicine

Maria, a 13-year-old Hispanic girl, has had severe nosebleeds. She is admitted to the hospital for a complete workup in an attempt to determine the cause. Her parents and grandparents have gathered around her bed. When you enter her room to begin admitting procedures, you notice an unusual scent. Maria's mother is rubbing the contents from an unfamiliar bottle of liquid on Maria. Meanwhile, the grandmother is rubbing Maria's head. She is startled at your entry and drops something on the floor near your feet. You bend over to pick it up and discover that it is a penny.

Initial Assessment. Is there an external cause for the nosebleeds?

Expected Nursing Action. Determine what interventions are appropriate to use in patients with nosebleeds. Has the family used alternative methods to treat Maria's nosebleeds and why?

Teaching Points

- Most epistaxis in children is minor and is easily managed with direct compression of both nostrils at the bottom of the nose (cartilaginous area) for 5 to 10 minutes.
- In patients with marked nasal hemorrhage, rapid assessment and stabilization is followed immediately by attempts to identify the source of bleeding and initiation of measures to control it.
- Alternative medications are not recommended for the treatment of acute epistaxis, as these medications may have adverse effects such as delayed clotting and/or prolonged bleeding.
- Begin discussions of ethnic or folk remedies in the family's health care practice.

Critical Thinking Answers

Initial Assessment. Maria is experiencing acute epistaxis based on the history and exam.

Expected Nursing Action. Continue to apply pressure for at least 5 minutes while attempting to identify the source of the bleeding. The mother should not administer any alternative medications, including the topical liquid.

Fig. 19.4 The initial admission procedures give the nurse an opportunity to get to know the child and to assess the child's understanding of the hospital experience.

BOX 19.7 Guidelines for Admission

Preadmission

Assign a room based on developmental age, seriousness of diagnosis, communicability of illness, and projected length of stay.

Prepare roommate(s) for the arrival of a new patient; when children are too young to benefit from this consideration, prepare parents.

Prepare room for child and family, with admission forms and equipment nearby to eliminate need to leave child.

Admission

Introduce primary nurse to child and family.

Orient child and family to inpatient facilities, especially to assigned room and unit; emphasize positive areas of pediatric unit.

Room: Explain call light, bed controls, television, bathroom, telephone, and so on.

Unit: Direct to playroom, desk, dining area, or other areas.

Introduce family to roommate and his or her parents.

Apply identification band to child's wrist, ankle, or both (if not already done).

Explain hospital regulations and schedules (e.g., visiting hours, mealtimes, bedtime, limitations [give written information if available]).

Perform nursing admission history (see Box 19.5).

Take vital signs, blood pressure, height, and weight.

Obtain specimens as needed and order needed laboratory work.

Support child and assist practitioner with physical examination (for purposes of nursing assessment).

NURSING INTERVENTIONS

Preventing or Minimizing Separation

A primary nursing goal is to prevent separation, particularly in children younger than 5 years old. Many hospitals have developed a system of **family-centered care**. This philosophy of care recognizes the integral role of the family in a child's life and acknowledges the family as an essential part of the child's care and illness experience. The family is considered a partner in the care of the child (Smith & Conant Rees, 2000). Family-centered care also supports the family by establishing priorities based on the needs and values of the family unit (Lewandowski & Tesler, 2003). Efforts to collaborate with families and encourage their involvement in the patient's care include optimizing family visitation, family-centered rounding, family presence during procedures or interventions, and opportunities for formal and informal family conferences (Meert, Clark, & Eggly, 2013). Historically, hospitals have had restrictive visiting policies. Family-centered care started in pediatrics with the increased recognition of child and family separation trauma in the inpatient setting. Policies were adapted first in pediatrics to allow for rooming-in, longer visiting hours, sibling visits, and systems to allow families to accompany patients off the unit for procedures (Institute for Patient- and Family-Centered Care, 2010a, 2010b).

Most hospitals welcome parents at any time. Many provide facilities such as a chair or bed for at least one person per child, unit kitchen privileges, and other amenities that create a welcoming atmosphere for parents. Not all hospitals provide such amenities, and parents' own schedules may prevent rooming-in. In such instances, strategies to minimize the effects of separation must be implemented.

Nurses must have an appreciation of the child's separation behaviors. As discussed earlier, the phases of protest and despair are normal. The child should be allowed to cry. Even if the child rejects strangers, the nurse provides support through physical presence. **Presence** is defined as spending time being physically close to the child while using a quiet tone of voice, appropriate choice of words, eye contact, and touch in ways that establish rapport and communicate empathy. If behaviors of detachment are evident, the nurse maintains the child's contact with the parents by frequently talking about them; encouraging the child to remember them; and stressing the significance of their visits, telephone calls, or letters. The use of cellular phones can increase the contact between the hospitalized child and parents or other significant family members and friends. Wireless technology devices may not be compatible with medical equipment, and use may be restricted in certain areas within the hospital.

Parental Absence During Infant Hospitalization

Familiar surroundings also increase the child's adjustment to separation. If the parents cannot stay with the child, they should leave favorite articles from home, such as a blanket, toy, bottle, feeding utensil, or article of clothing, with the child. Because young children associate such inanimate objects with significant people, they gain comfort and reassurance from these possessions. The child makes the association that if the parents left an object, the parents will surely return. Placing an identification band on the toy lessens the chances of its being misplaced and provides a symbol that the toy is experiencing the same needs as the child. Other reminders of home include photographs and recordings of family members reading a story, singing a song, saying prayers before bedtime, relating events at home, or taking a "talking walk" through the home. These reminders can be played at lonely times, such as on awakening or before sleeping. Some units allow pets to visit, which can have therapeutic benefits for a child. Older children also appreciate familiar articles from home, particularly photographs, a radio, a favorite toy or game, and their own pajamas. Often the importance of treasured objects to school-age children is overlooked or criticized. Many school-age children have a special object to which they formed an attachment in early childhood. Therefore such treasured or transitional objects can help even older children feel more comfortable in a strange environment.

The strange sights, smells, and sounds in the hospital that are commonplace for the nurse can be frightening and confusing for children. It is important for the nurse to try to evaluate stimuli in the environment

Fig. 19.5 For extended hospitalizations, children enjoy doing projects to occupy time.

from the child's point of view (considering also what the child may see or hear happening to other patients) and to make every effort to protect the child from frightening and unfamiliar sights, sounds, and equipment. The nurse should offer explanations or prepare the child for experiences that are unavoidable. Combining familiar or comforting sights with the unfamiliar can relieve much of the harshness of medical equipment.

Helping children maintain their usual contacts also minimizes the effects of separation imposed by hospitalization. This includes continuing school lessons during the illness and confinement, visiting with friends either directly or through letter writing or telephone calls, and participating in stimulating projects whenever possible (Fig. 19.5). For extended hospitalizations, children enjoy personalizing the hospital room to make it "home" by decorating the walls with posters and cards, rearranging the furniture, and displaying a collection or hobby.

Minimizing Loss of Control

Feelings of loss of control result from separation, physical restriction, changed routines, enforced dependency, and magical thinking. Although some of these cannot be prevented, most can be minimized through individualized planning of nursing care.

Promoting Freedom of Movement

Younger children react most strenuously to any type of physical restriction or immobilization. Although temporary immobilization may be necessary for some interventions such as maintaining an intravenous line, most physical restriction can be prevented if the nurse gains the child's cooperation.

For young children, particularly infants and toddlers, preserving parent-child contact is the best means of decreasing the need for or stress of restraint. For example, almost the entire physical examination can be done in a parent's lap with the parent hugging the child for procedures, such as an otoscopic examination. For painful procedures, the nurse should assess the parents' preferences for assisting, observing, or waiting outside the room.

Environmental factors may also restrict movement. Keeping children in cribs or play yards may not represent immobilization in a concrete sense, but it certainly can limit sensory stimulation. Increasing mobility by transporting children in carriages, wheelchairs, carts, or wagons provides them with a sense of freedom.

In some cases, physical restraint or isolation is necessary because of the child's medical diagnosis. In these cases, the environment can be altered to increase sensory freedom (e.g., moving the bed toward the window; opening window shades; providing musical, visual, or tactile activities).

Eric's Daily Schedule

7:30 AM	– Breakfast, morning bath	3:00 PM	– Tutor (M, W, F)
			– Study time (T, Th)
9:00	– Medications, dressing change	4:00	– Physical therapy
		5:30	– Dinner
11:00	– Physical therapy	9:00	– Medications, dressing change
12:00 PM	– Lunch		
		9:15	– Bedtime

Fig. 19.6 Time structuring is an effective strategy for normalizing the hospital environment and increasing the child's sense of control.

Maintaining the Child's Routine

Altered daily schedules and loss of rituals are particularly stressful for toddlers and early preschoolers and may increase the stress of separation. The nursing admission history provides a baseline for planning care around the child's usual home activities. A frequently neglected aspect of altered routines is the change in the child's daily activities. A typical child's day, especially during the school years, is structured with specific times for eating, dressing, going to school, playing, and sleeping. This time structure vanishes when the child is hospitalized. Although nurses have a set schedule, the child is frequently unaware of it, and the new schedules that are imposed may be rigid. For example, some units have uniform nap times and bedtimes for all children, but others allow children to stay up late at night. Many children obtain significantly less sleep in the hospital than at home; the primary causes are a delay in sleep onset and early termination of sleep because of hospital routines. Not only are hours of sleep disrupted, but waking hours are spent in passive activities. For example, few institutions impose any limits on the amount of time the child spends watching television. This may lead to children being less "tired" at bedtime and delay the onset of sleep.

One technique that can minimize the disruption in the child's routine is establishing a daily schedule. This approach is most suitable for non–critically ill school-age and adolescent children who have mastered the concept of time. It involves scheduling the child's day to include all those activities that are important to the child and nurse, such as treatment procedures, schoolwork, exercise, television, playroom, and hobbies. Together, the nurse, parent, and child then plan a daily schedule with times and activities written down (Fig. 19.6). This schedule is left in the child's room, and a clock or watch is available for the child's use. Whenever possible, a calendar is also constructed with special events marked, such as favorite television programs, visits by friends or relatives, events in the playroom, and holidays or birthdays. If specific changes in treatment are expected (e.g., "beginning physical therapy in 2 days"), these are added.

NURSING TIP: Ask the young child to select or draw pictures or symbols to represent daily or weekly fun activities (e.g., favorite television programs, family visits, playroom times). Draw a visual schedule to help plan and prepare the activities of the day. Use your consultation skills to ask child life specialists for assistance.

Encouraging Independence

The dependent role of the hospitalized patient imposes tremendous feelings of loss on older children. Principal interventions should focus on respect for individuality and the opportunity for decision making.

Although these sound simple, their efficacy lies with nurses who are flexible and tolerant. It is also important for the nurse to empower the patient while not feeling threatened by a sense of lessened control.

Enabling children's control involves helping them maintain independence and promoting the concept of self-care. **Self-care** refers to the practice of activities that individuals personally initiate and perform on their own behalf in maintaining life, health, and well-being (Orem, 2001). Although self-care is limited by the child's age and physical condition, most children beyond infancy can perform some activities with little or no help. Whenever possible, these activities are encouraged in the hospital. Other approaches include jointly planning care, time structuring, wearing street clothes, making choices in food selections and bedtime, continuing school activities, and rooming with an appropriate age-mate.

Promoting Understanding

Loss of control can occur from feelings of having too little influence on one's destiny or from sensing overwhelming control or power over fate. Although preschoolers' cognitive abilities predispose them to magical thinking and delusions of power, all children are vulnerable to misinterpreting causes for stresses, such as illness and hospitalization.

Most children feel more in control when they know what to expect because the element of fear is reduced. Anticipatory preparation and provision of information help lessen stress and increase understanding (see Chapter 20, Preparation for Diagnostic and Therapeutic Procedures).

Informing children of their rights while hospitalized fosters greater understanding and may relieve some of the feelings of powerlessness they typically experience. An increasing number of hospitals and organizations have developed a patient "bill of rights" that is prominently displayed throughout the hospital or is presented to children and their families on admission (Box 19.8).

Preventing or Minimizing Fear of Bodily Injury

Beyond early infancy, all children fear bodily injury from mutilation, bodily intrusion, body image change, disability, or death. In general, preparation of children for painful procedures decreases their fears and increases cooperation. Modifying procedural techniques for children in each age-group also minimizes fear of bodily injury. For example, because toddlers and young preschoolers are traumatized by insertion of a rectal thermometer, less invasive axillary temperatures or temperatures taken with electronic or tympanic membrane devices can effectively be substituted. Whenever procedures are performed on young children, the most supportive intervention is to do the procedure as quickly as possible while maintaining parent-child contact.

Because of toddlers' and preschool children's poorly defined body boundaries, the use of bandages may be particularly helpful. For example, telling children that the bleeding will stop after the needle is removed does little to relieve their fears, but applying a small Band-Aid usually reassures them. The size of bandages is also significant to children in this age-group; the larger the bandage, the more importance is attached to the wound. Watching their surgical dressings become successively smaller is one way that young children can measure healing and improvement. Removing a dressing too soon may cause these children considerable concern for their well-being. Remember to consult child life specialists to use therapeutic measures to reduce fear and pain in children. Specific pain management strategies are discussed in Chapter 5.

For children who fear mutilation of body parts, it is essential that the nurse repeatedly stress the reason for a procedure and evaluate the child's understanding. For example, explaining cast removal to preschoolers may seem simple enough, but children's comprehension of the details may vary considerably from the explanation. Asking the child to draw a picture of what they foresee happening presents substantial evidence of how they perceive events.

Children may fear bodily injury from a great variety of sources. Imaging machines, strange equipment used for examination, unfamiliar rooms, and awkward positions can be perceived as potentially hazardous. In addition, thoughts and actions can be imagined sources of bodily damage. Therefore it is important to investigate imagined reasons, particularly of a sexual nature, for illness. Because children may fear revealing such thoughts, using techniques such as drawing or doll play may elicit previously undisclosed misconceptions.

Older children fear bodily injury of both internal and external origins. For example, school-age children are aware of the significance of the heart and may fear the actual operation as much as the pain, the stitches, and the possible scar. Adolescents may express concern about the actual procedure but be much more anxious over the resulting scar.

Children can grasp information if it is presented on or close to their level of cognitive development. This necessitates an awareness of the words used to describe events or processes. For example, young children told that they are going to have a CAT (i.e., CT, computed tomography) scan may wonder, "Will there be cats or something that scratches?" It is clearer to describe the procedure in simple terms and explain what the letters of the common name stand for. Therefore to prevent or alleviate fears, nurses must be keenly aware of the medical terminology and vocabulary that they use every day.

When children are upset about their illness, their perception can be changed by providing a somewhat different and less negative account of the disease or offering an explanation that is characteristic of the next stage of cognitive development. An example of the first strategy is reassuring a preschooler who fears that after a tonsillectomy, another sore throat means a second operation. Explaining that after tonsils are "fixed" they do not need fixing again can help relieve the fear. An example of the latter strategy is to explain that germs made the tonsils sick and even though germs can cause another sore throat, they cannot cause the tonsils to ever be sick again. This higher-level explanation is based on the school-age child's concept of germs as a cause of disease.

Providing Developmentally Appropriate Activities

A primary goal of nursing care for the child who is hospitalized is to minimize threats to the child's development. Many strategies (e.g., minimizing separation) have been discussed and may be all that the short-term patient requires. Children who experience prolonged or repeated hospitalization are at greater risk for developmental delays or regression. The nurse who provides opportunities for the child to participate in developmentally appropriate activities further normalizes the child's environment and helps reduce interference with the child's ongoing development.

BOX 19.8 Bill of Rights for Children and Teens

In this hospital, you and your family have the right to:

- Respect and personal dignity
- Care that supports you and your family
- Information you can understand
- Quality health care
- Emotional support
- Care that respects your need to grow, play, and learn
- Make choices and decisions

From Association for the Care of Children's Health. (1991). *A pediatric bill of rights.* Bethesda, MD: Author.

Interference with normal development may have long-term implications for developing infants and toddlers. The nurse plays a primary role in identifying children at risk and helping to plan, implement, and evaluate developmental intervention (see Chapters 9 and 11).

School is an integral part of the school-age child's and adolescent's development. Accreditation standards for hospitals serving children consider access to appropriate educational services a key factor in the accreditation decision process when a child's treatment requires a significant absence from school (The Joint Commission, 2011). The nurse can encourage children to resume schoolwork as quickly as their condition permits, help them schedule and protect a selected time for studies, and help the family coordinate hospital educational services with their children's schools. Children should have the opportunity to continue art and music classes, as well as their academic subjects.

To meet the unique developmental needs of adolescents, special units may be developed that provide privacy, increased socialization, and appropriate activities for these young people. Typically, these units can be set apart from the general pediatric facility so that the teenagers do not share space with younger children, who are often perceived as a threat to their maturity.

In caring for adolescent patients, it is essential to provide flexible routines and activities, such as more group activity, wearing of street clothes, and access to the items important to adolescents—wireless technology devices and Wi-Fi access for email, electronic video game systems, and streaming technology. Because adolescents' food habits are rarely limited to the three traditional meals a day, a ready supply of snacks should be available. The most important benefit of these units is increased socialization with peers. In addition, staff members usually enjoy working with this age-group and are able to establish the trust that is so essential for communication.

NURSING TIP: When adolescents must share a common activity room with younger patients, referring to the area as the "activity room" rather than the "playroom" may entice them to visit the room and participate in activities.

Although regression is expected and normal for all age-groups, nurses have the responsibility for fostering the child's growth and development. Hospitalization can become a significant opportunity for learning and advancing. Extended hospitalizations for long-term chronic illness or situations of failure to thrive, abuse, or neglect represent instances in which regression must be seen as an adjustment period to be followed by plans for promoting appropriate developmental skills.

Providing Opportunities for Play and Expressive Activities

Play is one of the most important aspects of a child's life and one of the most effective tools for managing stress. Illness and hospitalization constitute crises in a child's life and often involve overwhelming stresses, and children need to act out their fears and anxieties as a means of coping with these stresses. Play is essential to children's mental, emotional, and social well-being. Play does not stop when children are ill or in the hospital. On the contrary, play in the hospital serves many functions (Box 19.9). Of all hospital facilities, the playroom or activity room alleviates the stressors of hospitalization. In the playroom, children temporarily distance themselves from their illness, hospitalization, and the associated stressors. This room should be a safe haven for children, free from medical or nursing procedures (including medication administration), strange faces, and probing questions. The playroom then becomes a sanctuary in an otherwise frightening environment.

Engaging in play activities gives children a sense of control. In the hospital environment, most decisions are made for the child; play and other expressive activities offer the child much-needed opportunities to make choices for themselves. Even if a child chooses not to participate in a particular activity, the nurse has offered the child a choice, perhaps one of only a few real choices the child has had that day.

Hospitalized children typically have lower energy levels than healthy children of the same age. Children may not appear engaged and enthusiastic about an activity even though they are enjoying the experience. Activities may need to be adjusted or limited based on the child's age, endurance, and any special needs.

Diversional Activities

Almost any form of play can be used for diversion and recreation, but the activity should be selected based on the child's age, interests, and limitations (Fig. 19.7). Children do not necessarily need special direction for using play materials. All they require is the raw materials with which to work and adult approval and supervision to help keep their natural enthusiasm or expression of feelings from getting out of control. Small children enjoy a variety of small, colorful toys that they can play with in bed or in their room or more elaborate play equipment, such as playhouses, sandboxes, rhythm instruments, or large boxes and blocks that may be a part of the hospital playroom.

Games that can be played alone or with another child or an adult are popular with older children, as are puzzles; reading material; quiet, individual activities, such as sewing, stringing beads, and weaving; and Lego blocks and other building materials. Assembling models is an excellent pastime, but one should make certain that all pieces and necessary materials are included in the package so that the child is not disappointed and frustrated.

BOX 19.9 Functions of Play in the Hospital

- Provides diversion and brings about relaxation
- Helps the child feel more secure in a strange environment
- Lessens the stress of separation and the feeling of homesickness
- Provides a means for release of tension and expression of feelings
- Encourages interaction and development of positive attitudes toward others
- Provides an expressive outlet for creative ideas and interests
- Provides a means for accomplishing therapeutic goals (see Chapter 20, Use of Play in Procedures)
- Places child in active role and provides opportunity to make choices and be in control

Fig. 19.7 Play materials for children in the hospital need to be appropriate for their age, interests, and limitations.

Well-selected books are of infinite value to children. Children rarely tire of stories; having someone read aloud gives them endless hours of pleasure and is of special value to children who have limited energy to expend in play. Current electronic technology and communication devices should be included in most hospital room amenities as useful tools for entertaining children. Computers with access to the Internet can provide diversion, educational opportunities, and online support groups.

When supervising play for ill or recuperating children, it is best to select activities that are simpler than would normally be chosen for the child's specific developmental level. These children usually do not have the energy to cope with more challenging activities. Other limitations also influence the type of activities. Special consideration must be given to children who are confined in terms of movement, have a restricted extremity, or are isolated. Toys for isolated children must be disposable or need to be disinfected after every use.

Toys

Parents of hospitalized children often ask nurses about the types of toys that would be best to bring for their child. Although parents often want to buy new toys for the hospitalized child to offer cheer and comfort, it is often better to wait to bring new things, especially in the case of younger children. Small children need the comfort and reassurance of familiar things, such as the stuffed animal the child hugs for comfort and takes to bed at night. These familiar items can be a link with home and the world outside the hospital. All toys brought into the hospital should be assessed for safety.

Large numbers of toys often confuse and frustrate small children. A few small, well-chosen toys are usually preferred to one large, expensive one. Children who are hospitalized for an extended time benefit from changes. Rather than a confusing accumulation of toys, older toys should be replaced periodically as interest wanes.

A highly successful diversion for a child who is hospitalized for a length of time and whose parents are unable to visit frequently is having the parents bring a box with several small, inexpensive, brightly wrapped items with a different day of the week printed on the outside of each package. The child will eagerly anticipate the time for opening each one. If the parents know when their next visit will be, they can provide the number of packages that corresponds to the time between visits. In this way, the child knows that the diminishing packages also represent the anticipated visit from the parent.

Expressive Activities

Play and other expressive activities provide one of the best opportunities for encouraging emotional expression, including the safe release of anger and hostility. Nondirective play that allows children freedom for expression can be tremendously therapeutic. Therapeutic play, however, should not be confused with **play therapy**, a psychologic technique reserved for use by trained and qualified therapists as an interpretative method with emotionally disturbed children. **Therapeutic play**, on the other hand, is an effective, nondirective modality for helping children deal with their concerns and fears; at the same time, it often helps the nurse gain insights into children's needs and feelings.

Tension release can be facilitated through almost any activity; with younger ambulatory children, large-muscle activity such as use of tricycles and wagons is especially beneficial. Much aggression can be safely directed into pounding and throwing games or activities. Beanbags are often thrown at a target or open receptacle with surprising vigor and hostility. A pounding board is used with enthusiasm by young children; clay and play dough are beneficial for use at any age.

Fig. 19.8 Drawing and painting are excellent media for expression.

Creative Expression

Although all children derive physical, social, emotional, and cognitive benefits from engaging in art and other creative activities, children's need for such activities is intensified when they are hospitalized. Drawing and painting are excellent media for expression. Children are more at ease expressing their thoughts and feelings through art because humans think first in images and later learn to translate these images into words. Children need only be supplied with the raw materials, such as crayons and paper, large brushes, an ample supply of newsprint supported on easels, or materials for finger painting (Fig. 19.8). Children can work individually or together on a group project, such as a mural painted on a long piece of paper.

Although interpretation of children's drawings requires special training, observing changes in a series of the child's drawings over time can be helpful in assessing psychosocial adjustment and coping. The nurse can use children's drawings, stories, poetry, and other products of creative expression as a springboard for discussion of thoughts, fears, and understanding of concepts or events (see Chapter 4, Communication Techniques). A child's drawing before surgery, for example, may reveal unvoiced concerns about mutilation, body changes, and loss of self-control.

Nurses can incorporate opportunities for musical expression into routine nursing care. For example, simple musical instruments, such as bracelets with bells, can be placed on infants' legs for them to shake to accompany mealtime music or dressing changes. Dance and movement suggestions may encourage a child to ambulate.

Holidays provide stimulus and direction for unlimited creative projects. Children can participate in decorating the pediatric unit; making pictures and decorations for their rooms gives children a sense of pride and accomplishment. This is especially beneficial for children who are immobilized and isolated. Making gifts for someone at home helps maintain interpersonal ties.

Dramatic Play

Dramatic play is a well-recognized technique for emotional release, allowing children to reenact frightening or puzzling hospital experiences. Through use of puppets, replicas of hospital equipment, or some actual hospital equipment, children can act out the situations that are a part of their hospital experience. Dramatic play enables children to

learn about procedures and events that concern them and to assume the roles of the adults in the hospital environment.

Puppets are universally effective for communicating with children. Most children see them as peers and readily communicate with them. Children will tell the puppet feelings that they hesitate to express to adults. Puppets can share children's own experiences and help them find solutions to their problems. Puppets dressed to represent figures in the child's environment—for example, a physician, nurse, child patient, therapist, and members of the child's own family—are especially useful. Small, appropriately attired dolls are equally effective in encouraging the child to play out situations, although puppets are usually best for direct conversation.

Play must consider medical needs, but at times a procedure can be postponed briefly to allow the child to complete a special activity (see Critical Thinking Case Study box). Play must consider any limitations imposed by the child's condition. For example, small children may eat paste and other creative media; therefore a child who is allergic to wheat should not be given finger paint made from wallpaper paste or modeling dough made with flour. A child on a restricted salt intake should not play with modeling dough because salt is one of its major constituents. At home, the play program can be planned around the therapy regimen. However, play can be satisfactorily incorporated into the child's care if the nurse and others involved allow some flexibility and use creativity in planning for play.

CRITICAL THINKING CASE STUDY

Balancing Diagnostics With Play

Joel, an 8-year-old with cystic fibrosis, has been hospitalized numerous times with complications from the condition. He is playing a board game with his brother, sister, and several other children in the playroom on the pediatric unit. A pediatric phlebotomist enters the playroom and says, "Joel, I need to take some blood. I can see that you are playing a game, so I'll just do it while you play. It will just take a minute." The playroom is usually off limits for invasive procedures. As Joel's nurse, you are aware that Dr. Lung wants the results of the laboratory studies as soon as possible to make a decision about the course of therapy.

Initial Assessment. How would you balance the need for diagnostic interventions with a child's need to play?

Expected Nursing Action. What diagnostics can be delayed to allow a child to play and where is the best location to obtain diagnostic samples?

Teaching Points

- Play is one of the most important aspects of a child's life and one of the most effective tools for managing stress.
- Children derive physical, social, emotional, and cognitive benefits from engaging in play and other creative activities. Children's need for such activities is intensified when they are hospitalized.
- In the playroom, children temporarily distance themselves from their illness, hospitalization, and the associated stressors, and this room should be a safe haven for children, free from medical or nursing procedures (including medication administration), strange faces, and probing questions. The playroom then becomes a sanctuary in an otherwise frightening environment.

Critical Thinking Answers

Initial Assessment. Joel requires a laboratory study to determine the most appropriate course of therapy.

Expected Nursing Action. An appropriate nursing action is to notify Joel that he has to go back to his room to obtain the laboratory study and, upon completion, he can return to the playroom.

Maximizing Potential Benefits of Hospitalization

Although hospitalization generally represents a stressful time for children and families, it also represents an opportunity for facilitating positive change within the child and among family members. For some families, the stress of a child's illness, hospitalization, or both can lead to strengthening of family coping behaviors and the emergence of new coping strategies.

Fostering Parent-Child Relationships

The crisis of illness or hospitalization can mobilize parents into more acute awareness of their child's needs. For example, hospitalization provides opportunities for parents to learn more about their children's growth and development. When parents are helped to understand children's usual reactions to stress, such as regression or aggression, they are not only better able to support the child through the hospital experience but also may extend their insights into childrearing practices after discharge.

Difficulties in parent-child relationships that existed before hospitalization and are characterized by feeding problems, negative behavior, and sleep disturbances may decrease during hospitalization. The temporary cessation of such problems sometimes alerts parents to the role they may be playing in propagating the negative behavior. With assistance from health professionals, parents can restructure ways of relating to their children to foster more positive behavior.

Hospitalization may also represent a temporary reprieve or refuge from a disturbed home. Typically, abused or neglected children's dramatic physical and social improvement during hospitalization is proof of the benefits and potential growth that can occur during hospitalization. These children temporarily can seek support, reassurance, and security from new relationships, particularly with nurses and hospitalized peers.

Providing Educational Opportunities

Illness and hospitalization represent excellent opportunities for children and other family members to learn more about their bodies, each other, and the health professions. For example, during a hospital admission for a diabetic crisis, the child may learn about the disease; the parents may learn about the child's needs for independence, normalcy, and appropriate limits; and each of them may find a new support system in the hospital staff.

Illness or hospitalization can also help older children in choosing a career. Frequently, children have impressions of physicians or nurses that are disproportionately positive or negative. Actual experience with different health professionals can influence their attitude about health professionals and even a decision regarding a career in health care.

Promoting Self-Mastery

The experience of facing a crisis such as illness or hospitalization, coping successfully with it, and maturing as a result of it constitutes an opportunity for self-mastery. Younger children have the chance to test fantasy versus reality fears. They realize that they were not abandoned, mutilated, or punished. In fact, they were loved, cared for, and treated with respect for their individual concerns. It is not unusual for children who have undergone hospitalization or surgery to tell others that "it was nothing" or to display proudly their scars or bandages. For older children, hospitalization may represent an opportunity for decision making, independence, and self-reliance. They are proud of having survived the experience and may feel a genuine self-respect for their achievements. Nurses can facilitate such feelings of self-mastery by emphasizing aspects of personal competence in the child and not focusing on uncooperative or negative behavior.

Providing Socialization

Hospitalization may offer children a special opportunity for social acceptance. Lonely, asocial, and even delinquent children find a sympathetic

Fig. 19.9 Placing children of the same age-group with similar illnesses near each other on the unit is both psychologically and medically supportive. (Courtesy E. Jacob, Texas Children's Hospital, Houston, TX.)

environment in the hospital. Children who have a physical disability or are in some other way "different" from their age-mates may find an accepting social peer group (Fig. 19.9). Although this does not always occur spontaneously, nurses can structure the environment to foster a supportive child group. For example, the introduction of an age-compatible peer can help children gain a new friend and learn more about themselves. Forming relationships with significant members of the health care team, such as the physician, nurse, child life specialist, or social worker, can greatly enhance children's adjustment in many areas of life.

Parents may also encounter a new social group in other parents who have similar problems. The waiting room or hallway "self-help" groups are inherent to every institution. Parents meet while in the hospital or clinic and discuss their children's illnesses and treatments. Nurses can capitalize on this informal gathering by encouraging parents to discuss collectively their concerns and feelings. Nurses can also refer parents to organized parent groups or can use the help and support of parents of recovered hospitalized patients. It is important that nurses emphasize to families that each child responds differently to disease, treatments, and care. Any questions raised during group discussions should be clarified with a nurse or physician.

NURSING CARE OF THE FAMILY

Although it is not possible to predict exactly which factors are most likely to influence a family's reactions, important variables are the seriousness of the child's illness, the family's previous experience with hospitalization, and the medical procedures involved in the diagnosis and treatment. Important information is also obtained in the nursing admission history (see Box 19.5).

SUPPORTING FAMILY MEMBERS

Support involves the willingness to stay and listen to parents' verbal and nonverbal messages. Sometimes the nurse does not give this support directly. For example, the nurse may offer to stay with the child to allow the parents time alone or may discuss with other family members the parents' need for extra relief. Often relatives and friends want to help but do not know how. Suggesting ways, such as babysitting, preparing meals, doing laundry, or transporting the siblings to school, can prompt others to help reduce the responsibilities that burden parents.

Support may also be provided through the clergy. Parents with deep religious beliefs may appreciate the counsel of a clergy member, but because of their stress, they may not have sufficient energy to initiate the contact. Nurses can be supportive by arranging for clergy to visit, upholding parents' religious beliefs, and respecting the individual meaning and significance of those beliefs (Feudtner, Haney, & Dimmers, 2003).

Support involves accepting cultural, socioeconomic, and ethnic values. For example, health and illness are defined differently by various ethnic groups. For some, a disorder that has few outward manifestations of illness, such as diabetes, hypertension, or cardiac problems, is not a sickness. Consequently, following a prescribed treatment may be seen as unnecessary. Nurses who appreciate the influences of culture are more likely to intervene therapeutically. (See also Chapter 2, Sociocultural Influences on Children and Families.)

Parents need help in accepting their own feelings toward the ill child. If given the opportunity, parents often disclose their feelings of loss of control, anger, and guilt. They often resist admitting to such feelings because they expect others to disapprove of behavior that is less than perfect. Unfortunately, health personnel, including nurses, sometimes do exercise little tolerance for deviation from the norm. This only increases the psychologic impact of a child's illness on family members. Helping parents identify the specific reason for such feelings and emphasizing that each is a normal, expected, and healthy response to stress may reduce the parents' emotional burden.

Family-centered care also addresses the needs of siblings. Support may involve preparing siblings for hospital visits, assessing their adjustment, and providing appropriate interventions or referrals when needed. The Family-Centered Care box suggests ways in which parents can support siblings during hospitalization.

FAMILY-CENTERED CARE

Supporting Siblings During Hospitalization

Trade off staying at the hospital with spouse or have a surrogate who knows the siblings well stay in the home.

Offer information about the child's condition to young siblings as well as older siblings; respect the sibling who avoids information as a means of coping with the situation.

Arrange for children to visit their brother or sister in the hospital if possible.

Encourage phone visits and mail between brothers and sisters; provide children with phone numbers, writing supplies, and stamps.

Help each sibling identify an extended family member or friend to be their support person and provide extra attention during parental absence.

Make or buy inexpensive toys or trinkets for siblings, one gift for each day the child will be hospitalized.

- Wrap each gift separately and place them in a basket, box, or other container at the child's bedside.
- Instruct siblings to open one gift at bedtime and to remember that they are in their parents' thoughts.

If the child's condition is stable and distance is not prohibitive, plan a special time at home with the siblings or have spouse or another relative or friend bring the children to meet parent(s) at a restaurant or other location near the hospital.

- Have extended family members or friends schedule a visit to the child in the hospital during parental absence.
- Arrange to have the child leave the care unit with a staff member to have change of scenery if the child's condition permits.

Modified from Craft, M., & Craft, J. (1989). Perceived changes in siblings of hospitalized children: A comparison of sibling and parent reports. *Child Health Care, 18*(1), 42–48; Rollins, J. (1992). *Brothers and sisters: A discussion guide for families.* Landover, MD: Epilepsy Foundation of America.

PROVIDING INFORMATION

One of the most important nursing interventions is providing information about the disease, its treatment, prognosis, and home care; the child's emotional and physical reactions to illness and hospitalization; and the probable emotional reactions of family members to the crisis.

For many families, the child's illness is the first contact they have with the hospital experience. Often parents are not prepared for the child's behavioral reactions to hospitalization, such as separation behaviors, regression, aggression, and hostility. Providing the parents with information about these normal and expected behavioral responses can lessen the parents' anxiety during the hospital admission. The family is equally unfamiliar with hospital rules, which often compounds their confusion and anxiety. Therefore the family needs clear explanations of what to expect and what is expected of them.

Parents also need to be aware of the effects of illness on the family and strategies to prevent negative changes. Specifically, parents should keep the family well informed and communicate with everyone as much as possible. They should treat all of their children equally and as normally as before the illness occurred. Discipline, which initially may be lessened for the ill child, should be continued to provide a measure of security and predictability. When ill children know that their parents expect certain standards of conduct from them, they feel certain that they will recover. Conversely, when all limits are removed, they fear that something catastrophic will happen.

Helping parents understand the meaning of post-hospitalization behaviors in the sick child is necessary for them to tolerate and support such behaviors. In addition, parents should be forewarned of the common reactions after discharge (see Box 19.2). Parents who do not expect such reactions may misinterpret them as evidence of the child's "being spoiled" and demand perfect behavior at a time when the child is still reacting to the stress of illness and hospitalization. If the behaviors, especially the demand for attention, are dealt with in a supportive manner, most children can relinquish them and assume prior levels of functioning.

Nurses should also prepare parents for the reactions of siblings—particularly anger, jealousy, and resentment. Older siblings may deny such reactions because they provoke feelings of guilt. However, everyone needs outlets for emotions, and the repressed feelings may surface as problems in school or with age-mates, as psychosomatic illnesses, or in delinquent behavior.

Probably one of the most neglected areas of communication involves giving information to siblings. Frequently, age becomes the only factor that leads to an awareness of this problem because older children may begin to ask questions or request explanations. Even in this situation, however, the information may be seriously inadequate. Children in every age-group deserve some explanation of the sibling's illness or hospitalization. In addition, nurses can minimize a sibling's fear of also getting sick or having caused the illness.

ENCOURAGING PARENT PARTICIPATION

Preventing or minimizing separation is a key nursing goal with the child who is hospitalized, but maintaining parent-child contact is also beneficial for the family. One of the best approaches is encouraging parents to be present with their child and to participate in the care whenever possible. Although some health facilities provide special accommodations for parents, the concept of rooming-in can be instituted anywhere. The first requirement is the staff's positive attitude toward parents. A negative attitude toward parent participation can create barriers to collaborative working relationships.

When hospital staff genuinely appreciate the importance of continued parent-child attachment, they foster an environment that encourages parents to stay. When parents are included in the care planning and understand that they are a contributing factor to the child's recovery, they are more inclined to remain with their child and have more emotional reserves to support themselves and the child through the crisis. Family-centered rounds for pediatric patients have shown improved nurse satisfaction and increased family participation (Rappaport, Ketterer, Nilforoshan, et al., 2012). An empowerment model of helping allows the nurse to focus on parents' strengths and seek ways to promote growth and family functioning so that the parents become empowered in caring for their child. Strategies such as bedside family-centered rounds that allow parents to be involved in the discussion of the child's current status are moving health care settings closer to family-centered care (Anderson & Mangino, 2006). Liaison nursing roles—for example, a patient-nurse educator—in tertiary care settings are also focused on improving communication between parents and health care providers (Caffin, Linton, & Pellegrini, 2007).

Because one parent may tend to be the usual family caregiver, they usually spend more time in the hospital than the other parent. Not all parents feel equally comfortable assuming responsibility for their child's care. Some may be under such great emotional stress that they need a temporary reprieve from total participation in caregiving activities or may be insecure about participating in specialized areas of care, such as bathing the child after surgery. On the other hand, some parents may feel a great need to control their child's care. This seems particularly true of young parents, who have recently established their role as a parent; parents of children too young to verbalize their needs; and ethnic-minority parents when the hospital setting is predominantly staffed by nonminority personnel. Individual assessment of each parent's preferred involvement is necessary to prevent the effects of separation while also supporting parents in their needs.

With lifestyles and gender roles changing, some of the usual "parenting" roles in the household may change. Both parents need to be included in the care plan and respected for their parental role. For some parents, the child's hospitalization may represent an opportunity to alter their usual caregiving role and increase their involvement. In single-parent families, the caregiver may not be a parent but an extended family member, such as a grandparent or aunt.

One of the potential problems with continuous parent involvement is neglect of the parent's need for sleep, nutrition, and relaxation. Often the sleeping accommodations are limited to a chair, and sleep is disrupted by hospital care. Encouraging the parents to leave for brief periods, arranging for sleeping quarters on the unit or outside the child's room, and planning a schedule of alternating visits with another family member can minimize the stresses for the parent.

All too often, nurses respond to parent participation by assuming that the parent will take over the care responsibilities. Nurses need to restructure their roles to complement and augment the caregiving functions of parents (Hopia, Tomlinson, Paavilainen, et al., 2005).

Even in units structured to provide care by parents, parents frequently feel anxiety in their caregiving responsibilities; those more involved in direct care may feel more anxiety than those less involved in direct care. Responsibility 24 hours per day may be too much for some parents. Assistance and relief by nursing personnel should always be available to these families, and nurses may need to work diligently to establish the strong bond of trust that some parents need to take advantage of these opportunities.

PREPARING FOR DISCHARGE AND HOME CARE

Most hospitalizations necessitate some type of discharge preparation. Often this involves education of the family for continued care and follow-up in the home. Depending on the diagnosis, this may be relatively simple or highly complex. Preparing the family for home care demands a high degree of competence in planning and implementing discharge instructions.

Nurses are often key individuals in initiating and carrying out the discharge process. They collaborate with others in the planning and implementation phases to ensure appropriate care after hospitalization. Throughout the hospitalization, the nurse should be aware of the need for discharge planning and those assessment factors that affect the family's ability to provide home care. A thorough assessment of the family and home environment should occur to ensure that the family's emotional and physical resources are sufficient to manage the tasks of home care. (For discussion of family and home assessment strategies, see Chapter 4.) In addition to adequate family resources, an investigation of community services, including respite care, is needed to ensure that appropriate support agencies, such as emergency facilities, home health agencies, and equipment vendors, are available. Financial resources and insurance are also a significant consideration. To coordinate the immense task of assessment and to plan implementation, a care coordinator should begin early in the discharge process.

The preparation for hospital discharge and home care begins during the admission stage. Short- and long-term goals are established to meet the child's physical and psychosocial needs. For children with complex care needs, discharge planning focuses on obtaining appropriate equipment and health care personnel for the home. Discharge planning is also concerned with treatments that parents or children are expected to continue at home. In planning appropriate teaching, nurses need to assess the actual and perceived complexity of the skill, the parents' or child's ability to learn the skill, and the parents' or child's previous or present experience with such procedures.

The teaching plan incorporates levels of learning, such as observing, participating with assistance, and finally demonstrating without help or guidance. The skill is divided into discrete steps, and each step is taught to the family member until it is learned. Return demonstration of the skill is requested before new skills are introduced. A record of teaching and performance provides an efficient checklist for evaluation. All families need to receive detailed written instructions about home care, with telephone numbers for assistance, before they leave the hospital. Communication between discharge planning and home health care is essential to ensure a smooth transition for the child and family.

After the family is competent in performing the skill, they are given responsibility for the care. When possible, the family should have a transition or trial period to assume care with minimal health care supervision. This may be arranged on the unit; during a home pass; or in a facility, such as a hotel near the hospital. Such transitions provide a safe practice period for the family, with assistance readily available when needed, and are especially valuable when the family lives far from the hospital.

In many instances, parents need only simple instructions and understanding of follow-up care. The often overwhelming care assumed by some families, coupled with other stressors, necessitates continued professional support after discharge. A follow-up home visit or telephone call gives the nurse an opportunity to individualize care and provide information in perhaps a less stressful learning environment than the hospital. Appropriate referrals and resources may include visiting nurse or home health agencies, private nurse services, the school system, a physical therapist, a mental health counselor, a social worker, and any number of community agencies. Sharing the important issues surrounding the child's and family's needs is essential. Referral summaries should be concise, specific, and factual. When numerous support services are required, collaboration among the professionals involved and the family is an excellent strategy to ensure efficient use and comprehensive delivery of services.

CARE OF THE CHILD AND FAMILY IN SPECIAL HOSPITAL SITUATIONS

In addition to a general pediatric unit, children may be admitted to special facilities, such as an ambulatory or outpatient setting, an isolation room, or intensive care.

AMBULATORY OR OUTPATIENT SETTING

The ambulatory or outpatient setting provides needed medical services for the child while eliminating the necessity of overnight admission. The benefits of ambulatory care are minimized stressors of hospitalization, especially separation from the family; reduced chances of infection; and increased cost savings. Admission to the ambulatory or outpatient hospital setting usually is for surgical or diagnostic procedures.

In the ambulatory or outpatient setting, adequate preparation is particularly challenging. Ideally, the child and parents should receive preadmission preparation, including a tour of the facility and a review of a typical schedule. Parents need information in advance to help prepare the child and themselves for surgery and enable them to care for the child at home afterwards. Parents also appreciate suggestions for personal items to bring to the hospital. When preadmission preparation is not possible, time should be allowed on the day of the procedure for children to become acquainted with their surroundings and for nurses to assess, plan, and implement appropriate teaching.

Explicit discharge instructions are important after outpatient surgery (see Family-Centered Care box and the Preparing for Discharge and Home Care section earlier in this chapter). Parents need guidelines on when to call their provider about a change in the child's condition. A follow-up telephone call system allows for nurses to check on the child's progress within 48 to 72 hours after discharge to review information and answer questions.

FAMILY-CENTERED CARE

Discharge From Ambulatory Settings

1. Explain that all instructions will also be presented in writing for the family to refer to later.
2. Provide an overview of the typical expected pattern of recovery.
3. Discuss expected progression of the child's activity level during the post-discharge period (e.g., "Mary will probably sleep for the rest of the day and feel kind of tired most of tomorrow but will be back to her usual activities on the next day.").
4. Explain which activities the child is allowed and what is not permitted (e.g., bed rest, bathing).
5. Discuss dietary restrictions, being very specific and giving examples of "clear fluids" or what is meant by a "full liquid diet."
6. Discuss nausea and vomiting, if applicable, explaining how much is "normal" and what to do if more occurs (e.g., "Juan may be sick to his stomach and vomit. This is normal. However, if he vomits more than three times, please call us at this number right away.").
7. Discuss fever and appropriate comfort measures, explaining how much fever is considered "acceptable" and specifically what to do if the child goes beyond the range.
8. Explain the amount, location, and kind of pain or discomfort the child may experience.
   - Give any prescribed medication before leaving the facility.
   - Send a pain scale home with the family.
   - Explain how much pain and discomfort is "normal" and what to do if the child surpasses that level or if pain management interventions are unsuccessful.
   - Discuss pain management, including dosage for pain medications and details on how to administer them.
   - Describe appropriate nonpharmacologic comfort measures, such as holding, rocking, or swaddling.
9. Provide information about each medication that the child will be taking at home.
   - Request that all prescriptions be filled and given to the family before discharge
   - Review the details, including dose and route.
   - Demonstrate how to administer medications.
   - Discuss guidelines for requesting other medications.
10. Make certain the family has all equipment and supplies that they will need at home.
11. Discuss complications that may occur and the steps to take if they do.
12. Ensure that appropriate measures are in place for safe transport home.
    - Remind family to use a seat belt or car seat for the child.
    - Determine if there will be one person whose sole responsibility is helping ensure the child's safety and comfort during transport.
13. Provide emergency phone numbers for the family to call with any concerns.
14. Explain that the family may be contacted to follow up on the child but that they should not hesitate to call if concerns arise before then.
15. Ask the family and child if they have any questions and problem solve with family members to meet their unique needs.

NURSING TIP: Help the family prepare for the transportation home by offering these suggestions:

- Have a blanket and pillow in the car. (Always use the car safety restraint system.)
- Take a basin or plastic bag in case of vomiting.
- Use a cup with a cap and straw for the child to drink fluids (except in cases of oral facial surgery in which a straw may be contraindicated).
- Give any prescribed pain medication before leaving facility.
- Provide parents with verbal and written information on potential side effects of pain medication for which they should be vigilant after discharge.

ISOLATION

Admission to an isolation room increases all of the stressors typically associated with hospitalization. There is further separation from familiar persons; additional loss of control; and added environmental changes, such as sensory deprivation and the appearance of strangers. Orientation to time and place is affected. These stressors may be compounded by a child's limited understanding of isolation. Preschool children have difficulty understanding the rationale for isolation, as they cannot comprehend the cause-and-effect relationship between infections and illness. They are likely to view isolation as punishment. Older children understand the causality better but still require information to decrease fantasizing or misinterpretation.

When a child is placed in isolation, preparation is essential for the child to feel in control. With young children, the best approach is a simple explanation, such as "You need to be in this special room to help you get better. The infection made you sick and you could not help that."

All children, but especially younger ones, need preparation in terms of what they will see, hear, and feel in isolation. Therefore they are shown the mask, gloves, and gown and are encouraged to "dress up" in them. Playing with the hospital personal protective equipment can lessen the fear of hospital personnel entering the room. Nurses and other health personnel should introduce themselves and let the child see their faces before donning masks. In this way, the child associates them with significant experiences and gains a sense of familiarity in an otherwise strange and lonely environment.

When the child's condition improves, appropriate play activities are provided to minimize boredom and stimulate the senses. The environment can be manipulated to increase sensory freedom by moving the bed toward the door or window. Opening window shades; providing musical, visual, or tactile toys; and increasing interpersonal contact can substitute mental mobility for the limitations of physical movement. Rather than dwelling on the negative aspects of isolation, the child can be encouraged to view this experience as challenging and positive.

NURSING TIP: Have the child select a place he or she would like to visit. Help the child decorate the bed and equipment to suit the theme (e.g., truck, circus tent, spaceship, sky). At a set time each day, pretend to go with the child to the special place. Consider including props such as a suitcase or picnic basket.

EMERGENCY ADMISSION

One of the most traumatic hospital experiences for the child and parents is an emergency admission. The sudden onset of an illness or the occurrence of an injury leaves little time for preparation and explanation. Sometimes the emergency admission is compounded by admission to an intensive care unit (ICU) or the need for immediate surgery.

In instances requiring only outpatient treatment, the child is exposed to a strange, frightening environment and to experiences that may elicit fear or cause pain.

There is a wide discrepancy between what constitutes a medically defined emergency and a patient-defined emergency. A growing concern is the use of major emergency departments for routine primary care health visits. To offset overcrowding in emergency departments, many facilities have minor emergency units or pediatric minor emergency units for after-hours health care. Telephone triage for minor illnesses for patients is also emerging as a health care delivery mode to differentiate illnesses such as a common cold from true life-threatening conditions that require immediate practitioner attention and intervention. Other factors contributing to the overuse of emergency departments include the increasing number of uninsured persons and households where both parents work full time and cannot afford to take time off during the day to take the sick child to a practitioner.

In pediatric populations, most visits to an emergency department are for respiratory infections; skin conditions, gastrointestinal disorders, and trauma (such as poisoning) account for the remaining cases. The most common reason parents give for bringing the child to the emergency department is concern about the illness worsening. Providers may not think that the progressive symptoms need immediate or emergency care. One of the nurse's primary goals is to assess the parents' perception of the event and their reasons for considering it serious or life threatening.

Emergency situations usually do not allow for lengthy preparatory admission procedures. In such instances, nurses must focus their nursing interventions on the essential components of admission counseling (Box 19.10) and complete the process as soon as the child's condition has stabilized.

Unless an emergency is life threatening, children need to participate in their care to maintain a sense of control. Because emergency departments are frequently hectic, there is a tendency to rush through procedures to save time. The extra few minutes needed to allow children to participate may save many more minutes of useless resistance and uncooperativeness during subsequent procedures. Other supportive measures include ensuring privacy, accepting various emotional responses to fear or pain, preserving parent-child contact, explaining all events before or as they occur, and personally remaining calm. Pain management strategies are discussed in Chapter 5.

BOX 19.10 Guidelines for Special Hospital Admission[a]

Emergency Admission

Lengthy preparatory admission procedures are often impossible and inappropriate for emergency situations.

Focus assessment on airway, breathing, and circulation; weigh child whenever possible for calculation of drug dosages.

Unless an emergency is life threatening, children need to participate in their care to maintain a sense of control.

Focus on essential components of admission counseling, including:

- Appropriate introduction to the family
- Use of child's name, not terms such as "honey" or "dear"
- Determination of child's age and some judgment about developmental age (If the child is of school age, asking about the grade level will offer some evidence of intellectual ability.)
- Information about child's general state of health, any problems that may interfere with medical treatment (e.g., allergies), and previous experience with hospital facilities
- Information about the chief complaint from both the parents and the child

Admission to Intensive Care Unit

Prepare child and parents for elective intensive care unit (ICU) admission, such as for postoperative care after cardiac surgery.

Prepare child and parents for unanticipated ICU admission by focusing primarily on the sensory aspects of the experience and on usual family concerns (e.g., persons in charge of child's care, schedule for visiting, area where family can stay).

Prepare parents regarding child's appearance and behavior when they first visit child in ICU.

Accompany family to bedside to provide emotional support and answer questions.

Prepare siblings for their visit; plan length of time for sibling visitation; monitor siblings' reactions during visit to prevent them from becoming overwhelmed.

Encourage parents to stay with their child:

- If visiting hours are limited, allow flexibility in schedule to accommodate parental needs.
- Give family members a written schedule of visiting times.
- If visiting hours are liberal, be aware of family members' needs and suggest periodic respites.
- Assure family they can call the unit at any time.

Prepare parents for expected role changes and identify ways for parents to participate in child's care without overwhelming them with responsibilities:

- Help with bath or feeding.
- Touch and talk to child.
- Help with procedures.

Provide information about child's condition in understandable language:

- Repeat information often.
- Seek clarification of understanding.
- During bedside conferences, interpret information for family members and child or, if appropriate, conduct report outside room.

Prepare child for procedures even if it involves explanation while procedure is performed.

Assess and manage pain; recognize that a child who cannot talk, such as an infant or child in a coma or on mechanical ventilation, can be in pain.

Establish a routine that maintains some similarity to daily events in child's life whenever possible:

- Organize care during normal waking hours.
- Keep regular bedtime schedules, including quiet times when television or radio is lowered or turned off.
- Provide uninterrupted sleep cycles (60 minutes for infants; 90 minutes for older children).
- Close and open drapes and dim lights to allow for day and night.
- Place curtain around bed for privacy.
- Orient child to day and time; have clocks or calendars in easy view for older children.

Schedule a time when child is left undisturbed (e.g., during naps, visit with family, playtime, or favorite program).

Provide opportunities for play.

Reduce stimulation in environment:

- Refrain from loud talking or laughing.
- Keep equipment noise to a minimum.
- Turn alarms as low as safely possible.
- Perform treatments requiring equipment at one time.
- Turn off bedside equipment that is not in use, such as suction and oxygen.
- Avoid loud, abrupt noises.

[a]See also Box 19.7.

Fig. 19.10 Parental presence during hospitalization provides emotional support for the child and increases the parents' sense of empowerment in the caregiver role. (Courtesy E. Jacob, Texas Children's Hospital, Houston, TX.)

At times, because of the child's physical condition, little or no preparatory counseling for emergency hospitalization can be done. In such situations, counseling subsequent to the event has therapeutic value. The counseling should focus on evaluating children's thoughts on admission and related procedures. Projective techniques such as drawing, doll play, or storytelling are especially effective. The nurse then bases additional information on what has already been understood.

INTENSIVE CARE UNIT

Admission to an ICU can be traumatic for both the child and parents (Fig. 19.10). The nature and severity of the illness and the circumstances surrounding the admission are major factors, especially for parents. Parents experience significantly more stress when the admission is unexpected rather than expected. Stressors for the child and parent are described in Box 19.11. Although several studies have described what parents perceive as most stressful, the most effective strategy may be to simply ask parents what is stressful and implement interventions that will enhance their ability to cope (Board & Ryan-Wenger, 2003). Assessment should be repeated periodically to account for changes in perceptions over time. The use of daily patient goal sheets has been successful in improving communication among health care providers caring for children in the ICU (Agarwal, Frankel, Tourner, et al., 2008; Phipps & Thomas, 2007). By clearly defining daily patient care goals, health care providers believed that care was improved. Standardized rounding structure improved adherence to daily goal sheet use, with the intent of improved communication among caregivers (Seigel, Whelan, et al., 2014).

The family's emotional needs are paramount when a child is admitted to an ICU. A major stressor for parents of a child in the ICU is the child's appearance (Latour, van Goudoever, & Hazelzet, 2008). Although the same interventions discussed earlier for the stressors of separation and loss of control apply here, additional interventions may also benefit the family and child (see Box 19.11). In a qualitative study of 19 parents of 10 children in an ICU, parents reported that they simply wanted nurses to nurture the child in the same way the family would (Harbaugh, Tomlinson, & Kirschbaum, 2004). Nurse behaviors that exemplified caring and affection were perceived as helpful in decreasing stress. Behaviors perceived as not helpful included separating the child from the parents and communicating poorly with parents. Therefore even critical care must be centered on the family.

BOX 19.11 Neonatal or Pediatric Intensive Care Unit Stressors for the Child and Family

Physical Stressors

Pain and discomfort (e.g., injections, intubation, suctioning, dressing changes, other invasive procedures)
Immobility (e.g., use of restraints, bed rest)
Sleep deprivation
Inability to eat or drink
Changes in elimination habits

Environmental Stressors

Unfamiliar surroundings (e.g., crowding)
Unfamiliar sounds
- Equipment noise (e.g., monitors, telephone, suctioning, computer printout)
- Human sounds (e.g., talking, laughing, crying, coughing, moaning, retching, walking)

Unfamiliar people (e.g., health care professionals, patients, visitors)
Unfamiliar and unpleasant smells (e.g., alcohol, adhesive remover, body odors)
Constant lights (disturb day-night rhythms)
Activity related to other patients
Sense of urgency among staff
Unkind or thoughtless comments from staff

Psychologic Stressors

Lack of privacy
Inability to communicate (if intubated)
Inadequate knowledge and understanding of situation
Severity of illness
Parental behavior (expression of concern)

Social Stressors

Disrupted relationships (especially with family and friends)
Concern with missing school or work
Play deprivation

Data primarily from Tichy, A. M., Braam, C. M., Meyer, T. A., et al. (1988). Stressors in pediatric intensive care units. *Pediatric Nursing, 14*(1), 40–42.

It is important that visiting hours be liberal and flexible enough to accommodate parental needs and involvement.

Critically ill children become the focus of their parents' lives, and parents' most pressing need is for information. They want to know if their child will live and, if so, whether the child will be the same as before. They need to know why various interventions are being done for the child, that the child is being treated for pain or is comfortable, and that the child may be able to hear them even though not awake. When parents first visit the child in the ICU, they need preparation regarding the child's appearance. Ideally, the nurse should accompany the parents to the bedside to provide emotional support and answer any questions.

Despite the stresses normally associated with ICU admission, a special security develops from being carefully monitored and receiving individualized care. Therefore planning for transition to the regular unit is essential and should include:

- Assignment of a primary nurse on the regular unit
- Continued visits by the ICU staff to assess the child's and parents' adjustment and to act as a temporary liaison with the nursing staff
- Explanation of the differences between the two units and the rationale for the change to less intense monitoring of the child's physical condition
- Selection of an appropriate room, such as one that is close to the nursing station, and a compatible roommate

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. The nurse is caring for a 5-year-old girl who is newly diagnosed with a seizure disorder. She observes that the child is having separation anxiety when her parents leave the room. What are important aspects of separation anxiety that are specific to this stage of development? **Use an X for the health teaching statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
"Separation anxiety may be seen in your child by refusing to eat, having trouble sleeping, crying quietly for you when gone, or withdrawing from others."			
"Separation anxiety comes in stages: denial, despair, and detachment."			
"Loss of peer group contact may pose a severe emotional threat because of loss of group status, and loss of group acceptance."			
"Your child may need and desire parental guidance or support from other adult figures as she returns to school."			
"Young children can react "negatively" to their parents during hospitalization; they may cling to you to ensure your continued presence."			

2. A 3-year-old child has been hospitalized for the past week for pneumonia. Since his condition is stable, his mother has returned to work and the child is often alone during the day. The nurse caring for the child reviews the medical record and performs an assessment and findings are listed below. Which findings are reflective of the Stage of Despair that can occur because of separation anxiety? **Select the assessment findings that are reflective of the Stage of Despair in separation anxiety. Select all that apply.**
   - **A.** Appears happy
   - **B.** Refuses to communicate
   - **C.** Withdraws from the nurse
   - **D.** Appears depressed and sad
   - **E.** Verbally attacks the nurse
   - **F.** Attempts to escape the room
   - **G.** Lacks interest in the environment
   - **H.** Cries and screams when the nurse enters the room

3. The nurse is admitting an 8-year-old child to the hospital for further evaluation of a congenital heart disorder. Her mother is with her. What are important aspects of the admission process that the nurse needs to remember during this first encounter with the patient and family? **Select all that apply.**
   - **A.** Introduce yourself
   - **B.** Orient the child and family to the unit
   - **C.** Apply identification band on the child's wrist
   - **D.** Apply identification band to the mother's wrist
   - **E.** Take vital signs, blood pressure, height and weight
   - **F.** Draw extra blood in case labs will be ordered later
   - **G.** Discuss hospital schedules and regulations
   - **H.** Explain how to use the electronic devices in the room such as call light, bed controls, television
   - **I.** Take the child to the cafeteria so family will know where to go for dinner

4. When discharging an 8-year-old boy who was hospitalized for an appendectomy, the nurse reviews the plan for continued care at home. He was hospitalized 4 days ago after a 2-day history of abdominal pain and fever. The patient underwent an emergency appendectomy. What health teaching would the nurse include as part of the discharge instructions? **Select all that apply.**
   - **A.** "Your son can have soft foods at home, examples include Jell-O, pudding, and apple juice."
   - **B.** "You can use other things to help with pain, such as distraction (reading a book, music, or a movie), after the pain medication is given."
   - **C.** "You can get your child's prescription in the next couple of days."
   - **D.** "You can drive your son home without concern; make sure you both wear a seatbelt."
   - **E.** "We will contact you tomorrow for follow-up, but do not hesitate to call if you have any concerns before then."
   - **F.** "If fever develops in the next 10 days, start oral antibiotics again at home."

CONCEPTS

- Informed Consent
- Procedure Preparation
- Medication Administration
- Specimen Collection
- Fluid Balance and Nutrition
- Respiratory Support

GENERAL CONCEPTS RELATED TO PEDIATRIC PROCEDURES

INFORMED CONSENT

Before undergoing any invasive procedure, the patient or the patient's legal surrogate must receive sufficient information on which to make an informed health care decision. **Informed consent** should include the nature of the illness or condition, proposed care, or treatment; potential risks, benefits, and alternatives; and what might happen if the patient chooses not to consent. In addition, discussions should include the procedure team roles, including trainees involved in care (Firdouse, Wajchendler, Koyle, et al., 2017). To obtain valid informed consent, health care providers must meet the following three conditions:

1. The person must be capable of giving consent; he or she must be over the age of majority (usually age 18 years) and must be considered competent (i.e., possess the mental capacity to make choices and understand their consequences).
2. The person must receive the information needed to make an intelligent decision.
3. The person must act voluntarily when exercising freedom of choice without force, fraud, deceit, duress, or other forms of constraint or coercion.

The patient has the right to accept or refuse any health care. If a patient is treated without consent, the hospital or health care provider may be charged with assault and held liable for damages. In addition, consent is a two-way process that requires both the health care provider to share all required information and the patient to hear and understand the information. Health care providers must deliver information in the appropriate language and health literacy level for the patient and family. There must also be adequate time for questions and opportunity to clarify concerns. Informed consent and medical decision making is not a one-time event but an ongoing process that requires continual communication among the health care team, patient, and caregivers (American Academy of Pediatrics, Committee on Bioethics, 2016).

REQUIREMENTS FOR OBTAINING INFORMED CONSENT

Written informed consent of the patient, parent, or legal guardian is usually required for medical or surgical treatment of a minor, including many diagnostic procedures. One universal consent is not sufficient. Separate informed permissions must be obtained for each surgical or diagnostic procedure, including the following:

- Major surgery
- Minor surgery (e.g., cutdown, biopsy, dental extraction, suturing a laceration [especially one that may have a cosmetic effect], removal of a cyst, closed reduction of a fracture)
- Diagnostic tests with an element of risk (e.g., bronchoscopy, angiography, lumbar puncture, cardiac catheterization, bone marrow aspiration)
- Medical treatments with an element of risk (e.g., blood transfusion, thoracentesis or paracentesis, radiotherapy)

Other situations that require patient or parental consent include the following:

- Photographs for medical, educational, or public use
- Removal of the child from the health care institution against medical advice
- Postmortem examination, except in unexplained deaths, such as sudden infant death, violent death, or suspected suicide
- Release of medical information

Decision making involving the care of older children and adolescents (older than 7 years of age with appropriate age, maturity, and psychologic state) should include the patient's **assent** (if feasible) as well as the parent's consent (Poston, 2016). Assent means that the child or adolescent has been informed about the proposed treatment, procedure, or research and is willing to permit a health care provider to perform it. If the child or adolescent merely fails to object, this does not equate assent. Assent should include the following:

- Helping the patient achieve a developmentally appropriate awareness of the nature of his or her condition
- Telling the patient what he or she can expect

- Making a clinical assessment of the patient's understanding
- Soliciting an expression of the patient's willingness to accept the proposed procedure

Health care providers should use multiple methods to provide information, including age-appropriate methods (e.g., videos, peer discussion, diagrams, written materials). The nurse should provide an assent form for the child to sign, and the child should keep a copy. By including the child in the decision-making process and gaining his or her acceptance, staff members demonstrate respect for the child. Assent is not a legal requirement but an ethical one to protect the rights of children. Chapter 17 provides further discussion on the dying child's right to refuse treatment.

Eligibility for Giving Informed Consent

Informed Consent of Parents or Legal Guardians

Parents have full responsibility for the care and rearing of their minor children, including legal control over them. As long as children are minors, their parents or legal guardians are required to give informed consent before medical treatment is rendered or any procedure is performed. If the parents are married to each other, consent from only one parent is required for nonurgent pediatric care. If the parents are divorced, consent usually rests with the parent who has legal custody (American Academy of Pediatrics, Committee on Bioethics, 2016). Emergency care of a pediatric patient should never be withheld due to the absence of a parent or legal guardian. Parents also have a right to withdraw consent later. If the legal caregivers disagree on the treatment course, it is within the health care providers' scope to request consultation of a hospital ethics board to determine what care is in the best interest of the patient (Dahl, Sinha, Rosenberg, et al., 2015).

Evidence of Consent

Regulations on obtaining informed consent vary from state to state, and policies differ at each health care facility. It is the physician's legal responsibility to explain the procedure, risks, benefits, and alternatives. The nurse witnesses the patient's, parent's, or legal guardian's signature on the consent form and may reinforce what the patient has been told. A signed consent form is the legal document that signifies that the process of informed consent has occurred. If parents are unavailable to sign consent forms, verbal consent may be obtained via the telephone in the presence of two witnesses. Both witnesses record that informed consent was given and by whom. Their signatures indicate that they witnessed the verbal consent. If the parents or legal guardians cannot be reached for an extended period, the nurse may request the assistance of social work or law enforcement officers to locate a legal guardian.

Informed Consent of Mature and Emancipated Minors

State laws differ with regard to the age of majority, the age at which a person is considered to have all the legal rights and responsibilities of an adult. In most states, 18 years is the age of majority. Competent adults can give informed consent on their own behalf. An **emancipated minor** is one who is legally under the age of majority but is recognized as having the legal capacity or social status of an adult under circumstances prescribed by state law, such as pregnancy, marriage, high school graduation, independent living, or military service. A **mature minor** exception to consent laws is recognized in a few states for children age 14 years and older who possesses the maturity and cognitive abilities to understand all elements of informed consent and make a choice based on the information. Legal action may be required for designation as a mature minor (American Academy of Pediatrics, Committee on Bioethics, 2016).

Treatment Without Parental Consent

Exceptions to requiring parental consent before treating minor children occur in situations in which children need urgent medical or surgical treatment and a parent is not readily available to give consent or refuses to give consent. For example, a child may be brought to an emergency department accompanied by a grandparent, child care provider, teacher, or others. In the absence of parents or legal guardians, persons in charge of the child may be given permission by the parents to give informed consent by proxy. A medical screening examination is required by federal law under the Emergency Medical Treatment and Active Labor Act for all patients presenting to an emergency center. In emergencies, including danger to life or the possibility of permanent injury, appropriate care should not be withheld or delayed because of problems obtaining consent (American Academy of Pediatrics, Committee on Bioethics, 2016). The nurse should document any efforts made to obtain consent.

Parental refusal to give consent for life-saving treatment or to prevent serious harm can occur and requires notification to child protective services to render emergency treatment. For example, Jehovah's Witnesses commonly choose to avoid receiving blood products due to religious beliefs. In cases where a blood product is crucial for the child's survival, it is important to work together with the family, medical team, and child protective services to determine the course of action that is in the best interest of the child. "Parental decision-making should primarily be understood as parents' responsibility to support the interests of their child and to preserve family relationships, rather than being focused on their rights to express their own autonomous choices" (American Academy of Pediatrics, Committee on Bioethics, 2016). Evaluation for child abuse or neglect can occur without parental consent and without notification to the state before evaluation in most states.

Adolescents, Consent, and Confidentiality

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) was passed to help protect and safeguard the security and confidentiality of health information. Because adolescents are not yet adults, parents have the right to make most decisions on their behalf and receive information. Adolescents, however, are more likely to seek care in a setting in which they believe their privacy will be maintained. All 50 states have enacted legislation that entitles adolescents to consent to treatment without the parents' knowledge to one or more "medically emancipated" conditions such as sexually transmitted infections, mental health services, substance abuse and addiction, pregnancy, and contraceptive advice (American Academy of Pediatrics, Committee on Bioethics, 2016). Consent to abortion is controversial, and statutes vary widely by state. The Planned Parenthood Federation of America provides consent and notification law requirements listed by state. State law preempts HIPAA regardless of whether that law prohibits, mandates, or allows discretion about a disclosure.

Informed Consent and Parental Right to the Child's Medical Chart

Some state statutes give parents the unrestricted right to a copy of their children's medical records. In states without statutes, the best practice is to allow parents to review or have a copy of minors' charts under reasonable circumstances. Practitioners should avoid restrictive requirements such as review permitted only in the presence of a clinician. Rather, an appropriate practitioner should be available to answer any questions that parents may have during their reviews. It is important for the nurse to check the state and health care institution's policies surrounding providing printed copies of medical records to patients and families.

PREPARATION FOR DIAGNOSTIC AND THERAPEUTIC PROCEDURES

Technologic advances and changes in health care have resulted in more pediatric procedures being performed in a variety of settings. Many procedures are both stressful and painful experiences. For many procedures, the focus of care is psychologic preparation of the child and family. However, some procedures require the administration of sedatives and analgesics.

The child life specialist is an especially valued member of the health care team when preparing a child for diagnostic and therapeutic procedures. Child life specialists address the psychosocial concerns that accompany stressful life experiences by promoting optimal child development and minimizing adverse effects. Child life specialists receive advanced education and training in the developmental stages of childhood as well as strategies to cope with illness and injury. Therapeutic play, procedural preparation and support, developmentally appropriate education, and promoting normalcy are all significant ways in which the child life specialist can have a positive impact on the health care experience of the child and family. Child life specialists and nursing staff can work together to implement evidence-based interventions to decrease fear, anxiety, and discomfort experienced by children in the health care environment (Association of Child Life Professionals, 2017).

Psychologic Preparation

Preparing children for procedures decreases their anxiety, promotes their cooperation, supports their coping skills and may teach them new ones, and facilitates a feeling of mastery in experiencing a potentially stressful event. Many institutions have developed preadmission teaching programs designed to educate the pediatric patient and family by offering hands-on experience with hospital equipment, the procedure performed, and departments they will visit. Preparatory methods may be formal, such as group preparation for hospitalization. Most preparation strategies are informal, focus on providing information about the experience, and are directed at stressful or painful procedures. The most effective preparation includes the provision of sensory-procedural information and helping the child develop coping skills, such as imagery, distraction, or relaxation.

The Applying Evidence to Practice boxes describe general guidelines for preparing children for procedures along with age-specific guidelines that consider children's developmental needs and cognitive abilities. In addition to these suggestions, nurses should consider the child's temperament, existing coping strategies, and previous experiences in individualizing the preparatory process. Stress point coping can be used to determine the child's most stressful or upsetting part of previous procedural experiences (Thompson, 2018). Once the stress point is identified, coping strategies to address this specific point in the procedure can be discussed with the child. Children who are distractible and highly active or those who are "slow to warm up" may need individualized sessions—shorter for active children and more slowly paced for shy children. Whereas children who tend to cope well may need more emphasis on using their present skills, those who appear to cope less adequately can benefit from more time devoted to simple coping strategies, such as relaxing, breathing, counting, squeezing a hand, or singing. Children with previous health-related experiences still need preparation for repeat or new procedures; however, the nurse must assess what they know, correct their misconceptions, supply new information, and introduce new coping skills as indicated by their previous reactions. Especially for painful procedures, the most effective preparation includes providing sensory-procedural information and helping the child develop coping skills, such as imagery or relaxation (see Applying Evidence to Practice boxes).

All experiences of childhood can affect development and influence the way in which a child responds to the health care environment, even into adulthood. Adverse childhood experiences can include abuse, neglect, substance abuse, or any other traumatic experiences and may result in negative health behaviors, chronic health conditions, and even early death (Centers for Disease Control and Prevention, 2019). While in the health care environment, children can experience medical traumatic stress during difficult or frightening medical events or from simply being present in the hospital environment. As care providers, it is important to practice trauma-informed care; consider the impact that past physical, mental, and emotional trauma may have on a patient; and adapt care appropriately. This may include reducing distress through pain control, offering choices, psychologic preparation for procedures, providing emotional support, and including the family in what health care providers may perceive as routine care (National Child Traumatic Stress Network, 2019).

APPLYING EVIDENCE TO PRACTICE

Preparing Children for Procedures

- Determine details of exact procedure to be performed.
- Review parents' and child's present understanding through open-ended questions.
- Base teaching on developmental age and existing knowledge.
- Incorporate parents in the teaching if they desire, especially if they plan to participate in care.
- Inform parents of their supportive role during the procedure, such as standing near child's head or in child's line of vision and talking softly to child, participating in comfort holding positions, and typical responses of children undergoing the procedure.
- Allow for ample discussion to prevent information overload and ensure adequate feedback.
- Use concrete, not abstract, terms and visual aids to describe procedure. For example, use a simple line drawing of a boy or girl and mark the body part that will be involved in the procedure. Use nonthreatening but realistic models.[a]
- Emphasize that no other body part will be involved.
- If the body part is associated with a specific function, stress the change or noninvolvement of that ability (e.g., after tonsillectomy, child can still speak).
- Use words and sentence length appropriate to child's level of understanding (a rule of thumb for the number of words in a child's sentence is equal to his or her age in years plus 1).
- Avoid words and phrases with dual meanings (see Table 20.1) unless child understands such words.
- Clarify all unfamiliar words (e.g., "Anesthesia is a *different kind of* sleep").
- Emphasize sensory aspects of procedure—what child will feel, see, hear, smell, taste, and touch, and what child can do during procedure (e.g., lie still, count out loud, squeeze a hand, hug a doll).
- Allow child to practice procedures that will require cooperation (e.g., turning, deep breathing, using an incentive spirometer).
- Introduce anxiety-inducing information last (e.g., starting an intravenous line).
- Be honest with child about unpleasant aspects of a procedure but avoid creating undue concern. When discussing that a procedure may be uncomfortable, state that it feels differently to different people.
- Emphasize end of procedure and any pleasurable events afterwards (e.g., going home, seeing parents).
- Stress positive benefits of procedure (e.g., "After your tonsils are fixed, you won't have as many sore throats").
- Provide a positive ending, praising efforts at cooperation and coping.

APPLYING EVIDENCE TO PRACTICE

Age-Specific Preparation of Children for Procedures Based on Developmental Characteristics

Infant—Developing Trust and Sensorimotor Thought

Attachment to Parent

Involve parent in procedure if desired.[a]
Keep parent in infant's line of vision.
If parent is unable to be with infant, place familiar object with infant (e.g., stuffed toy, blanket).

Stranger Anxiety

Have usual caregivers perform or assist with procedure.[a]
Make advances slowly and in a nonthreatening manner.
Limit number of strangers entering room during procedure.[a]

Sensorimotor Phase of Learning

During procedure, use sensory soothing measures (e.g., stroking skin, talking softly, giving pacifier, providing sucrose water solution with pacifier, breastfeeding).
Use analgesics (e.g., topical anesthetic, intravenous opioid) to control discomfort.[a]
Cuddle and hug infant after stressful procedure; encourage parent to comfort infant.

Increased Muscle Control

Expect older infants to resist.
Restrain adequately using comfort holds.
Keep harmful objects out of reach.

Memory for Past Experiences

Realize that older infants may associate objects, places, or persons with prior painful experiences and will cry and resist at the sight of them.
Keep frightening objects out of view.[a]
Perform painful procedures in a separate room, not in crib (or bed).[a]
Use nonintrusive procedures whenever possible (e.g., axillary or tympanic temperatures, oral medications).[a]

Imitation of Gestures

Model desired behavior (e.g., opening mouth).

Toddler—Developing Autonomy and Sensorimotor to Preoperational Thought

Use same approaches as for infant plus the following.

Egocentric Thought

Explain procedure in relation to what child will see, hear, taste, smell, and feel.
Emphasize those aspects of procedure that require cooperation (e.g., lying still).
Tell child it is okay to cry, yell, or use other means to express discomfort verbally.
Designate one health care provider to speak during procedure. Hearing more than one provider can be confusing and overwhelming to a child.[a]

Negative Behavior

Expect treatments to be resisted; child may try to run away.
Use firm, direct approach.
Ignore temper tantrums.
Use distraction techniques (e.g., singing a song *with* child).
Restrain adequately using a comfort hold technique.

Animism

Keep frightening objects out of view (young children believe that objects have lifelike qualities and can harm them).

Limited Language Skills

Communicate using gestures or demonstrations.
Use a few simple terms familiar to child.
Give child one direction at a time (e.g., "Lie down" and then "Hold my hand").
Use small replicas of equipment; allow child to handle equipment.
Use play; demonstrate on doll but avoid child's favorite doll because child may think doll is really "feeling" procedure.
Prepare parents separately to avoid child's misinterpreting words.

Limited Concept of Time

Prepare child shortly or immediately before procedure.
Keep teaching sessions short (about 5 to 10 minutes).
Have preparations completed before involving child in procedure.
Have extra equipment nearby (e.g., alcohol swabs, new needle, adhesive bandages) to avoid delays.
Tell child when procedure is completed.

Striving for Independence

Allow choices whenever possible but realize that child may still be resistant and negative.
Allow child to participate in care and to help whenever possible (e.g., drink medicine from a cup, hold a dressing).

Preschooler—Developing Initiative and Preoperational Thought

Egocentric

Explain procedure in simple terms and in relation to how it affects child (as with toddler, stress sensory aspects).
Demonstrate use of equipment.
Allow child to play with miniature or actual equipment.
Encourage "playing out" experience on a doll both before and after procedure to clarify misconceptions.
Use neutral words to describe the procedure (see Table 20.1).

Increased Language Skills

Use verbal explanation but avoid overestimating child's comprehension of words.
Encourage child to verbalize ideas and feelings.

Limited Concept of Time and Frustration Tolerance

Implement same approaches as for toddler but may plan longer teaching session (10 to 15 minutes); may divide information into more than one session.

Illness and Hospitalization Viewed as Punishment

Clarify why each procedure is performed; child will find it difficult to understand how medicine can make him or her feel better and can taste bad at the same time.
Ask child thoughts regarding why a procedure is performed.
State directly that procedures are never a form of punishment.

Animism

Keep equipment out of sight except when shown to or used on child.

Fears of Bodily Harm, Intrusion, and Castration

Point out on drawing, doll, or child where procedure is performed.
Emphasize that no other body part will be involved.
Use nonintrusive procedures whenever possible (e.g., axillary temperatures, oral medication).
Apply an adhesive bandage over puncture site.
Encourage parental presence.
Realize that procedures involving genitalia provoke anxiety.

APPLYING EVIDENCE TO PRACTICE—cont'd

Age-Specific Preparation of Children for Procedures Based on Developmental Characteristics

Allow child to wear underpants with gown.
Explain unfamiliar situations, especially noises or lights.

Striving for Initiative

Involve child in care whenever possible (e.g., hold equipment, remove dressing).
Give choices whenever possible, but avoid excessive delays.
Praise child for helping and attempting to cooperate; never shame child for lack of cooperation.
Identify one thing the child did well during the procedure.

School-Age Child—Developing Industry and Concrete Thought

Increased Language Skills; Interest in Acquiring Knowledge

Explain procedures using correct scientific and medical terminology.
Explain procedure using simple diagrams and photographs.
Discuss why procedure is necessary; concepts of illness and bodily functions are often vague.
Explain function and operation of equipment in concrete terms.
Allow child to manipulate equipment; use doll or another person as model to practice using equipment whenever possible (doll play may be considered childish by older school-age child).
Allow time before and after procedure for questions and discussion.

Improved Concept of Time

Plan for longer teaching sessions (about 20 minutes).
Prepare up to 1 day in advance of procedure to allow for processing of information.

Increased Self-Control

Gain child's cooperation.
Tell child what is expected.
Suggest several ways of maintaining control the child may select from (e.g., deep breathing, relaxation, counting).

Striving for Industry

Allow responsibility for simple tasks (e.g., collecting specimens).
Include child in decision making when choices are possible (e.g., time of day to perform procedure, preferred site).
Encourage active participation (e.g., removing dressings, handling equipment, opening packages).

Developing Relationships With Peers

Prepare two or more children for same procedure or encourage one to help prepare another.
Provide privacy from peers during procedure to maintain self-esteem.

Adolescent—Developing Identity and Abstract Thought

Increasing Abstract Thought and Reasoning

Discuss why procedure is necessary or beneficial.
Explain long-term consequences of procedures; include information about body systems working together.
Realize adolescent may fear death, disability, or other potential risks.
Encourage questioning regarding fears, options, and alternatives.

Consciousness of Appearance

Provide privacy; describe how the body will be covered and what will be exposed.
Discuss how procedure may affect appearance (e.g., scar) and what can be done to minimize it.
Emphasize any physical benefits of procedure.

Concern More With Present Than With Future

Realize that immediate effects of procedure are more significant than future benefits.

Striving for Independence

Involve adolescent in decision making and planning (e.g., time, place, individuals present during procedure, clothing, whether they will watch procedure).
Impose as few restrictions as possible.
Explore what coping strategies have worked in the past; they may need suggestions of various techniques.
Accept regression to more childish methods of coping.
Realize that adolescent may have difficulty accepting new authority figures and may resist complying with procedures.

Developing Peer Relationships and Group Identity

Same as for school-age child but assumes even greater significance.
Allow adolescents to talk with other adolescents who have had the same procedure.

[a] Applies to any age.

Children differ in their "information-seeking dimension." Some actively ask for information about the intended procedure, but others characteristically avoid information. Parents can often guide nurses in deciding how much information is enough for the child because parents know whether the child is typically inquisitive or satisfied with short answers. Asking older children their preferences about the amount of explanation is also important.

The exact timing of the preparation for a procedure varies with the child's age and developmental level and the type of procedure. No exact guidelines govern timing, but in general, the younger the child, the closer the explanation should be to the actual procedure to prevent undue fantasizing and worrying. Concurrent preparation is a strategy that can be used during a procedure to explain what a child can expect to occur and sense immediately before it happens (Thompson, 2018). This can be helpful for emergency procedures, for a highly anxious child, or for younger age-groups where extensive prior preparation is not possible or beneficial. With complex procedures, more time may be needed for assimilation of information, especially with older children. For example, the explanation for an injection can immediately precede the procedure for all ages, but preparation for surgery may begin the day before for young children and a few days before for older children, although the nurse should elicit older children's preferences.

NURSING TIP Use photographs or videos of children in different areas of the hospital (e.g., radiology department, operating room) to give children a more realistic idea of equipment they may encounter.

Establish Trust and Provide Support

The nurse who has spent time with and established a positive relationship with a child usually finds it easier to gain cooperation. If the relationship is based on trust, the child will associate the nurse with caregiving activities that give comfort and pleasure most of the time rather than discomfort and stress. If the nurse does not know the child, it is best

for the nurse to be introduced by another staff person whom the child trusts. The first visit with the child should not include any painful procedure and ideally should focus on the child first and then on an explanation of the procedure. A simple way to begin the process of creating trust is by engaging in play with the patient through favorite activities or toys. Body language is another key element of promoting trust. Positive body language, such as sitting instead of standing, and avoiding the use of technical medical terminology in conversation can enhance the therapeutic caregiver relationship with the child and family (Lidgett, 2016).

Parental Presence and Support

Children need support during procedures, and for young children, the greatest source of support is the parents. They represent security, protection, safety, and comfort. Parental presence has a positive impact on the level of pain and negative behavior experienced by the child, as well as on parental distress and satisfaction (Saglik & Caglar, 2018). In addition, there is no difference in technical complications when parents remain with children. However, controversy exists regarding the role parents should assume during the procedure, especially if discomfort is involved. The nurse should assess the parents' preferences for assisting, observing, or waiting outside the room, as well as the child's preference for parental presence. Respect the child's and parents' choices. Give parents who wish to stay appropriate explanation about the procedure and coach them about where to sit or stand and what to say or do to help the child through the procedure. Support parents who decide they do not want to be present and encourage them to remain close by so that they can be available to support the child immediately after the procedure. It can be helpful for parents to assist the health care team in identifying an alternative support person for their child, such as a child life specialist or nurse, if they are unable to be present during the procedure. Parents should know that someone will be with their child to provide support. Ideally, this person should inform the parents after the procedure about how the child did.

Provide an Explanation

Age-appropriate explanations are one of the most widely used interventions for reducing anxiety in children undergoing procedures. Before performing a procedure, explain what is to be done, what sensations the child may feel, what is expected of the child, and why the procedure is being done. It is important that the child understand that the procedure is not punishment. The explanation should be short, simple, and appropriate to the child's level of comprehension. Long explanations may increase anxiety in a young child. When explaining the procedure to parents with the child present, the nurse uses language appropriate to the child because unfamiliar words can be misunderstood (Table 20.1). If the parents need additional preparation, it is done in an area away from the child. Teaching sessions are planned at times most conducive to the child's learning (e.g., after a rest period) and for the usual span of attention.

Special equipment is not necessary for preparing a child, but for young children who cannot yet think conceptually, using objects to supplement verbal explanation is important. Children often learn through behavior modeling such as seeing a doll experience the procedure, watching a video, or seeing a picture. In addition, allowing children to handle actual items that will be used in their care, such as a stethoscope, sphygmomanometer, or oxygen mask, helps them develop familiarity with these items and reduces the fear often associated with their use. Miniature versions of hospital items such as gurneys and x-ray and intravenous (IV) equipment can be used to explain what the children can expect and permit them to safely experience situations that are unfamiliar and potentially frightening. Written and illustrated materials are also valuable aids to preparation.[a]

[a]Preparatory materials include Berenstain Bears Go to the Doctor and Berenstain Bears Visit the Dentist (New York, NY: Random House).

TABLE 20.1 Selecting Nonthreatening Words or Phrases

Words and Phrases to Avoid	Suggested Substitutions
Shot, bee sting, stick	Medicine under the skin, poke that will feel like a pinch
Organ	Place in body
Test	To see how (specify body part) is working
Incision, cut	Make an opening
Edema	Puffiness
Stretcher, gurney	Rolling bed, bed on wheels
Stool, urine	Child's usual term
Dye	Medicine to help place in your body show up on a picture
Pain	Hurt, discomfort, "owie," "boo-boo," sore, achy, scratchy, pinch
Deaden, numb	Not feel body part as much
Fix	Make better
Take (as in "take your temperature")	See how warm you are
Take (as in "take your blood pressure")	Check your pressure, hug your arm
Put to sleep, anesthesia	Different kind of sleep so you won't feel anything
Catheter	Soft tube, small straw
Monitor	Television screen
Electrodes	Stickers, ticklers
Specimen	Take some blood

NURSING TIP To avoid a delay during a procedure, have extra supplies handy. For example, have tape, bandages, alcohol swabs, and an extra needle when performing an injection or venipuncture.

NURSING TIP Prepare a basket, toy chest, or cart to keep near the treatment area. Items ideal for the basket include a Slinky; a sparkling "magic" wand (sealed, acrylic tube partially filled with liquid and suspended metallic confetti); a soft foam ball; bubble solution; party blowers; pop-up books with foldout, three-dimensional scenes; real medical equipment, such as a syringe, adhesive bandages, and alcohol packets; toy medical supplies or a toy medical kit; marking pens; a notepad; and stickers. Have the child choose an item to help distract and relax during the procedure. After the procedure, allow the child to choose a small gift, such as a sticker, or to play with items, such as medical equipment. Do not allow a child to keep a syringe to play with because it can cause harm (e.g., air embolism or infection) if connected to a needleless infusion port.

Physical Preparation

One area of special concern is the administration of appropriate sedation and analgesia before stressful procedures.

Performance of the Procedure

Supportive care continues during the procedure and can be a major factor in a child's ability to cooperate. Ideally, the same nurse who explains the procedure should perform or assist with the procedure. The child may also benefit from a parent or trusted caregiver who can offer coaching techniques and support during the procedure. Before beginning, all

equipment is assembled, and the room is readied to prevent unnecessary delays and interruptions that increase the child's anxiety. Minimizing the number of people present and allowing one person to speak during the procedure also can decrease the child's anxiety.

To promote long-term coping and adjustment, give special consideration to the patient's age, coping skills, and procedure to be performed in determining where a procedure will occur. Treatment rooms should be used for procedures requiring sedation, such as bone marrow aspirates and lumbar punctures in younger children. Traumatic procedures should never be performed in "safe" areas, such as the playroom. If the procedure is lengthy, avoid conversation that could be misinterpreted by the child. As the procedure is nearing completion, the nurse may inform the child "this is the last piece of tape" or simply inform the child when the procedure is completed.

NURSING TIP Help the child select and practice a coping technique before the procedure. Consider having the parent or some other supportive person, such as a child life specialist, "coach" the child in learning and using the coping skill.

Expect Success

Nurses who approach children with confidence and who convey the impression that they expect to be successful are less likely to encounter difficulty. It is best to approach a child as though cooperation is expected. Children sense anxiety and uncertainty in an adult and respond by striking out or actively resisting. Although it is not possible to eliminate such behavior in every child, a firm approach with a positive attitude tends to convey a feeling of security to most children.

Involve the Child

Involving children helps gain their cooperation. Permitting choices gives them some measure of control. However, a choice is given only in situations in which one is available. Asking children, "Do you want to take your medicine now?" leads them to believe they have an option and provides them the opportunity to legitimately refuse or delay the medication. This places the nurse in an awkward, if not impossible, position. It is much better to state firmly, "It's time to drink your medicine now." Children usually like to make choices, but the choice must be one that they do indeed have (e.g., "It's time for your medicine. Do you want to drink it plain or with a little water?").

Many children respond to tactics that appeal to their maturity or courage. This also gives them a sense of participation and achievement. For example, preschool children will be proud that they can hold the dressing during the procedure or remove the tape. The same is true for school-age children, who often cooperate with minimal resistance.

Provide Distraction

Distraction is a powerful coping strategy during painful procedures (Dastgheyb, Fishlock, Daskalakis, et al., 2018). It is accomplished by focusing the child's attention on something other than the procedure. Singing favorite songs, listening to music with a headset, counting aloud, or blowing bubbles to "blow the hurt away" are effective techniques. (For other nonpharmacologic interventions, see Chapter 5.)

Allow Expression of Feelings

The child should be allowed to express feelings of anger, anxiety, fear, frustration, or any other emotion. It is natural for children to strike out in frustration or to try to avoid stress-provoking situations. The child needs to know that it is all right to cry. Behavior is children's primary means of communication and coping and should be permitted unless it inflicts harm on them or those caring for them. Harmful behavior should be acknowledged and appropriate limitations should be set to promote patient and caregiver safety.

Fig. 20.1 Playing with medical objects provides children with the opportunity to play out fears and concerns with supervision by a nurse or child life specialist.

Postprocedural Support

After the procedure, the child continues to need reassurance that he or she performed well and is accepted and loved. If the parents did not participate, the child is united with them as soon as possible so that they can provide comfort.

Encourage Expression of Feelings

Planned activity after the procedure is helpful in encouraging constructive expression of feelings. For verbal children, reviewing the details of the procedure can clarify misconceptions and garner feedback for improving the nurse's preparatory strategies. Play is an excellent activity for all children. Infants and young children should have the opportunity for gross motor movement. Older children are able to vent their anger and frustration in acceptable pounding or throwing activities. Play-Doh is a remarkably versatile medium for pounding and shaping. Dramatic play provides an outlet for anger and places the child in a position of control, in contrast to the position of helplessness in the real situation. Puppets also allow the child to communicate feelings in a nonthreatening way. One of the most effective interventions is **therapeutic play**, which includes well-supervised activities such as permitting the child to give an injection to a doll or stuffed toy to reduce the stress of injections (Fig. 20.1).

Positive Reinforcement

Children need to hear from adults that they did the best they could in the situation—no matter how they behaved. There should be specific acknowledgment of what aspect of the procedure the child performed well. It is important for children to know that their worth is not being judged based on their behavior in a stressful situation. Reward systems, such as earning stars, stickers, or a supportive care program such as Beads of Courage that celebrates a child's milestones in medical treatment, are appealing to children.[b]

Returning to the child a short while after the procedure helps the nurse strengthen a supportive relationship. Relating with the child in a relaxed and nonstressful period allows him or her to see the nurse not

[b]Beads of Courage information is available at http://www.beadsofcourage.org/.

BOX 20.1 Play Activities for Specific Procedures

Fluid Intake

Make ice pops using child's favorite juice.
Cut gelatin into fun shapes.
Make a game out of taking a sip when turning page of a book or in games such as Simon Says.
Use small medicine cups; decorate the cups.
Color water with food coloring or powdered drink mix.
Have a tea party; pour at a small table.
Cut straws in half and place in a small container (much easier for child to suck liquid).
Use a "crazy" straw.
Make a "progress poster"; give rewards for drinking a predetermined quantity.

Deep Breathing

Blow bubbles with a bubble blower.
Blow bubbles with a straw (no soap).
Blow on a pinwheel, feather, whistle, harmonica, balloon, or party blower.
Practice band instruments.
Have a blowing contest using balloons,[a] boats, cotton balls, feathers, marbles, ping-pong balls, pieces of paper; blow such objects on a tabletop over a goal line, over water, through an obstacle course, up in the air, against an opponent, or up and down a string.
Suck paper or cloth from one container to another using a straw.
Dramatize stories such as "I'll huff and I'll puff, and I'll blow your house down" from the "Three Little Pigs."
Do straw-blowing painting.
Take a deep breath and "blow out the candles" on a birthday cake.
Use a little paintbrush to "paint" nails with water and blow nails dry.

Range of Motion and Use of Extremities

Throw beanbags at a fixed or movable target or throw wadded-up paper into a wastebasket.
Touch or kick Mylar balloons held or hung in different positions (if child is in traction, hang balloon from a trapeze).
Play "tickle toes"; have the child wiggle the toes on request.
Play Twister game or Simon Says.
Play pretend and guessing games (e.g., imitate a bird, butterfly, or horse).
Have tricycle or wheelchair races in safe area.
Play kickball or throw ball with a soft foam ball in a safe area.
Position bed so that child must turn to view television or doorway.
Climb wall with fingers like a "spider."
Pretend to teach aerobic dancing or exercises; encourage parents to participate.
Encourage swimming if feasible.
Play video games or pinball (fine motor movement).
Play hide and seek: hide toy somewhere in bed (or room if ambulatory) and have child find it using specified hand or foot.
Provide clay to mold with fingers.
Paint or draw on large sheets of paper placed on floor or wall.
Encourage combing own hair; play "beauty shop" with "customer" in different positions.

Soaks

Play with small toys or objects (e.g., cups, soap dishes) in water.
Wash dolls or toys.
Pick up marbles or pennies[a] from bottom of bath container.
Make designs with coins on bottom of container.
Pretend a boat is a submarine by keeping it immersed.
Read to child during soaks; sing with child; or play game, such as cards, checkers, or other board game (if both hands are immersed, move board pieces for child).
Sitz bath: give child something to listen to (e.g., music, stories) or look at (e.g., View-Master, book).
Punch holes in bottom of plastic cup, fill with water, and let it "rain" on child.

Injections

Let child handle syringe, vial, and alcohol swab and give an injection to doll or stuffed animal.
Draw a "magic circle" on area before injection; draw smiling face in circle after injection but avoid drawing on puncture site.
If multiple injections or venipunctures are planned, make a "progress poster"; give rewards for predetermined number of injections.
Have child count to 10 or 15 during injection.

Ambulation

Give child something to push:
- Toddler: push-pull toy
- School-age child: wagon or a doll in a stroller or wheelchair
- Adolescent: decorated intravenous stand

Have a parade; make hats, drums, and so on.

Extending Environment (e.g., for Patients in Traction)

Make bed into a pirate ship or airplane with decorations.
Put up mirrors so patient can see around room.
Move bed frequently to playroom, hallway, or outside.

[a]Small objects such as marbles and coins, as well as gloves and balloons, are unsafe for young children because of possible aspiration. Latex products also carry the risk of an allergic reaction.

only as someone associated with stressful situations but also as someone with whom to share pleasurable experiences.

Use of Play in Procedures

The use of play is an integral part of relationships with children. As such, its value in specific situations is discussed throughout this book, such as in Chapter 19 in relation to hospitalization. Many institutions have elaborate and well-organized play areas and programs under the direction of child life specialists. Other institutions have limited facilities. No matter what the institution provides for children, nurses can include play activities as part of nursing care. Play can be used to teach, express feelings, or achieve a therapeutic goal. Consequently, it should be included in preparing children for and encouraging their cooperation during procedures. Play sessions after procedures can be structured, such as directed toward needle play, or general, with a wide variety of equipment available for children to play with.

Routine procedures such as measuring blood pressure and oral administration of medication may be of concern to children. Box 20.1 describes suggestions for incorporating play into nursing procedures and activities for the hospitalized child that facilitate learning and adjustment to a new situation.

Preparing the Family

The process of patient education involves giving the family information about the child's condition, the regimen that must be followed and why, and other health teaching as indicated. The goal of this education is to enable the family to modify behaviors and adhere to the regimen that has been mutually established (see Applying Evidence to Practice box).

APPLYING EVIDENCE TO PRACTICE

General Principles of Family Education

- Establish a rapport with the family.
- Avoid using confusing specialized terms or jargon. Clarify all terms with the family and use the term that is clear to the child.
- When possible, allow family members to decide how they want to be taught (e.g., all at once or over a day or two). This gives the family a chance to incorporate the information at a rate that is comfortable.
- Provide accurate information to the family about the illness.
- Assist family members in identifying obstacles to their ability to comply with the regimen and in identifying the means to overcome those obstacles. Then help family members find ways to incorporate the plan into their daily lives.
- Incorporate teach-back strategies that allow the family to provide return demonstration and discussion of the material taught.

If equipment will be needed at home (e.g., suction machines, syringes), begin making the necessary arrangements in advance so that discharge can proceed smoothly. Whenever possible, make arrangements for the family to use the same equipment in the home that they are using in the hospital. This allows them to become familiar with the items. In addition, the staff can help troubleshoot the equipment in a controlled environment. Plan the teaching sessions well in advance of the time the family will be responsible for performing the care. The more complex the procedure, the more time is needed for training.

Review the instructions with family members (see Applying Evidence to Practice box). Encourage note taking if they desire. Allow ample practice time under supervision. At least one family member, but preferably two members, should demonstrate the procedure before they are expected to care for the child at home. Provide the family with the telephone numbers of resource individuals who are available to assist them in the event of a problem.

APPLYING EVIDENCE TO PRACTICE

Family Preparation for Procedures

Family education for specific procedures is included throughout this unit. General concepts applicable to most family education sessions include the following:

- Name of the procedure
- Purpose of the procedure
- Length of time anticipated to complete the procedure
- Anticipated effects
- Signs of adverse effects
- Assess the family's level of understanding
- Demonstrate and have family return demonstration (if appropriate)

SURGICAL PROCEDURES

Preoperative Care

Children experiencing surgical procedures require both psychologic and physical preparation. An important concern is restriction of food and fluids before surgery to avoid pulmonary aspiration during anesthesia. In addition, fasting for too long can cause discomfort, headache, dehydration, or hypoglycemia and can delay recovery and hospital discharge (Dolgun, Yavuz, Eroğlu, et al., 2017). Infants require special attention to fluid needs. They should not be without oral fluids for an extended period preoperatively to avoid glycogen depletion and dehydration. If surgical procedures are delayed, it is the nurse's responsibility to communicate with the surgical team to adjust fasting guidelines appropriately (Williams, Johnson, Guzzetta, et al., 2014). Table 20.2 contains current preoperative fasting guidelines.

TABLE 20.2 Fasting Recommendations to Reduce the Risk of Pulmonary Aspiration[a]

Ingested Material	Minimum Fasting Period (hr)[b]
Clear liquids[c]	>2
Breast milk	4
Infant formula	6
Nonhuman milk[d]	6
Light meal[e]	6

[a]These recommendations apply to healthy patients who are undergoing elective procedures. They are not intended for women in labor. Following the guidelines does not guarantee that complete gastric emptying has occurred.
[b]Fasting periods noted in chart apply to all ages.
[c]Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.
[d]Because nonhuman milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining appropriate fasting period.
[e]A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period.
From American Society of Anesthesiologists, Committee on Standards and Practice Parameters. (2011). Practice guidelines for preoperative fasting and the use of pharmacological agents to reduce the risk of pulmonary aspiration: Application to healthy patients undergoing elective procedures. *Anesthesiology, 114*(3), 495–511.

In general, psychologic preparation is similar to that discussed earlier for any procedure and uses many of the same techniques used in preparing a child for hospitalization, such as films, books, brochures, play, and tours (see Chapter 19). Stress points before and after surgery include the admission process, blood tests, administration of preoperative medication (if prescribed), transport to the operating room, the mask on the face during induction, and the stay in the postanesthesia care unit. Wearing a hospital gown without the security of underpants or pajama bottoms can also be traumatic. Therefore these articles of clothing should be allowed to be worn into the operating room and removed after induction of anesthesia. Children are at higher risk of ineffective response to anesthesia and complications in the recovery period because of higher anxiety in the preoperative period associated with stranger anxiety (infants), separation anxiety (toddlers and preschoolers), and fear of injury or death (adolescents) (Al-Yateem, Brenner, Shorrab, et al., 2016).

Individualized psychologic intervention consisting of systematic preparation, rehearsal of the forthcoming events, and supportive care at each of these points has shown to be more effective than a single-session preparation or consistent supportive care without systematic preparation and rehearsal (Fortier, Kain, & Morton, 2015). A family-centered preoperative preparation program may consist of a tour of the perioperative areas with short explanations of the events 5 to 7 days before surgery, a video to take home and review a couple of times with additional explanations and demonstrations of perioperative processes, a mask to take home and practice with, pamphlets to guide parents on supporting children during induction, phone calls to coach parents on preparing children 1 or 2 days before surgery, toys and supplies in the holding area, and mobile phone applications with interactive tours and videos. In addition, the use of interactive electronic games, tablets, or

therapy dogs in the preoperative setting can provide effective alternatives or complements to pharmacologic premedication. Therapeutic play is an effective strategy in preparing children, and increased familiarity with medical procedures can decrease anxiety.

Parental Presence

Some institutions support parental presence during induction of anesthesia. Benefits of well-prepared children and parents along with parental presence during induction of anesthesia include reduced anxiety for children and parents, lower doses of postoperative analgesia, lower incidence of severe emergence delirium symptoms, decreased postoperative maladaptive behaviors, and shorter discharge time for short procedures (Fortier et al., 2015). Other studies have not supported a reduction in children's anxiety (Erhaze, Dowling, & Devane, 2016; Manyande, Cyna, Yip, et al., 2015).

Concern exists regarding the appropriateness of parental presence during induction for all parents. Some parents may become upset by the rapid succession of induction events, by observing their child becoming limp, and by leaving the child in the care of strangers. Although parents who are anxious before surgery tend to become even more anxious after the induction, the reverse is true of parents with little anxiety. There is little evidence to suggest that parental presence during induction provides decreased anxiety for parents and caregivers (Al-Yateem et al., 2016). Appropriate education is essential to help parents understand the stages of anesthesia, what to expect, and how to support their child.

Preoperative Sedation

The goals for using preoperative medications include anxiety reduction, amnesia, sedation, antiemetic effect, and reduction of secretions (Manworren & Fledderman, 2000). (Chapter 5 includes a discussion of pain management strategies for children undergoing surgery.) When drugs are administered, they should be delivered atraumatically via oral, intranasal, or IV routes. Numerous preanesthetic drug regimens are used with children, and no consensus exists on the optimal method. Some institutions promote distraction or parental support instead of medications due to the incidence of postoperative medication delirium (Batawi, 2015).

Intraoperative Care

The role of the pediatric operating room nurse is to advocate for care of the patient in surgery through the verification of procedure and laterality, implants, skin preparation, necessary instrumentation, and supplies. The operating room nurse assesses, recognizes, and intervenes for the pediatric surgical patient at high risk for pressure injury due to patient diagnosis, patient anatomy, general anesthesia, intraoperative positioning, immobility, moisture, and nothing-by-mouth (NPO) status. Clear communication is used through collaboration with the interdisciplinary team (anesthesia, surgeon, scrub technician, nurses, radiology, etc.) to coordinate the intraoperative and postoperative disposition of the surgical patient. Family-centered care is provided through engaging the family in the preoperative procedure verification and updating them throughout the procedure (Herd & Rieben, 2014).

Postoperative Care

Various psychologic and physical interventions and observations help prevent or minimize possible unpleasant effects from anesthesia and the surgical procedure. Although serious postoperative complications in healthy children undergoing surgery are rare, continuous monitoring of the child's cardiopulmonary status is essential during the immediate postoperative period to reduce this risk (Pawar, 2012). Postanesthesia complications such as airway obstruction, postextubation croup, laryngospasm, and bronchospasm make maintaining a patent airway and maximum ventilation critical.

Monitoring the patient's oxygen saturation and providing supplemental oxygen as needed, maintaining body temperature, and promoting fluid and electrolyte balance are important aspects of immediate postoperative care. Vital signs are continuously monitored, and each vital sign is evaluated in terms of side effects from anesthesia, shock, or respiratory compromise (Table 20.3).

A change in vital signs that demands immediate attention in the perioperative period is caused by **malignant hyperthermia (MH)**, a potentially fatal pharmacogenetic disorder of muscle metabolism. In susceptible children, inhaled anesthetics and the muscle relaxant succinylcholine trigger the disorder, producing hypermetabolism. Symptoms of MH include hypercarbia (increasing end-tidal carbon dioxide), elevated temperature, tachycardia, tachypnea, acidosis, muscle rigidity, hyperkalemia, and rhabdomyolysis. A family or previous history of sudden high fever associated with a surgical procedure and myotonia increase the risk for MH. Children who have successfully undergone prior surgery without adverse effects may still be considered susceptible (Salazar, Yang, Shen, et al., 2014).

Treatment of MH includes immediate discontinuation of the triggering agent, hyperventilation with 100% oxygen, and IV dantrolene sodium. If the child is hyperthermic, initiate cooling measures such as ice packs to the groin, axillae, and neck and iced nasogastric (NG) lavage. The surgery may be discontinued, or if it is emergent, it may be continued with a different anesthetic agent. The patient should be transferred to an intensive care unit for at least 36 hours and closely monitored for stabilization of vital signs, metabolic state, and possible recurrence of symptoms.

Managing pain is a major nursing responsibility after surgery. The nurse should assess pain frequently and administer analgesics to provide comfort and facilitate cooperation with postoperative care such as ambulation and deep breathing. Opioids are the most commonly used analgesics. Routinely scheduled IV analgesics, patient-controlled analgesia, regional blocks, and epidural infusions, rather than as-needed orders, provide excellent analgesia in postoperative pediatric patients.

Nonpharmacologic postoperative recovery interventions include the use of distraction, videos, interactive game applications, and therapy dogs. Therapy dogs can facilitate decreased pain perception, increase in activity, and emotional stabilization in the postoperative period (Calcaterra, Veggiotti, Palestrini, et al., 2015).

NURSING TIP Because deep breathing is usually painful after surgery, be certain that the child has received analgesics. Have the child splint the operative site (depending on its location) by hugging a small pillow or a favorite stuffed animal.

Because respiratory tract infections are a potential complication of anesthesia, make every effort to aerate the lungs and remove secretions. The lungs are auscultated regularly to identify abnormal sounds or any areas of diminished or absent breath sounds. To prevent pneumonia, encourage respiratory movement with incentive spirometers or other motivating activities (see Box 20.1). If these measures are presented as games, the child is more likely to comply. The child's position is changed every 2 hours, and deep breathing is encouraged. Patients with preexisting pulmonary disease may be advised to begin incentive spirometry before the day of surgery (Azhar, 2015). Early respiratory movement can decrease the patient's need for supplemental oxygen and promote discharge home sooner (Shaughnessy, White, Shah, et al., 2015).

During the recovery period, spend some time with the child to assess his or her perceptions of surgery. Play, drawing, and storytelling are excellent methods of discovering the child's thoughts. With such information, the nurse can support or correct the child's perceptions and boost his or her self-esteem for having endured a stressful procedure.

Many pediatric patients are discharged shortly after surgery. Preparation for discharge begins with the preadmission preparation visit. Thorough

TABLE 20.3 Potential Causes of Postoperative Vital Sign Alterations in Children

Alteration	Potential Cause	Comments
Heart Rate		
Increase	Decreased perfusion (shock) Elevated temperature Pain Respiratory distress (early) Medications (atropine, morphine, epinephrine) Hypoxia	Heart rate may increase to maintain cardiac output.
Decrease	Vagal stimulation Increased intracranial pressure Respiratory distress (late) Medications (neostigmine [Prostigmin])	Bradycardia is of more concern in young child than tachycardia.
Respiratory Rate		
Increase	Respiratory distress Fluid volume excess Hypothermia Elevated temperature Pain	Body responds to respiratory distress primarily by increasing rate.
Decrease	Anesthetics, opioids Pain	Decreased respiratory rate from opioids may be compensated for by increased depth of respiration.
Blood Pressure		
Increase	Excess intravascular volume Increased intracranial pressure Carbon dioxide retention Pain Medication (ketamine, epinephrine)	This is serious in premature infants because it increases risk of intraventricular hemorrhage.
Decrease	Vasodilating anesthetic agents (halothane, isoflurane, enflurane) Opioids (e.g., morphine)	Decreased blood pressure is late sign of shock because of elasticity and constriction of vessels to maintain cardiac output.
Temperature		
Increase	Shock (late sign) Infection Environmental causes (warm room, excess coverings) Malignant hyperthermia	Fever associated with infection usually occurs later than fever of noninfectious origin. Absence of fever does not rule out infection, especially in infants. Malignant hyperthermia requires immediate treatment.
Decrease	Vasodilating anesthetic agents (halothane, isoflurane, enflurane) Muscle relaxants Environmental causes (cool room) Infusion of cool fluids or blood	Neonates are especially susceptible to hypothermia, with serious or fatal consequences.

discharge processes and education can greatly assist in the prevention of unplanned readmissions (Payne & Flood, 2015). The nurse should discuss instructions for postoperative care and review them throughout the perioperative visit with the strategy that works best for the patient and family. After discharge, the nursing staff often makes phone calls to check the patient's status. Patient education and compliance with discharge instructions can also be assessed during these phone calls (Flippo, NeSmith, Stark, et al., 2015) (see Applying Evidence to Practice box).

APPLYING EVIDENCE TO PRACTICE

Postoperative Care

- Ensure that preparations are made to receive child:
  - Bed or crib is ready.
  - Intravenous pumps and poles, suction apparatus, and oxygen flow meter are at bedside.
- Obtain baseline information:
  - Take vital signs, including blood pressure and pulse oximetry; keep blood pressure cuff in place and deflated to lessen disturbance to child.
  - Take and record vital signs more frequently if any value fluctuates.
- Inspect operative area.
- Check dressing if present.
- Outline any bleeding area on dressing or cast with pen.
- Reinforce, but do not remove, loose dressing.
- Observe areas below or underneath surgical site for blood that may have drained toward bed.
- Assess for compartment syndrome with any restrictive dressings.
- Assess for bleeding and other symptoms in areas not covered with a dressing, such as throat after tonsillectomy.
- Assess skin color and characteristics.
- Assess level of sedation and activity.
- Notify physician of any irregularities in child's condition.
- Assess for evidence of pain. (See Chapter 5, Pain Assessment.)
- Review surgeon's orders after completing initial assessment and check that any preoperative orders, such as seizure or cardiac medications, have been reordered and can be given by available routes (oral preparations may be contraindicated).
- Monitor vital signs as ordered and more often if indicated.
- Check dressings for bleeding or other abnormalities.
- Check bowel sounds.
- Observe for signs of shock, abdominal distention, and bleeding.
- Assess for bladder distention.
- Observe for signs of dehydration.
- Detect presence of infection:
  - Take vital signs every 2 to 4 hours as ordered.
  - Collect or request needed specimens.
  - Inspect wound for signs of infection—redness, swelling, heat, pain, and purulent drainage.

Compliance

Compliance, also called **adherence**, refers to the extent to which the patient's behavior coincides with the prescribed regimen in terms of taking medication, following diets, or executing other lifestyle changes. In developing strategies to improve compliance, the nurse must first assess level of compliance. Because many children are too young to assume partial or total responsibility for their care, parents are usually primarily responsible for home management.

Factors relating to the care setting are important in ensuring compliance and should be considered in planning strategies to improve compliance. Basically, any aspect of the health care setting that increases the

family's satisfaction with the physical setting and the relationship with the provider positively influences adherence to the treatment regimen. However, the more complex, expensive, inconvenient, and disruptive the treatment protocol, the less likely the family is to comply. During long-term conditions that involve multiple treatments and considerable rearrangement of lifestyle, compliance is severely affected.

Although it is helpful to know those factors that influence compliance, assessment must include more direct measurement techniques. When inquiring about a patient's compliance, it can be helpful to ask details about how medication administration or other interventions are carried out instead of asking yes-or-no questions. For example, a health care provider could ask about what time of day patients perform their prescribed interventions, what beverages they prefer to take their medications with, or how many doses were missed this week. A number of methods exist, each with advantages and disadvantages. The most successful approach includes a combination of at least two of the following methods:

Clinical judgment—This is subject to bias and inaccuracy unless the nurse carefully evaluates the criteria used in assessment.

Self-reporting—Most people overestimate their compliance even when they admit to lapses.

Direct observation—This is difficult to use outside the health care setting, and awareness of being observed frequently affects performance.

Monitoring appointments—Keeping appointments indirectly indicates compliance with the prescribed care.

Monitoring therapeutic response—Few treatments yield directly measurable results (e.g., decreased blood pressure, weight loss); record on a graph or chart.

Pill counts—The nurse counts the number of pills remaining in the original container and compares the number missing with the number of times the medication should have been taken. Although this is a simple method, families may forget to bring the container or deliberately alter the number of pills to avoid detection. This method is also poorly suited to liquid medication. Another technique is the use of pill container caps that record every opening as a presumptive dose.

Chemical assay—For certain drugs, such as digoxin, measurement of plasma drug levels provides information on the amount of drug recently ingested. However, this method is expensive, indicates only short-term compliance, and requires precise timing of the assay for accurate results.

Compliance Strategies

Strategies to improve compliance involve interventions that encourage families to follow the prescribed treatment regimen. Some evidence suggests that higher levels of self-esteem and increased autonomy favorably affect adolescent compliance (Letitre, DeGroot, Draaisma, et al., 2014). In addition, anxiety, depression, and self-esteem can be negatively affected when treatment regimens are inadequately followed. However, family factors are important, and characteristics associated with good compliance include family support, family reminders, good communication, and expectations for successful completion of the therapeutic regimen. No one approach is always successful, and the best results occur when at least two strategies are used.

Organizational strategies involve the care setting and the therapeutic plan. This may involve increasing the frequency of appointments, designating a primary provider, reducing the cost of medication by prescribing generic brands, reducing the treatment's disruption of the family's lifestyle, and using "cues" to minimize forgetting. Numerous devices are available commercially or can be improvised for cueing, such as pill dispensers; watches with alarms; charts to record completed therapy; messages on the refrigerator or morning coffee pot; mobile phone applications; and individualistic, self-timed schedules that incorporate the treatment plan into the daily routine, such as physical therapy after the evening bath (Britto, Munafo, Schoettker, et al., 2012; Carbone, Zebrack, Plegue, et al., 2013).

The nurse instructs the family about the treatment plan. Although education is an important factor in enhancing compliance, and patients who are more knowledgeable about their condition are more likely to comply, education alone does not ensure compliant behavior. The nurse should incorporate teaching principles known to enhance understanding and retention of material. Written materials are essential, especially in any regimen requiring multiple or complex treatments, and they need to be understandable to the average individual, who reads at about the fourth-grade level. Learning disabilities can negatively affect medication adherence and should be routinely assessed along with health literacy (Dharmapuri, Best, Kind, et al., 2015). Individualized teaching strategies appropriate for developmental and cognitive levels of the individual, as well as involvement of the immediate and extended family (e.g., grandparents) in education sessions, may enhance compliance.

Treatment strategies relate to the child's refusal or inability to take the prescribed medication. The family may also have difficulty following a prescribed treatment regimen. They may remember and understand the instructions but may not be able to give the medicine as prescribed. Assess the reason for refusal. For example, the child may not be able to swallow pills. In this case, perhaps pills could be crushed or a liquid medication substituted (always review medication to ensure that crushing is acceptable before giving this instruction).

Assess the treatment and medication schedule to determine whether it is reasonable for a home situation. Although an every-6-hour or every-8-hour schedule is reasonable for hospitals, a parent would have difficulty getting up once or twice nightly. Instead, the patient could take a medication during the day at times that would be easy to remember.

Behavioral strategies are designed to modify behavior directly. Nurses can use several effective strategies with children to encourage the desired behavior. Positive reinforcement is one strategy that strengthens the behavior. One example of this is the child earning stars or tokens, which can be exchanged for a special privilege or gift. Sticker charts also serve as a visual reminder of positive behavior and motivation to continue compliance. At times, however, disciplinary techniques, such as a time-out for young children or withholding privileges for older children, may be needed to improve compliance. The child life specialist can be especially helpful in determining behavioral compliance strategies across the developmental spectrum.

SKIN CARE AND GENERAL HYGIENE

MAINTAINING HEALTHY SKIN

Maintaining an IV line, removing a dressing, positioning a child in bed, changing a diaper, using electrodes, and using restraints all have the potential to contribute to skin injury. General guidelines for skin care are listed in the Applying Evidence to Practice box. (Specific guidelines for skin care of neonates are provided in Chapter 8, Skin Care.)

Assessment of the skin is easiest to accomplish during the bath. Examine for early signs of injury, including redness, flaking, decreased perfusion, or skin breakdown. Risk factors include impaired mobility, protein malnutrition, edema, incontinence, sensory loss, anemia, infection, failure to turn the patient, and intubation. Identification of risk factors helps determine children who need a more thorough skin assessment. Several risk assessment scales, such as the Braden Q Scale, the Neonatal Skin Risk Assessment Scale, the Waterlow Scale, and the Glamorgan Scale, are available for use in pediatrics (Razmus & Bergquist-Beringer, 2017). Initial assessment should occur on admission to identify pressure ulcers and wounds that occurred before

APPLYING EVIDENCE TO PRACTICE

Skin Care

- Keep skin free of excess moisture (e.g., urine or fecal incontinence, wound drainage, excessive perspiration). All diapered patients should have a barrier cream applied.
- Cleanse skin with mild nonalkaline soap or soap-free cleaning agents for routine bathing.
- Provide daily cleansing of eyes, oral and diaper or perineal areas, and any areas of skin breakdown.
- Apply non–alcohol-based moisturizing agents after cleansing to retain moisture and rehydrate skin.
- Use minimum amount of tape and adhesives. On very sensitive skin, use a protective, pectin-based or hydrocolloid skin barrier between skin and tape or adhesives.
- Place pectin-based or hydrocolloid skin barriers directly over excoriated skin. Leave barrier undisturbed until it begins to peel off or for 5 to 7 days. With wet, oozing excoriations, place a small amount of stoma powder on site, remove excess powder, and apply skin barrier. Hold barrier in place for several minutes to allow barrier to soften and mold to skin surface.
- Alternate electrode and probe placement sites and thoroughly assess underlying skin typically every 8 to 24 hours.
- Eliminate pressure secondary to medical devices such as tracheostomy tubes, wheelchairs, braces, and gastrostomy tubes.
- Be certain fingers or toes are visible whenever extremity is used for intravenous (IV) or arterial line.
- Use a draw sheet to move child in bed or onto a stretcher; do not drag child from under the arms.
- Position in neutral alignment; pillows, cushions, or wedges may be needed to prevent hip abduction and pressure to bony prominences, such as heels, elbows, and sacral and occipital areas. When child is positioned laterally, pillows or cushions between the knees, under the head, and under the upper arm will help promote neutral body alignment. Avoid donut cushions because they can cause tissue ischemia. Elevate the head of bed 30 degrees or less to reduce pressure unless contraindicated.
- Do not massage reddened bony prominences because this can cause deep tissue damage; provide pressure relief to bony prominences with gel pads or pillows.
- Routinely assess the child's nutritional status. A child who is NPO (nothing by mouth) for several days and is receiving only IV fluid is nutritionally at risk, which can also affect the skin's ability to maintain its integrity. Consider parenteral nutrition.

admission. Skin assessment should be repeated every shift and at least every 4 hours in perfusion-compromised patients.

Pressure ulcers, a form of pressure injuries, are localized damage to the skin and/or underlying soft tissue due to decreased perfusion as a result of increased pressure. Pressure ulcers most often occur over bony prominences or related to medical or other devices. Pressure injuries are staged to classify the amount of tissue damage that has occurred.[c] Necrotic tissue must be removed so that the tissue depth can accurately be assessed. Accurate documentation of redness or obvious skin breakdown is essential. Color, size (diameter and depth), location, presence of sinus tracts, odor, exudate, and response to treatment are observed and recorded at least daily.

[c]Staging of pressure ulcers and guidelines for prevention and management of pressure ulcers are available online from the National Pressure Ulcer Advisory Panel.

Pressure ulcers in children typically occur on the occiput, earlobes, sacrum, heels, and scapula (Schober-Flores, 2012); the heels and sacrum are common sites in adults. Critically ill children; children with sensory deficits, mobility deficits, or cardiopulmonary abnormalities; and bariatric patients are at a higher risk of pressure ulcers and skin breakdown because they often have several risk factors combined. Although pressure ulcers in hospitalized children are generally uncommon, the incidence in critically ill children can be significantly higher. Interventions found to prevent pressure ulcers in critically ill children include the following:

- Assessing the patient's skin from head to toe on admission and each shift
- Turning children every 2 hours
- Using pillows, blanket rolls, and positioning devices
- Using draw sheets to minimize shear
- Using pressure reduction surfaces (e.g., foam overlays, gel pads, specialty beds)
- Allowing moisture reduction by using dry-weave diapers and disposable underpads
- Using skin moisturizers
- Conducting nutrition consults

Medical devices such as pulse oximeter probes, bilevel and continuous positive airway pressure masks, oxygen cannulas, tracheostomy tubes, orthotics, and casts can also cause pressure ulcers (Freundlich, 2017). In addition, both medical devices and special garments such as shoes, slippers, jewelry, hair ties, and restraints should be removed to inspect skin at least every shift.

Friction and shear contribute to pressure ulcers. **Friction** occurs when the surface of the skin rubs against another surface, such as bed sheets. The skin may have the appearance of an abrasion. The skin damage is usually limited to the epidermal and upper layers. It most often occurs over the elbows, heels, or occiput. Prevention of friction injury includes the use of foam matresses that redistribute pressure; customized splinting or foam-padded boots over the heels; gel pillows; moisturizing agents; protective, transparent barrier dressings over susceptible areas; and soft, smooth bed linens and clothing (Freundlich, 2017). By itself, friction does not cause tissue necrosis, but when it acts with gravity, it results in shear injury.

Shear is the result of the force of gravity pushing down on the body and friction of the body against a surface, such as the bed or chair. For example, when a patient is in the semi-Fowler position and begins to slide to the foot of the bed, the skin over the sacral area remains in the same place because of the resistance of the bed surface. The blood vessels, bone, and muscle in the area are stretched and slide parallel to the stationary skin, which may cause small-vessel thrombosis and tissue death. Prevention of shear injury includes using lift sheets when repositioning a patient, elevating the bed no more than 30 degrees for short periods, and elevating the knees to interrupt the pull of gravity on the body toward the foot of the bed.

Epidermal stripping results when the epidermis is unintentionally removed when tape is pulled off the skin. These lesions are usually shallow and irregularly shaped. Babies are at increased risk for epidermal injury. Prevention includes using no tape when possible or securing dressings with laced binders (Montgomery straps) or stretchy netting (Spandage or stockinette). Using porous or low-tack tapes (e.g., Medipore, paper, hydrogel), using alcohol-free skin sealants (No Sting Barrier Film), or picture-framing wounds with hydrocolloid or wafer barriers (e.g., DuoDERM, Coloplast, Stomahesive) and then taping on top of the barrier also will reduce epidermal stripping.

Tape should be placed so that there is no tension, traction, or wrinkles on the skin. To remove tape, slowly peel the tape away while stabilizing the underlying skin. Adhesive remover may be used to break the adhesive bond but may be drying to the skin. Avoid adhesive removers in preterm neonates because absorption rates vary and toxicity may

occur. Remove the adhesive with water to prevent absorption and irritation. Wetting the tape with water or alcohol-based foam hand cleansers may facilitate removal.

Chemical factors can also lead to skin damage. Fecal incontinence, especially when mixed with urine; wound drainage; or gastric drainage around gastrostomy tubes can erode the epidermis. The skin can quickly progress from redness to denudement if exposure continues. Moisture barriers, gentle cleansing with alcohol-free cleansers or wipes as soon after exposure as possible, and skin barriers can be used to prevent damage caused by chemical factors. For nonintact skin, a barrier cream with zinc oxide should be applied. It is important to cleanse only the stool and urine during diaper changes, not the paste. In addition, foam dressings that wick moisture away from the skin are helpful around gastrostomy tubes and tracheostomy sites.

BATHING

Most infants and children can be bathed at the bedside or in a standard bathtub or shower. Assess the child's and family's preferences for bath time frequency and family involvement. For infants and young children confined to bed, use commercially available bath cloths or the towel method. Immerse two towels in a dilute soap solution and wring them damp. With the child lying supine on a dry towel, place one damp towel on top of the child and use it to gently clean the body. Discard the towel, dry the child, and turn him or her prone. Repeat the procedure using the second damp towel. If bar soap is used, discard the basin and bar soap after a single bath because they can serve as a reservoir for pathogens in the hospital setting. Chlorhexidine is much less likely to harbor microbes, but it is generally not approved for use in infants younger than 2 months of corrected gestational age. Daily chlorhexidine gluconate bathing in the pediatric population can reduce bacteremia and prevent hospital-acquired infections (Karcz, Kelley, Conrad, et al., 2015; Raulji, Clay, Velasco, et al., 2015).

Infants and small children are never left unattended in a bathtub, and infants who are unable to sit alone are securely held with one hand during the bath. The nurse securely supports the infant's head with one hand or grasps the infant's farther arm while the head rests comfortably on the nurse's arm. Children who are able to sit without assistance need only close supervision and a pad placed in the bottom of the tub to prevent slipping and loss of balance.

School-age children and adolescents may shower or bathe. Nurses need to use judgment regarding the amount of supervision the child requires. Some children can assume this responsibility unaided, but others need someone in constant attendance. Children with cognitive impairments, physical limitations such as severe anemia or leg deformities, or suicidal or psychotic problems (who may commit bodily harm) require close supervision.

Areas that require special attention are the ears, between skinfolds, the neck, the back, and the genital area. The genital area should be carefully cleansed and dried, with particular care given to skinfolds. In uncircumcised boys younger than 3 years of age, the foreskin is not fully retractile. For older males, the foreskin should be gently retracted, the exposed surfaces cleansed, and the foreskin then replaced. If the condition of the glans indicates inadequate cleaning, such as accumulated smegma, inflammation, phimosis (condition in which the foreskin cannot be retracted), or foreskin adhesions, teaching proper hygiene is indicated. Do not forcibly retract the foreskin to avoid trauma and further complications (Hunter, 2012). Notify the provider of abnormal clinical findings during genitourinary assessment. In the Vietnamese and Cambodian cultures, the foreskin is traditionally not retracted until adulthood. Older children have a tendency to avoid cleaning the genitalia; therefore they may need a gentle reminder.

ORAL HYGIENE

Mouth care is an integral part of daily hygiene and should be continued in the hospital. Oral hygiene can prevent infection and promote comfort, adequate nutrition, and verbal communication. For some young children, this is their first introduction to the use of a toothbrush. Infants and debilitated children require the nurse or a family member to perform mouth care. For infants who do not yet have teeth, a soft moistened cloth or swab can be used to gently clean the gums. Children should begin brushing their teeth after the first teeth emerge around 6 months of age. For children younger than 3 years of age, a grain-sized amount of fluoride toothpaste should be used. For children 3 to 6 years of age, a pea-sized amount of fluoride toothpaste should be used (American Dental Association, 2017). Although young children can manage a toothbrush and are encouraged to use it, most need assistance to perform satisfactorily. Older children, although capable of brushing and flossing without assistance, sometimes need to be reminded.

HAIR CARE

Children should have their hair brushed and combed at least once daily for hair and scalp health. The hair is styled for comfort and in a manner pleasing to the child and parents. The hair should not be cut without parental permission, although clipping hair to provide access to a scalp vein for IV insertion may be necessary.

If children are hospitalized for more than a few days, the hair may need shampooing. With infants, the hair may be washed during the daily bath or less frequently. For most children, washing the hair and scalp once or twice weekly is sufficient unless there is an indication for more frequent washing, such as after a high fever and profuse sweating. Adolescents normally have increased oily sebaceous secretions that require frequent hair care and more frequent shampoos.

Almost any child can be transported to an accessible sink for shampooing. Inspect the hair and scalp before shampooing using a fine toothcomb to assess for the presence of lice or other scalp abnormalities. Nits are a gray-white color, the size of a knot of thread, and difficult to remove from the scalp in comparison to dandruff. Adult lice are a red-black color and the size of a sesame seed and can live on the scalp for 3 to 4 weeks if untreated (Cummings, Finlay, & McDonald, 2018). If lice are suspected, an order for a pediculicide treatment and nit combing must be obtained. It is important for the nurse to don personal protective equipment, including a gown and cap, during the lice removal process. In addition, other members of the household should be evaluated for the presence of lice and the family educated on the importance of individual hair care products.

Patients who are unable to be transported can receive a shampoo in their beds with adequate protection, specially adapted equipment or positioning, or dry shampoo caps. Comb or brush the hair before washing. When necessary, a shampoo basin may be used or the child may be positioned near the edge of the bed, towels placed under the shoulders and neck, a large plastic garbage bag draped at the edge of the bed with one open end under the shoulders, and the hair placed inside the opening. The other end is opened and placed in a collection container. Water can be transported in a basin.

For African American children with curly hair, most standard combs are inadequate and may cause hair breakage and discomfort. Use a special comb with widely spaced teeth. It is also much easier to comb the hair after shampooing when it is wet. Use a special hair dressing or pomade, which usually has a coconut oil base. Rub the preparation on the hands and then transfer it to the hair to make it more pliable and manageable. Consult the child's parents regarding the preparation to use on the child's hair and ask if they can provide some for use during the child's hospitalization. Petroleum jelly should

not be used. If braiding or plaiting the hair, weave it loosely while the hair is damp. The hair tightens as it dries, which could result in tension folliculitis. Tight braids should be avoided, as braiding can increase pressure on the scalp or hide pressure injuries.

FEEDING THE SICK CHILD

Loss of appetite is a symptom common to most childhood illnesses. Decreased appetite can be a result of pain or discomfort, nausea and vomiting, emotional concerns, or loss of control. Because an acute illness is usually short, the nutritional state is seldom compromised. Urging food on the sick child may precipitate nausea and vomiting. In most cases, children can usually determine their own need for food.

Refusing to eat may also be one way children can exert power and control in an otherwise helpless situation. For young children, loss of appetite may be related to depression caused by separation from their parents. Parents' concern with eating can intensify the problem. Forcing a child to eat meets with rebellion and reinforces the behavior as a control mechanism. Encourage parents to relax any pressure during an acute illness. Although it is best to provide high-quality, nutritious foods, the child may desire foods and liquids that contain mostly empty or nonnutritional calories. Some well-tolerated foods include gelatin, diluted clear soups, carbonated drinks, flavored ice pops, dry toast, and crackers. Even though these substances are not nutritious, they can provide necessary fluid and calories.

Dehydration is always a hazard when children have a fever or anorexia, especially when accompanied by vomiting or diarrhea. Fluids should not be forced, and the child should not be awakened to take fluids. Forcing fluids may create the same difficulties as urging the child to eat unwanted food. Gentle persuasion with preferred beverages will usually meet with success. Using play techniques can also be effective (see Applying Evidence to Practice box).

An understanding of children's feeding habits can also increase food consumption. For example, if children are given all their food at one time, they generally eat the dessert first. Likewise, if they are presented with large portions, they often push the food away because the amount overwhelms them. If young children are not supervised during mealtime, they tend to play with the food rather than eat it. Therefore nurses should present food in the usual order, such as soup first followed by small portions of meat, potatoes, and vegetables, and ending with dessert.

When the child is feeling better, appetite usually begins to improve. It is best to take advantage of any hungry period by serving high-quality foods and snacks. If the child still refuses to eat, offer nutritious fluids, such as prepared breakfast drinks. Parents can help by bringing in food items from home, especially if the family's cultural eating habits differ from the hospital food. A clinical dietitian may be consulted for alternative food choices.

When children are placed on special diets, such as clear liquids after surgery or during episodes of diarrhea, assessment of their intake and readiness to advance to more complex foods is essential.

Regardless of the type of diet, charting the amount consumed is an important nursing responsibility. Descriptions need to be detailed and accurate, such as "4 ounces of orange juice, one pancake, and 8 ounces of milk." Comments such as "ate well" or "ate poorly" are inadequate. Charting the percentage of the meal eaten is also inadequate unless food is measured before serving. For infants, assess the duration, amount, and frequency of breastfeeding or bottle-feeding and the possible addition of solid foods to determine whether nutrition is adequate.

If the parents are involved in the child's care, encourage them to keep a list of everything the child eats. Using a premeasured cup for fluids ensures a more accurate estimate of intake. A comparison of the intake at each meal can isolate food deficiencies, such as insufficient intake of meat or vegetables. Behaviors associated with mealtime also identify possible factors influencing appetite. For example, the observation "Child eats well when with other children but plays with food if left alone in room" helps the nurse plan mealtime activities that stimulate the child's appetite.

Although sick children's appetites may be poor and not characteristic of their home eating habits, the hospital stay provides numerous opportunities for nurses to assess the family's knowledge of good nutrition and to implement teaching as needed to improve nutritional intake.

APPLYING EVIDENCE TO PRACTICE

Feeding a Sick Child

Take a dietary history (see Chapter 4) and use information to make eating time as similar as possible to eating at home.

Encourage parents or other family members to feed child or to be present at mealtimes.

Make mealtimes pleasant; avoid any procedures immediately before or after eating; make certain child is rested and pain free.

Serve small, frequent meals rather than three large meals or serve three meals and nutritious between-meal snacks.

Provide finger foods for young children.

Involve children in food selection and preparation whenever possible.

Serve small portions and serve each course separately, such as soup first, followed by meat, potatoes, and vegetables and ending with dessert. With young children, camouflage size of food by cutting meat thicker so less appears on plate or by folding a cheese slice in half. Offer second helpings.

Ensure a variety of foods, textures, and colors.

Provide food selections that are favorites of most children, such as peanut butter and jelly sandwiches, hot dogs, hamburgers, macaroni and cheese, pizza, spaghetti, tacos, fried chicken, corn, and fruit yogurt.

Avoid foods that are highly seasoned, have strong odors, or are all mixed together unless typical of cultural practices.

Provide fluid selections that are favorites of most children, such as fruit punch, cola, ginger ale, sweetened tea, flavored ice pops, sherbet, ice cream, milk, milkshakes, pudding, gelatin, clear broth, or creamed soups.

Offer nutritious snacks, such as frozen yogurt or pudding, ice cream, oatmeal or peanut butter cookies, hot cocoa, cheese slices, pieces of raw vegetable or fruit, and dried fruit or cereal.

Make food attractive and different—for example:

- Serve a "picnic lunch" in a paper bag.
- Pack food in a Chinese takeout container; decorate container.
- Put a "face" or a "flower" on a hamburger or sandwich with pieces of vegetable.
- Use a cookie cutter to shape a sandwich.
- Serve pudding, yogurt, or juice frozen as an ice pop.
- Make Slurpies or snow cones by pouring flavored syrup on crushed ice.
- Serve fluids through brightly colored or unusually shaped straws.
- Make "bowtie" sandwiches by cutting them in triangles and placing two points together.
- Slice sandwiches into "fingers."
- Grate mounds of cheese.
- Cut apples horizontally to make circles.
- Put a banana on a hot dog bun and spread with peanut butter.
- Break uncooked spaghetti into toothpick lengths and skewer cheese, cold meat, vegetables, or fruit chunks.

Praise children for what they do eat.

Do not punish children for not eating by removing their dessert or putting them to bed.

CONTROLLING ELEVATED TEMPERATURES

An elevated temperature, most frequently from fever but occasionally caused by hyperthermia, is one of the most common symptoms of illness in children. This manifestation is a great concern to parents. To facilitate an understanding of fever versus hyperthermia, the following terms are defined:

Set point—The temperature around which body temperature is regulated by a thermostat-like mechanism in the hypothalamus

Fever (hyperpyrexia)—An elevation in set point such that body temperature is regulated at a higher level; may be arbitrarily defined as rectal temperature above 38°C (100.4°F)

Hyperthermia—Body temperature exceeding the set point, which usually results from the body or external conditions creating more heat than the body can eliminate, such as in heat exhaustion, heatstroke, aspirin toxicity, seizures, or hyperthyroidism

Body temperature is regulated by a thermostat-like mechanism in the hypothalamus. This mechanism receives input from centrally and peripherally located receptors. When temperature changes occur, these receptors relay the information to the thermostat, which either increases or decreases heat production to maintain a constant set point temperature. However, during an infection, pyrogenic substances cause an increase in the body's normal set point, a process that is mediated by prostaglandins. Consequently, the hypothalamus increases heat production until the core temperature reaches the new set point.

During the fever (febrile) state, shivering and vasoconstriction generate and conserve heat during the chill phase of fever, raising central temperatures to the level of the new set point. The temperature reaches a plateau when it stabilizes in the higher range. When the temperature is greater than the set point or when the pyrogen is no longer present, a crisis, or defervescence, of the temperature occurs.

Most fevers in children are of brief duration with limited consequences and are viral in origin (Patricia, 2014). Children may experience warm, flushed skin, chills, aches, malaise, or irritability during a fever. However, children who appear very ill, immunocompromised children, and neonates are at high risk for serious bacterial illness, such as urinary tract infections or bacteremia, and will likely receive a sepsis workup, antibiotics, and hospitalization.

Fever has physiologic benefits, including increased white blood cell activity, interferon production and effectiveness, and antibody production and enhancement of some antibiotic effects such as penicillin (Patricia, 2014). Contrary to popular belief, neither the rise in temperature nor its response to antipyretics indicates the severity or etiology of the infection, which casts doubt on the value of using fever as a diagnostic or prognostic indicator.

Therapeutic Management

Treatment of elevated temperature depends on whether it is attributable to a fever or hyperthermia. Because the set point is normal in hyperthermia but increased in fever, different approaches must be used to lower body temperature successfully.

Fever

The principal reason for treating fever is the relief of discomfort. However, children with cardiopulmonary disease or immunocompromised children may not tolerate the increase in metabolic demand from a fever and should receive antipyretic therapy. Relief measures include pharmacologic and environmental intervention. The most effective intervention is the use of antipyretics to lower the set point.

Antipyretics include acetaminophen, aspirin, and nonsteroidal antiinflammatory drugs (NSAIDs). Acetaminophen is the preferred drug. Aspirin should not be given to children because of its association in children with influenza virus or chickenpox and Reye syndrome. One nonprescription NSAID, ibuprofen, is approved for fever reduction in children as young as 6 months of age.

Another antipyretic, acetaminophen, can be given every 4 hours but no more than five times in 24 hours due to the risk of hepatotoxicity. Because body temperature normally decreases at night, three or four doses in 24 hours will control most fevers. The temperature is usually retaken 30 to 60 minutes after the antipyretic is given to assess its effect but should not be measured repeatedly. The child's level of discomfort is the best indication for continued treatment.

The nurse can use environmental measures to reduce fever if they are tolerated by the child and if they do not induce shivering. Shivering is the body's way of maintaining the elevated set point by producing heat. Compensatory shivering greatly increases metabolic requirements above those already caused by the fever.

Traditional cooling measures, such as wearing minimum clothing; exposing the skin to air; reducing room temperature; increasing air circulation; and applying cool, moist compresses to the skin (e.g., the forehead), are effective if used approximately 1 hour after an antipyretic is given so that the set point is lowered. Cooling procedures such as sponging or tepid baths are ineffective in treating febrile children (these measures are effective for hyperthermia) either when used alone or in combination with antipyretics, and they cause considerable discomfort (Monsma, Richerson, & Sloand, 2015).

Seizures associated with a fever occur in 2% to 5% of all children, usually in those between 6 months and 5 years of age. About 30% to 50% of children have subsequent febrile seizures; a younger age at onset and a family history of febrile seizures are associated with increased incidence of recurring episodes. Evidence does not support the use of antipyretic drugs or anticonvulsants to prevent a second febrile seizure. Nursing interventions should focus on ways to provide care and comfort during a febrile illness. Simple febrile seizures lasting less than 10 minutes do not cause brain damage or other debilitating effects (Patricia, 2014). (See Chapter 27, Febrile Seizures.)

Hyperthermia

Unlike in fever, antipyretics are of no value in hyperthermia because the set point is already normal. Consequently, cooling measures are used. If a child is severely hyperthermic with a core temperature above 40°C, it may be necessary to perform continuous monitoring of vital signs, including core temperature and urinary output, and administer IV fluids in a critical care environment (Chan & Mamat, 2015). Cool applications to the skin help reduce the core temperature. Cooled blood from the skin surface is conducted to inner organs and tissues, and warm blood is circulated to the surface, where it is cooled and recirculated. The surface blood vessels dilate as the body attempts to dissipate heat to the environment and facilitate this cooling process.

Commercial cooling devices, such as cooling blankets or mattresses, are available to reduce body temperature. Place the patient on the bed and cover with a sheet or lightweight blanket. Frequent temperature monitoring is essential to prevent excessive cooling of the body.

Traditionally, cool compresses decrease high temperature. For tepid tub baths, it is usually best to start with warm water and gradually add cool water until the desired water temperature of 37°C (98.6°F) is reached to acclimate the child to the lower water temperature. Generally, the temperature of the water has to be only 1°C (2°F) less than the child's temperature to be effective. The child is placed directly in the tub of tepid water for 15 to 20 minutes while water is gently squeezed from a washcloth over the back and chest or gently sprayed over the body from a sprayer. In the bed or crib, cool washcloths or towels are used, exposing only one area of the body at a time. Continue sponging for approximately 20 minutes.

After the tub or sponge bath, the child is dried; dressed in lightweight pajamas, a nightgown, or a diaper; and placed in a dry bed.

The child is dried by gently rubbing the skin surface with a towel to stimulate circulation. The temperature is retaken 30 minutes after the tub or sponge bath. The tub or sponge bath should not be continued or restarted until the skin surface is warm or if the child feels chilled. Chilling causes vasoconstriction, which defeats the purpose of the cool applications. In this condition, little blood is carried to the skin surface; the blood remains primarily in the viscera to become heated.

Whether a temperature elevation in the critically ill child is caused by fever or hyperthermia, it should be treated aggressively. The metabolic rate increases 10% for every 1°C increase in temperature and three to five times during shivering, thus increasing oxygen, fluid, and caloric requirements. If the child's cardiovascular or neurologic system is already compromised, these increased needs are especially hazardous. In all children with an elevated temperature, attention to adequate hydration is essential. Most children's needs can be met through additional oral fluids.

FAMILY TEACHING AND HOME CARE

Fever is one of the most common problems for which parents seek health care. High levels of parental anxiety (fever phobia) surrounding potential complications of fever such as seizures and dehydration are prevalent and can result in overusing antipyretics. Parents need to know that sponging is indicated for elevated temperatures from hyperthermia rather than fever and that ice water and alcohol are inappropriate, potentially dangerous solutions (Monsma et al., 2015). Parents should know how to take the child's temperature, how to read the thermometer accurately, and when to seek professional care (see Family-Centered Care box). A dedicated thermometer should be used for the rectal route. Oral temperatures should not be taken within 15 minutes of the child eating or drinking hot or cold food. Some of the newer temperature-measuring devices, such as plastic strip or digital thermometers, may be better suited for home use. (See Chapter 4, Temperature.) If the use of acetaminophen or ibuprofen is indicated, the parents need instructions in administering the drug. Emphasize accuracy in both the amount of drug given and the time intervals at which the drug is administered. Along with reduced activity, encourage small, frequent sips of clear liquids. Dress the child in light clothing; use a light blanket for children who are cold or shivering (Monsma et al., 2015).

FAMILY-CENTERED CARE

The Child With Fever

Call the doctor immediately if:

- Your child is younger than 3 months old and has a temperature of 38°C (100.4°F) or higher.
- The fever is over 40°C (104°F).
- Your child looks or acts very sick or sleepy, or has a stiff neck, severe headache, severe ear pain, severe sore throat, repeated vomiting or diarrhea, unexplained rash on the skin, confusion, trouble breathing, or inability to be comforted.
- Your child has had a recent seizure.
- Your child has a history of immune system problems such as cancer or sickle cell disease.
- Your child has been in a very hot place such as a car.
- Your child has taken steroid medication.
- The fever continues for more than 24 hours in a child younger than 2 years old or more than 3 days in a child older than 2 years of age.

Modified from American Academy of Pediatrics. (2015). When to call the pediatrician: Fever. Retrieved from https://www.healthychildren.org/English/health-issues/conditions/fever/Pages/When-to-Call-the-Pediatrician.aspx

SAFETY

Safety is an essential component of any patient's care, but children have special characteristics that require an even greater concern for safety. Because small children in the hospital are separated from their usual environment and do not possess the capacity for abstract thinking and reasoning, it is the responsibility of everyone who comes in contact with them to maintain protective measures throughout their hospital stay. Nurses need to understand the age level at which each child is operating and plan for safety accordingly.

Identification bands and the use of two patient identifiers are particularly important for children. Infants and unconscious patients are unable to tell or respond to their names. Toddlers may answer to any name or to a nickname only. Older children may exchange places, give an erroneous name, or choose not to respond to their own names as a joke, unaware of the hazards of such practices. In addition, allergy bands for medications and food should be worn by all patients as should bands for other precautions such as fall risks or antineoplastic precautions.

ENVIRONMENTAL FACTORS

All of the environmental safety measures for the protection of adults apply to children, including good illumination, floors that are clear of fluid and objects that might contribute to falls, and nonskid surfaces in showers and tubs. All staff members should be familiar with the area-specific fire plan. Elevators and stairways should be made safe.

All windows should be secured. Window blind and curtain cords should be out of reach, with split cords to prevent strangulation. Pacifiers should not be tied around the neck or attached to an infant by a string.

Electrical equipment should be in good working order and used only by personnel familiar with its use. It should not be in contact with moisture or situated near tubs. Electrical outlets should have covers to prevent burns in small children, whose exploratory activities may extend to inserting objects into the small openings.

Staff members should practice proper care and disposal of small objects such as syringe caps, needle covers, and temperature probes. Staff also must carefully check bathwater before placing the child in it and never leave children alone in a bathtub. Infants are helpless in water, and small children (and some older ones) may turn on the hot water faucet and be severely burned.

Furniture is safest when it is scaled to the child's proportions, is sturdy, and is well balanced to prevent its being easily tipped over. A special hazard for children is the danger of entrapment under an electronically controlled bed when it is activated to descend. Infants and small children must be securely strapped into infant seats, feeding chairs, and strollers. Baby walkers should not be used because they provide access to hazards, resulting in burns, falls, and poisonings. Infants; young children; and children who are weak, paralyzed, agitated, confused, sedated, or cognitively impaired should never be left unattended on treatment tables, on scales, or in treatment areas. Even premature infants are capable of surprising mobility; therefore portholes in incubators must be securely fastened when not in use. For patients at risk of suicide, it is necessary to remove all items such as sharp objects, cords, and plastic bags that can be used to impose self-harm. Depending on patient diagnosis, a one-to-one sitter should also be considered. In addition, visitors, personal items, and Internet access may be restricted to protect the patient.

Crib sides should always be raised and fastened securely. Use cribs that meet federal safety standards (https://www.cpsc.gov/safety-education/safety-education-centers/cribs). Anyone attending to an infant

Fig. 20.2 The nurse maintains hand contact when her back is turned.

or small child on a stretcher or table should never turn away without maintaining hand contact with the child—that is, keeping one hand on the child's back or abdomen to prevent rolling, crawling, or jumping from the open crib (Fig. 20.2). A child who is likely to climb over the sides of the crib is safest when placed in a specially constructed crib with a cover over the top. Never tie nets to the movable crib sides or use knots that do not permit quick release.

The safest sleeping position to prevent sudden infant death syndrome is wholly supine until at least 1 year of age (American Academy of Pediatrics, Task Force on Sudden Infant Death Syndrome, 2016). No pillows should be placed in a young infant's crib while the infant is sleeping. A firm sleep surface with no other bedding or any soft items in the crib in a shared room (not a shared bed) and the avoidance of overheating or exposure to tobacco smoke, alcohol, and illicit drugs further increase the safety of an infant's sleeping environment. The use of car seats, strollers, swings, or other sitting devices should not be used for routine sleep. In addition, swaddling is not recommended for infants over 2 months of age due to the risk of death if the infant rolls into the prone position. In accordance with the American Academy of Pediatrics guidelines to avoid extra bedding in the crib, many institutions recommend an infant sleep sack for adequate warmth and safety.

Toys

Toys play a vital role in the everyday lives of children, and they are no less important in the hospital setting. Nurses are responsible for assessing the safety of toys brought to the hospital by well-meaning parents and friends. Toys should be appropriate to the child's age, condition, and treatment. For example, if the child is receiving oxygen, electrical or friction toys or equipment are not safe because sparks can cause oxygen to ignite. Inspect toys to ensure that they are nonallergenic, washable, and unbreakable and that they have no small, removable parts that can be aspirated or swallowed or can otherwise inflict injury on a child. All objects within reach of children younger than 3 years of age should pass the choke tube test. A toilet paper roll is a handy guide. If a toy or object fits into the cylinder (items less than 1¼ inches across or balls less than 1¾ inches in diameter), it is a potential choking danger to the child. Latex balloons pose a serious threat to children of all ages. If the balloon breaks, a child may put a piece of the latex in his or her mouth. If it is aspirated or swallowed, the latex piece is difficult to remove, resulting in choking. Latex balloons should never be permitted in the hospital setting.

Preventing Falls

Although children have a known predisposition to falls based on normal growth and development, falls risk identification and prevention for children with medical conditions is especially important due to greater risk for injury from a fall (Murray, Edlund, & Vess, 2016). Falls prevention begins with identification of children most at risk for falls. Pediatric hospitals use various methods to identify a child's risk of falls. After a risk assessment is performed, multiple interventions are needed to minimize pediatric patients' risk of falling, including education of patient, family, and staff.

To identify children at risk of falling, perform a falls risk assessment on patients on admission and throughout hospitalization. Risk factors for hospitalized children include the following:

- **Medication effects**—Postanesthesia or sedation; analgesics or narcotics, especially in those who have never had narcotics in the past and in whom effects are unknown
- **Altered mental status**—Secondary to seizures, brain tumors, or medications
- **Altered or limited mobility**—Reduced skill at ambulation secondary to developmental age, disease process, tubes, drains, casts, splints, or other appliances; new to ambulation with assistive devices such as walkers or crutches
- **Postoperative children**—Risk of hypotension or syncope secondary to large blood loss, a heart condition, or extended bed rest
- History of falls
- Infants or toddlers in cribs with side rails down or on the daybed with family members
- Changes to the patient's environment

Once children at risk of falls have been identified, alert other staff members by posting signs on the door and at the bedside, applying a special-colored armband labeled "Fall Precautions," labeling the chart with a sticker, or documenting information on the chart.

Prevention of falls requires alterations in the environment, including the following:

- Keep the bed in the lowest position with the breaks locked and the side rails up.
- Place the call bell within reach and orient the patient and caregivers to the bed and room.
- Ensure that all necessary and desired items are within reach (e.g., water, glasses, tissues, snacks).
- Offer toileting on a regular basis, especially if the patient is taking diuretics or laxatives.
- Keep lights on at all times, including dim lights while sleeping.
- Lock wheelchairs before transferring patients.
- Ensure that the patient has an appropriate-size gown and nonskid footwear. Do not allow gowns or ties to drag on the floor during ambulation.
- Keep the floor clean and free of clutter. Post a "wet floor" sign if the floor is wet.
- Ensure that the patient has glasses on if he or she normally wears them.
- Use a gait belt during ambulation.
- Keep the patient's door open unless isolation status prohibits.

Preventing falls also relies on age-appropriate education of patients. Assist the child with ambulation even though he or she may have ambulated well before hospitalization. Patients who have been lying in bed need to get up slowly, sitting on the side of the bed before standing.

The nurse also needs to educate family members:

- Call the nursing staff for assistance and do not allow patients to get up independently.
- Keep the side rails of the crib or bed up whenever patient is in the crib or bed.
- Do not leave infants on the daybed; put them in the crib with the side rails up.
- When all family members need to leave the bedside, notify the staff and ensure that the patient is in the bed or crib with the side rails up and call bell within reach (if appropriate).

In the event of a fall, it is important to immediately respond to the needs of the patient; notify appropriate personnel, including caregivers; and document the event.

INFECTION CONTROL

According to the Centers for Disease Control and Prevention, nosocomial (health care–associated) infections pose a significant threat to patient safety. These infections occur when there is interaction among patients, health care personnel, equipment, and bacteria. Health care–associated infections include infections such as *Clostridium difficile* or hospital-onset methicillin-resistant *Staphylococcus aureus,* as well as central line–associated bloodstream infections (CLABSIs), catheter-associated urinary tract infections (CAUTIs), and some surgical site infections. Health care–associated infections can be preventable if caregivers practice meticulous cleaning and disposal techniques.

Standard Precautions synthesize the major features of Universal (blood and body fluid) Precautions (designed to reduce the risk of transmission of bloodborne pathogens) and body substance isolation (designed to reduce the risk of transmission of pathogens from moist body substances). Standard Precautions involve vigilant hand hygiene and the use of barrier protection, such as gloves, goggles, gown, or mask, to prevent contamination from (1) blood; (2) all body fluids, secretions, and excretions except sweat, regardless of whether they contain visible blood; (3) nonintact skin; and (4) mucous membranes. Standard Precautions are designed for the care of all patients to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources of infection.

Transmission-Based Precautions are designed for patients with documented or suspected infection or colonization (i.e., presence of microorganisms in or on the patient but without clinical signs and symptoms of infection) with highly transmissible or epidemiologically important pathogens for which additional precautions beyond Standard Precautions are needed to interrupt transmission in hospitals. There are three types of Transmission-Based Precautions: Airborne Precautions, Droplet Precautions, and Contact Precautions. They may be combined for diseases that have multiple routes of transmission (Box 20.2). They are to be used in addition to Standard Precautions.

Airborne Precautions reduce the risk of airborne transmission of infectious agents. Airborne transmission occurs by dissemination of either airborne droplet nuclei (small-particle residue [<5 mm] of evaporated droplets that may remain suspended in the air for long periods) or dust particles containing the infectious agent. Microorganisms carried in this manner can be dispersed widely by air currents and may become inhaled by or deposited on a susceptible host within the same room or over a longer distance from the source patient, depending on environmental factors. Individuals who have not had direct face-to-face contact with the source individual may become infected. Special air handling and ventilation are required to prevent airborne transmission. Airborne Precautions apply to patients with known or suspected infection with pathogens transmitted by the airborne route such as measles, varicella, and tuberculosis.

Droplet Precautions reduce the risk of droplet transmission of infectious agents. Droplet transmission involves contact of the conjunctivae or the mucous membranes of the nose or mouth of a susceptible person with large-particle droplets (>5 mm) containing microorganisms generated from a person who has a clinical disease or who is a carrier of the microorganism. Droplets are generated from the source person primarily during coughing, sneezing, or talking, and during procedures such as suctioning and bronchoscopy. Transmission requires close contact between source and recipient persons because droplets do not remain suspended in the air and generally travel only short distances, usually 3 feet or less but up to 10 feet, through the air. Because droplets

BOX 20.2 Types of Precautions and Patients Requiring Them

Standard Precautions for Prevention of Transmission of Pathogens

Use Standard Precautions for the care of all patients.

Airborne Precautions

In addition to Standard Precautions, use Airborne Precautions for patients known or suspected to have serious illnesses transmitted by airborne droplet nuclei. Examples of such illnesses include measles, varicella (including disseminated zoster), and tuberculosis.

Droplet Precautions

In addition to Standard Precautions, use Droplet Precautions for patients known or suspected to have serious illnesses transmitted by large-particle droplets. Examples of such illnesses include the following:

- Invasive *Haemophilus influenzae* type b disease, including meningitis, pneumonia, epiglottitis, and sepsis
- Invasive *Neisseria meningitidis* disease, including meningitis, pneumonia, and sepsis
- Other serious bacterial respiratory tract infections spread by droplet transmission, including diphtheria (pharyngeal), mycoplasma pneumonia, pertussis, pneumonic plague, streptococcal pharyngitis, pneumonia, and scarlet fever in infants and young children
- Serious viral infections spread by droplet transmission, including adenovirus, influenza, mumps, parvovirus B19, and rubella

Contact Precautions

In addition to Standard Precautions, use Contact Precautions for patients known or suspected to have serious illnesses easily transmitted by direct patient contact or by contact with items in the patient's environment. Examples of such illnesses include the following:

- Gastrointestinal, respiratory, skin, or wound infections or colonization with multidrug-resistant bacteria judged by the infection control program, based on current state, regional, or national recommendations, to be of special clinical and epidemiologic significance
- Enteric infections with a low infectious dose or prolonged environmental survival, including *Clostridium difficile;* for diapered or incontinent patients: enterohemorrhagic *Escherichia coli* O157:H7, *Shigella* organisms, hepatitis A, or rotavirus
- Respiratory syncytial virus, parainfluenza virus, or enteroviral infections in infants and young children
- Skin infections that are highly contagious or that may occur on dry skin, including diphtheria (cutaneous), herpes simplex virus (neonatal or mucocutaneous), impetigo, major (noncontained) abscesses, cellulitis or decubitus, pediculosis, scabies, staphylococcal furunculosis in infants and young children, zoster (disseminated or in the immunocompromised host)
- Multidrug-resistant organisms, infection, or colonization (methicillin-resistant *Staphylococcus aureus,* vancomycin-resistant enterococci)
- Viral or hemorrhagic conjunctivitis
- Viral hemorrhagic infections (Ebola, Lassa, or Marburg)

A complete list of the guidelines for isolation precautions for the prevention of transmission of infectious agents in health care can be found at https://www.cdc.gov/infectioncontrol/guidelines/isolation/index.html.

do not remain suspended in the air, special air handling and ventilation are not required to prevent droplet transmission. Droplet Precautions apply to any patient with known or suspected infection with pathogens that can be transmitted by infectious droplets (see Box 20.2).

Contact Precautions reduce the risk of transmission of microorganisms by direct or indirect contact. Direct-contact transmission involves skin-to-skin contact and physical transfer of microorganisms to a susceptible host from an infected or colonized person, such as occurs when turning or bathing patients. Direct-contact transmission also can occur between two patients (e.g., by hand contact). Indirect contact transmission involves contact of a susceptible host with a contaminated intermediate object, usually inanimate, in the patient's environment. Contact Precautions apply to specified patients known or suspected to be infected or colonized with microorganisms that can be transmitted by direct or indirect contact.

! NURSING ALERT

The most common piece of medical equipment, the stethoscope, can be a potent source of harmful microorganisms and nosocomial infections.

Nurses caring for young children are frequently in contact with body substances, especially urine, feces, and vomitus. Nurses need to exercise judgment concerning those situations when gloves, gowns, or masks are necessary. For example, wear gloves and possibly gowns for changing diapers when there are loose or explosive stools. Otherwise, the plastic lining of disposable diapers provides a sufficient barrier between the hands and body substances. During feedings or oral medication administration, wear gowns if the child is likely to vomit or spit up, which often occurs during burping. When wearing gloves, wash the hands thoroughly after removing the gloves because gloves fail to provide complete protection. The absence of visible leaks does not indicate that gloves are intact.

Another essential practice of infection control is that all needles (uncapped and unbroken) are disposed of in a rigid, puncture-resistant container located near the site of use. Consequently, these containers are installed in patients' rooms. Because children are naturally curious, extra attention is needed in selecting a suitable type of container and a location that prevents access to the discarded needles. Puncture-resistant containers should be changed when three-quarters full or when the fill line marker on the container is reached (US Food and Drug Administration, 2018). The use of needleless systems allows secure syringe or IV tubing attachment to vascular access devices without the risk of needlestick injury to the child or nurse.

TRANSPORTING INFANTS AND CHILDREN

Infants and children need to be transported within the unit and to areas outside the pediatric unit. Infants and small children can be carried for short distances within the unit, but for more extended trips, the child should be securely transported in a suitable conveyance.

Small infants can be held or carried in the horizontal position with the back supported and the thigh grasped firmly by the carrying arm (Fig. 20.3A). In the football hold, the infant is carried on the nurse's arm with the head supported by the hand and the body held securely between the nurse's body and elbow (see Fig. 20.3B). Both of these holds leave the nurse's other arm free for activity. The infant also can be held in the upright position with the buttocks on the nurse's forearm and the front of the body resting against the nurse's chest. The infant's head and shoulders are supported by the nurse's other arm in case the infant moves suddenly (see Fig. 20.3C). Older infants are able to hold their heads erect but are still subject to sudden movements. Medically stable infants can be carried in a variety of ways for transport as long as their head is supported at all times.

The method of transporting children depends on their age, condition, and destination. Older children are safe in wheelchairs or on stretchers. Younger children can be transported in a crib, on a stretcher, in a wagon with raised sides, or in a wheelchair with a safety belt. Stretchers should be equipped with high sides and a safety belt, both of which are secured during transport.

Special care is needed in transporting critically ill patients in the hospital. Critically ill children should always be transported on a stretcher or bed (rather than carried) by at least two appropriately trained staff members with monitoring continued during transport. A blood pressure monitor (or standard blood pressure cuff), pulse oximeter, and cardiac monitor/defibrillator should accompany every patient (Alamanou & Brokalaki, 2014). Airway equipment, oxygen, and emergency medications should accompany the patient. The monitoring and staff members required for transport will vary depending on the acuity and clinical status of the patient. In addition, it is important for the nurse to be familiar with emergency transport of patients

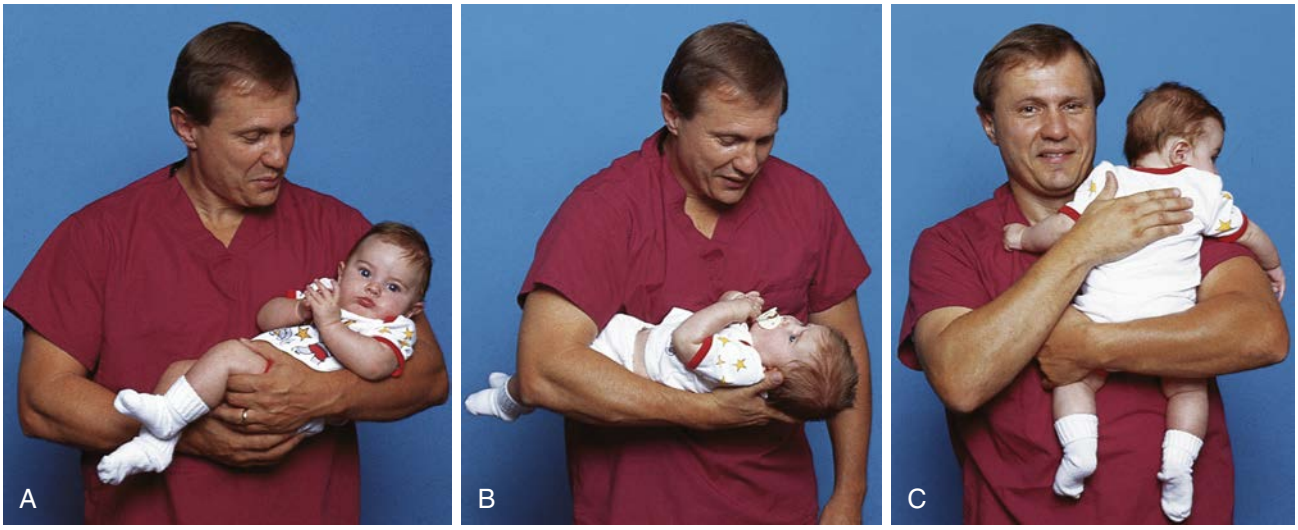

Fig. 20.3 Transporting infants. **A,** The infant's thigh is firmly grasped in the nurse's hand. **B,** Football hold. **C,** Back supported.

in the event of severe weather, fire, or security threats when power or elevators may be unavailable.

RESTRAINING METHODS

The Centers for Medicare and Medicaid Services (2015) has established regulations to minimize the use of and ensure the safety of patients in restraints. It defines *restraint* as "any manual method, physical or mechanical device, material, or equipment that immobilizes or reduces the ability of a patient to move his or her arms, legs, body, or head freely . . . or a drug or medication when it is used as a restriction to manage the patient's behavior or restrict the patient's freedom of movement and is not a standard treatment or dosage for the patient's condition." A restraint should be applied only by a health care team member with demonstrated competency in restraint management. The physical force may be human, mechanical devices, or a combination of the two. Examples of restraints include limb restraints, elbow restraints, vest restraints, and tight tucking of sheets to prevent movement in bed.

Mechanical supports such as immobilizers for fractures, orthopedic devices to maintain proper body alignment, leg braces, protective helmets, and surgical dressings are not considered restraints. An armboard to secure a peripheral IV line is not considered a restraint unless it is tied to the bed or immobilizes the entire limb such that the patient cannot access his or her body. Hand mitts are not considered a restraint unless tied to the bed or used in conjunction with a wrist restraint. Developmentally age-appropriate safety interventions for infants, toddlers, and preschoolers, such as net enclosures on beds, crib domes, crib side rails, and high chair lap safety belts, are generally not considered restraints. Picking up, redirecting, or holding an infant, toddler, or preschooler is not considered restraint. Interventions that typically would be used by a child care provider outside a health care environment to ensure safety in young children are not considered restraints.

Before initiating restraints, the nurse completes a comprehensive assessment of the patient to determine whether the need for a restraint outweighs the risk of not using one. Restraints can result in loss of dignity, violation of patient rights, psychologic harm, physical harm, and even death. Consider alternative methods first and document them in the patient's record. Some examples of alternative measures include bringing a child to the nurses' station for continuous observation, providing diversional activities such as music, and encouraging the participation of the parents. The use of restraints can often be avoided with adequate preparation of the child; parental or staff supervision of the child; or adequate protection of a vulnerable site, such as an infusion device.

The nurse needs to assess the child's development, mental status, potential to hurt others or self, and safety. The nurse is responsible for selecting the least restrictive type of restraint. Using less restrictive restraints is often possible by gaining the cooperation of the child and parents. An order must be obtained as soon as possible (during application or within a few minutes) after the initiation of restraints and specify the time frame in which they can be used, the reason they are being used, and reasons for discontinuation. Discontinuation of restraints should occur as soon as it is safe, even if the order time frame has not expired.

Restraints for violent, self-destructive behavior are limited to situations with a significant risk of patients physically harming themselves or others because of behavioral reasons and when nonphysical interventions are not effective. Before initiating a behavioral restraint, the nurse should assess the patient's mental, behavioral, and physical status to determine the cause for the child's potentially harmful behavior. If behavioral restraints are indicated, a collaborative approach involving the patient (if appropriate), the family, and the health care team should be used. Behavioral restraints can include personal restraints, such as a physical hold, or mechanical restraints, such as secured anklets and wristlets or bilateral arm immobilizers.

Unless state law is more restrictive, behavioral restraints for children must be reordered every 15 minutes for a personal restraint, every 1 hour for children under 9 years of age, and every 2 hours for children 9 to 17 years old; orders for adults 18 years and older are required every 4 hours. A licensed independent practitioner or specially trained nurse must conduct an in-person evaluation within 1 hour and at least every 24 hours to continue restraints.

Children in behavioral restraints must be observed and assessed according to facility policy—typically continuously, every 15 minutes, or every 2 hours. Assessment components include signs of injury associated with applying restraint, nutrition and hydration, circulation and range-of-motion of extremities, vital signs, hygiene and elimination, physical and psychologic status and comfort, and readiness for discontinuation of restraint. The nurse must use clinical judgment in setting a schedule within the facility's policy for when each of these parameters needs to be evaluated.

Nonviolent and non–self-destructive patients may also require restraints to support medical healing. Examples of situations where a nonbehavioral restraint may be necessary for the patient's safety include removal of an artificial airway or airway adjunct for delivery of oxygen, indwelling catheters, tubes, drains, lines, pacemaker wires, or disruption of suture sites. The medical-surgical restraint is used to ensure that safe care is given to the patient. Patient confusion, agitation, unconsciousness, and developmental inability to understand direct requests or instructions may warrant the use of nonbehavioral restraints to maintain patient safety. The potential risks of the restraint are offset by the potential benefit of providing safer care.

Nonbehavioral restraints can be initiated by an individual order or by protocol; the use of the protocol must be authorized by an individual order. The order for continued use of restraints must be renewed each day. Patients are monitored per facility policy, typically at least every 2 hours.

Restraints with ties must be secured to the stationary bed or crib frame, not the side rails. Suggestions for increasing safety and comfort while the child is in a restraint include leaving one fingerbreadth between skin and the device and tying knots that allow for quick release. The nurse can also increase safety by ensuring that the restraint does not tighten as the child moves and by decreasing wrinkles or bulges in the restraint. Placing jacket restraints over an article of clothing; placing limb restraints below waist level, below knee level, or distal to the IV; and tucking in dangling straps also increase safety and comfort. Do not place objects over a patient's face to protect staff from being spit on or bitten. Masks and face shields should be readily available for staff to wear; some facilities also provide bite gloves and arm and hand wraps made of strong barrier materials such as Kevlar for staff to wear to prevent injury from bites and scratches.

Mummy Restraint or Swaddle

When an infant or small child requires short-term restraint for examination or treatment that involves the head and neck (e.g., venipuncture, throat examination, gavage feeding), a papoose board with straps or a mummy wrap effectively controls the child's movements. When used only for the duration of the test or procedure, this is not considered a restraint. The mummy restraint or swaddle should not be used for behavior or long-term restraint. A blanket or sheet is opened on the bed or crib with one corner folded to the center. The infant is placed on the blanket with the shoulders at the fold and feet toward the opposite

Fig. 20.4 Restraint examples from most restrictive to least restrictive. **A,** Mummy restraint. **B,** Wrist restraints. **C,** Elbow restraints.

corner. With the infant's right arm straight down against the body, the right side of the blanket is pulled firmly across the infant's right shoulder and chest and secured beneath the left side of the body. The left arm is placed straight against the infant's side, and the left side of the blanket is brought across the shoulder and chest and locked beneath the body on the right side. The lower corner is folded and brought over the body and tucked or fastened securely with safety pins. Safety pins can be used to fasten the blanket in place at any step in the process. To modify the mummy restraint for chest examination, bring the folded edge of the blanket over each arm and under the back and then fold the loose edge over and secure it at a point below the chest to allow visualization and access to the chest (Fig. 20.4A).

Arm and Leg Restraints

Occasionally, the nurse needs to restrain one or more extremities or limit their motion. Several commercial restraining devices are available, including disposable wrist and ankle restraints (see Fig. 20.4B). Restraints must be appropriate to the child's size and padded to prevent undue pressure, constriction, or tissue injury, and the extremity must be observed frequently for signs of irritation or impaired circulation. The ends of the restraints are never tied to the side rails because lowering the rail will disturb the extremity, frequently with a jerk that may hurt or injure the child.

Elbow Restraint

Sometimes it is important to prevent the child from reaching the head or face (e.g., after cleft lip or palate surgery, when a scalp vein infusion is in place, or to prevent scratching in skin disorders). Bilateral elbow restraints fashioned from a variety of materials function well (see Fig. 20.4C). Commercial elbow restraints or immobilizers are available. They extend from just below the axilla to the wrist and are sometimes referred to as "no-no's." A shoulder strap to prevent slipping may be used in an awake, active older infant or toddler to prevent slippage but should not be used when sleeping.

POSITIONING FOR PROCEDURES

Infants and small children are unable to cooperate for many procedures. Therefore the nurse is responsible for minimizing their movement and discomfort with proper positioning. It can also be helpful to involve the caregivers or child life specialists during procedures to minimize distress in the child. Older children usually need only minimal, if any, positioning hold or movement restrictions. Careful explanation and preparation beforehand and support and simple guidance during the procedure are usually sufficient. For painful procedures, the child should receive adequate analgesia and sedation to minimize pain and the need for excessive restraint. For local anesthesia, use buffered

Fig. 20.5 Positioning infant for femoral venipuncture.

Fig. 20.6 Therapeutic comfort hold of child for extremity venipuncture with parental assistance.

lidocaine to reduce the stinging sensation or a topical anesthetic. (See Chapter 5, Pain Management.)

FEMORAL VENIPUNCTURE

The nurse places the child supine with the legs in a frog position to provide extensive exposure of the groin area. A towel can also be placed under the hips. The infant's legs can be effectively controlled by the nurse's forearms and hands (Fig. 20.5). Only the side used for the venipuncture is uncovered, so the practitioner is protected if the child urinates during the procedure. Apply pressure to the site to prevent oozing from the site.

EXTREMITY VENIPUNCTURE OR INJECTION

The most common sites of venipuncture are the veins of the extremities, especially the arm and hand. A convenient position is to place the child in the parent's (or assistant's) lap with the child facing the parent and in the straddle position. Next, place the child's arm for venipuncture on a firm surface, such as a treatment table. The nurse can partially stabilize the child's outstretched arm and have the parent hug the child's upper body, preventing movement; the nurse can then use the parent's arm to immobilize the venipuncture site. This type of comfort hold also comforts the child because of the close body contact, allows for distraction techniques for the child, and allows each person to maintain eye contact (Fig. 20.6).

LUMBAR PUNCTURE

Pediatric lumbar puncture (LP) sets contain smaller spinal needles, but sometimes the provider will specify a different size or type of needle depending on the child's size or obesity. The technique for the LP procedure in infants and children is similar to that in adults, although modifications are suggested in neonates, who have less distress in a side-lying position with modified neck extension than in flexion or a sitting position.

Children can be positioned in a side-lying or sitting position. Children are usually easiest to control in the side-lying position, with the head flexed and the knees drawn up toward the chest. Even cooperative children need to be held gently under the knees and around the shoulders to prevent possible trauma from unexpected, involuntary movement. They can be reassured that, although they are trusted, holding will serve as a reminder to maintain the desired position. It also provides a measure of support and reassurance to them (Fig. 20.7).

Fig. 20.7 Side-lying position for lumbar puncture.

A flexed sitting position may be used, depending on the child's ability to cooperate and whether sedation will be used. In the sitting position with the hips flexed and spine curved forward, the interspinous space is maximized between L3 and L5. The child is placed with the buttocks at the edge of the table. For an infant, the nurse's hands immobilize the arms and legs. Neck flexion has not been shown to enhance the interspinous space opening in children.

Specimens and spinal fluid pressure are obtained, measured, and sent for analysis in the same manner as for adult patients. Take vital signs as ordered throughout and after the procedure and observe the child for any changes in level of consciousness, motor activity, and other neurologic signs. Post-LP headache may occur and can be related to larger needle size, prior history of headaches, and postural changes. There is insufficient evidence to support the use of bed rest after LP to reduce post-LP headaches (Rusch, Schulta, Hughes, et al., 2014). Treatment generally includes rest and oral analgesics, such as acetaminophen, that do not inhibit platelet function.

BONE MARROW ASPIRATION OR BIOPSY

The position for a bone marrow aspiration or biopsy depends on the chosen site. In children, the posterior or anterior iliac crest is most frequently used, but in infants less than 18 months old, the tibia may be selected because the iliac crest has not yet ossified.

If the posterior iliac crest is used, the child is positioned prone, and if the anterior iliac crest is used, the child is typically positioned side-lying

or supine. Sometimes a small pillow or folded blanket is placed under the hips to facilitate obtaining the bone marrow specimen. Children should receive adequate analgesia or anesthesia to relieve pain and should be monitored appropriately throughout the procedure. If the child might awaken, he or she may need to be held, preferably by two people—one person to immobilize the upper body and a second person to immobilize the lower extremities. A pressure dressing is applied to the puncture site on completion of the procedure. The dressing will be removed after 24 hours and the site assessed for infection.

COLLECTION OF SPECIMENS

Many of the specimens needed for diagnostic examination of children are collected in much the same way as they are for adults. Older children are able to cooperate if given proper instruction regarding what is expected of them. Infants and small children, however, are typically unable to follow directions or control body functions sufficiently to help in collecting some specimens.

FUNDAMENTAL STEPS COMMON TO ALL PROCEDURES

The following steps are very important for every procedure and should be considered fundamental aspects of care. These steps, although important, are not listed in each of the specimen collection procedures.

1. Assemble the necessary equipment.
2. Introduce self to the family and verify the specimen that is to be collected.
3. Identify the child using two patient identifiers (e.g., patient name and medical record or birth date; neither identifier can be a room number). Compare the same two identifiers with the specimen container and order.
4. Perform hand hygiene, maintain aseptic technique, and follow Standard Precautions.
5. Explain the procedure to parents and child according to the developmental level of the child; reassure the child that the procedure is not a punishment.
6. Provide atraumatic care and position the child securely.
7. Prepare area with antiseptic agent.
8. Place specimens in appropriate containers with appropriate collection information such as date and time and apply a patient identification label to the specimen container in the presence of the child and family.
9. Discard puncture device in puncture-resistant container near the site of use.
10. Wash the procedural preparation agent off if povidone-iodine is used, if skin is sensitive, and for infants. Check that all collection supplies have been removed from the patient's bed area to ensure patient safety.
11. Remove gloves and perform hand hygiene after the procedure. Have children wash their hands if they have helped.
12. Praise the child for helping.
13. Document pertinent aspects of the procedure, such as number of attempts, site, and amount of blood or urine withdrawn, as well as type of test performed.

URINE SPECIMENS

Many diagnostic situations warrant urine specimens. The age of the child will affect the collection technique, as will developmental considerations. Children will better understand what is expected if the nurse uses familiar terms, such as "pee-pee," "wee-wee," or "tinkle." Preschoolers and toddlers are usually unable to void on request. It is often best to offer them water or other liquids that they enjoy and wait about 30 minutes until they are ready to void voluntarily. Some have difficulty voiding in an unfamiliar receptacle. Potty chairs or a potty hat placed on the toilet is usually satisfactory. Toddlers who have recently acquired bladder control may be especially reluctant because they undoubtedly have been admonished for "going" in places other than those approved by parents. Enlisting the parents' help usually leads to success. School-age children are generally cooperative with collection methods but curious. They are concerned about the reasons behind things and are likely to ask questions about the disposition of their specimen and what one expects to discover from it. Self-conscious adolescents may be reluctant to carry a specimen through a hallway or waiting room and appreciate a paper bag for disguising the container. The presence of menses may be an embarrassment or a concern to teenage girls; therefore it is a good idea to ask them about this and make adjustments as necessary. The specimen can be delayed or a notation made on the laboratory slip to explain the presence of red blood cells.

At times, parents may be asked to bring a urine sample to a health care facility for examination, especially when infants are unable to void during an outpatient visit. In these instances, parents need instructions on applying the collection device and storing the specimen. Ideally, the specimen should be brought to the designated place as soon as possible. If there is a delay, the sample should be refrigerated and the lapsed time reported to the examiner.

Although it is a convenient and noninvasive collection method, direct urine aspiration from a diaper can alter the specimen results. Superabsorbent gel disposable diapers may absorb all urine and may also produce a false crystalluria. Direct aspiration from the diaper may not be suitable for all urine specimen tests. Nurses should verify collection procedures with the laboratory before collection.

Urine Collection Bags

For infants and toddlers who are not toilet trained, special urine collection bags with self-adhering material around the opening at the point of attachment may be used. To prepare the infant, the genitalia, perineum, and surrounding skin are washed and dried thoroughly because the adhesive will not stick to a moist, powdered, or oily skin surface. The collection bag is easiest to apply if attached first to the perineum, progressing to the symphysis pubis (Fig. 20.8). With girls, the perineum is stretched taut during application to ensure a leakproof fit. With boys, the penis and sometimes the scrotum are placed inside the bag. The adhesive portion of the bag must be firmly applied to the skin all around the genital area to avoid leakage. The bag is checked frequently and removed as soon as the specimen is available because the moist bag may become loosened on an active child.

The American Academy of Pediatrics guidelines (American Academy of Pediatrics, Subcommittee on Urinary Tract Infections, 2011) for diagnosis and management of urinary tract infections in infants 2 to 24 months old recommend that any positive screen obtained from a bag specimen be confirmed by culture via bladder catheterization or suprapubic aspiration due to an unacceptably high rate of false-positive results. Although the bag specimen collection method is less invasive and traumatic to an infant, some families and clinicians may prefer to collect only one definitive specimen and avoid additional delay in obtaining a second specimen. Urine bag specimens may be most appropriate for a urine dipstick or urinalysis, not urine cultures (Stein, Dogan, Hoebeke, et al., 2015).

NURSING TIP In infants, wipe the abdomen with an alcohol pad and fan it dry; the cooling effect often causes voiding within 2 minutes. Apply pressure over the suprapubic area or stroke the paraspinal muscles (along the spine) to elicit the Perez reflex. In infants 4 to 6 months of age, this reflex causes crying, extension of the back, flexion of the extremities, and urination.

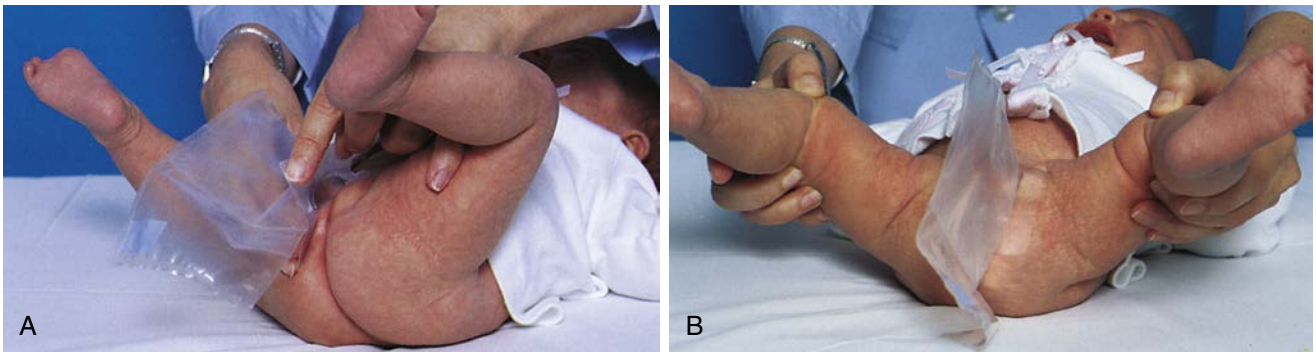

Fig. 20.8 Application of urine collection bag. **A,** On female infants, the adhesive portion is applied to the exposed and dried perineum first. **B,** The bag adheres firmly around the perineal area to prevent urine leakage.

Clean-Catch Specimens

Clean-catch specimen traditionally refers to a urine sample obtained for culture after the urethral meatus is cleaned and the first few milliliters of urine are voided (**midstream specimen**). In girls, the perineum is wiped with an antiseptic pad from front to back. In boys, the tip of the penis is cleansed. If the boy is uncircumcised, the foreskin is retracted and the glans is cleansed. It is important that the inside of the specimen cup or lid is not touched or contaminated during collection to ensure accurate results.

NURSING TIP When using a urine collection bag, cut a small slit in the diaper and pull the bag through to allow room for urine to collect and to facilitate checking on the contents.

Twenty-Four-Hour Collection

For a 24-hour collection, collection bags are required in infants and small children. Older children require special instruction about notifying someone when they need to void or have a bowel movement so that urine can be collected separately and is not discarded. Some older school-age children and adolescents can take responsibility for collection of their own 24-hour specimens and can keep output records and transfer each voiding to the 24-hour collection container.

The collection period always starts and ends with an empty bladder. At the time the collection begins, instruct the child to void and discard the specimen. All urine voided in the subsequent 24 hours is saved in a container with a preservative or is placed on ice. Twenty-four hours from the time the precollection specimen was discarded, the child is again instructed to void, the specimen is added to the container, and the entire collection is taken to the laboratory.

Infants and small children who are bagged for 24-hour urine collection require a special collection bag. Frequent removal and replacement of adhesive collection devices can produce skin irritation. A thin coating of sealant, such as Skin-Prep, applied to the skin helps protect it and aids adhesion (unless its use is contraindicated, such as in premature infants or children with irritated skin). Plastic collection bags with collection tubes attached are ideal when the container must be left in place for a time. These can be connected to a collecting device or emptied periodically by aspiration with a syringe. When such devices are not available, a regular bag with a feeding tube inserted through a puncture hole at the top of the bag serves as a satisfactory substitute. However, take care to empty the bag as soon as the infant urinates to prevent leakage and loss of contents. An indwelling catheter may also be placed for the collection period.

TABLE 20.4 Straight Catheter or Foley Catheter[a]

	Size (Length of Insertion [cm]) for Girls	Size (Length of Insertion [cm]) for Boys
Term neonate	5-6 (5)	5-6 (6)
Infant to 3 yr	5-8 (5)	5-8 (6)
4-8 yr	8 (5-6)	8 (6-9)
8 yr to prepubertal	10-12 (6-8)	8-10 (10-15)
Pubertal	12-14 (6-8)	12-14 (13-18)

[a]Foley catheters are approximately 1 Fr size larger because of the circumference of the balloon. Example: 10-Fr Foley catheter = approximately 12-Fr calibration.

Bladder Catheterization and Other Techniques

Bladder catheterization or suprapubic aspiration is used when a specimen is urgently needed or a child is unable to void or otherwise provide an adequate specimen. The American Academy of Pediatrics recommends that a urine specimen be obtained by bladder catheterization or suprapubic aspiration in ill-appearing febrile infants with no apparent source of infection before antimicrobial administration and to confirm a positive screen for infection (American Academy of Pediatrics, Subcommittee on Urinary Tract Infections, 2011).

Catheterization is a sterile procedure, and Standard Precautions for body substance protection should be followed. If the catheter is to remain in place, a Foley catheter is used. Table 20.4 gives guidelines for choosing the appropriate-size catheter and length of insertion. The supplies needed for this procedure include sterile gloves, sterile lubricant anesthetic, the appropriate-size catheter, povidone-iodine (Betadine) swabs or an alternative cleansing agent and 4- × 4-inch gauze squares, a sterile drape, and a syringe with sterile water if a Foley catheter is used. It may also be helpful to ensure that an extra catheter is readily available if needed. Many manufacturers no longer recommend testing the balloon of the Foley catheter by injecting sterile water before catheter insertion due to risk of weakening the balloon.

Adolescent boys and children with a history of urethral surgery may be catheterized with a curved, coudé-tipped catheter to assist with guiding the catheter past tight or partially blocked urethral openings. Children with myelodysplasia and those who have been identified as being sensitive or allergic to latex are catheterized with catheters manufactured from an alternative material. When an indwelling catheter is indicated for urinary drainage, a lubricious-coated or silicone catheter is selected because these materials produce less irritation of the

urethral mucosa compared with Silastic or latex catheters when left in place for more than 72 hours.

A 2% lidocaine lubricant with applicator is assembled according to the manufacturer's instructions, and several drops of the lubricant are placed at the meatus. The child is advised that the lubricant is used to reduce any discomfort associated with inserting the catheter and that introduction of the catheter into the urethra will produce a sensation of pressure and a desire to urinate (Gray, 1996) (see Translating Evidence Into Practice box).

NURSING TIP: Although lidocaine lubricant may reduce discomfort during urinary catheterization, it is important for the nurse to weigh the benefit of analgesia against a prolonged procedure time. Lidocaine gel lubricant takes approximately 5 to 10 minutes for the anesthetic benefit to take effect. This increase in procedure length may significantly increase the anxiety of a young child. Thus the lidocaine lubricant may be more appropriate in the older child or adolescent age-groups.

TRANSLATING EVIDENCE INTO PRACTICE

The Use of Lidocaine Lubricant for Urethral Catheterization

Ask the Question

PICOT Question

In children, does a lidocaine lubricant decrease the pain associated with urethral catheterization?

Search for the Evidence

Search Strategies

Search selection criteria included English-language publications, research-based studies, and review articles on the use of the lidocaine lubricant before urethral catheterization.

Databases Used

Cochrane Collaboration, PubMed, MD Consult, BestBETs, American Academy of Pediatrics

Critically Analyze the Evidence

- Gray (1996) published a review of strategies to minimize distress associated with urethral catheterization in children and supported intraurethral instillation of a local anesthetic that contains 2% lidocaine before catheter insertion.
- One prospective, double-blind, placebo-controlled trial evaluated the use of lidocaine lubricant for discomfort in 20 children before urethral catheterization. Two doses of lidocaine lubricant instilled into the urethra 5 minutes apart significantly reduced pain and distress during urethral catheterization (Gerard, Cooper, Duethman, et al., 2003).
- Boots and Edmundson (2010) conducted a randomized controlled trial in 200 children in a follow-up to the study by Gerard and colleagues (2003). Conclusions were that a topical application of 2% lidocaine gel followed by urethral instillation of lidocaine gel is effective in reducing discomfort before urinary catheterization, and two urethral instillations offered no significant difference over a single instillation.
- Mularoni and colleagues (2009) found in a three-armed placebo-controlled, double-blind, randomized controlled trial of 43 children younger than 2 years of age that topical and intraurethral lidocaine lubricant was superior to the placebos of topical aqueous lubricant alone and topical and intraurethral aqueous lubricant in lowering distress, but it did not fully alleviate pain.
- A placebo-controlled, double-blind, randomized controlled trial of 115 children younger than 2 years of age found no significant difference when 2% lidocaine gel was compared with a nonanesthetic lubricant. The lubricant was applied to the genital mucosa for 2 to 3 minutes and liberally applied to the catheter but not instilled into the urethra (Vaughn, Paton, Bush, et al., 2005).
- A randomized controlled trial of 126 children ages 4 days to 23 months found a significant decrease in pain response in children who received topical and intraurethral 2% lidocaine gel compared with children who received a nonanesthetic lubricant (Castelo, Li, Taddio, et al., 2014).
- A randomized controlled trial of 133 children ages 0 to 24 months found no difference in pain response in children who received intraurethral 2% lidocaine gel lubricant compared with children who received a nonanesthetic lubricant during urethral catheterization. However, there was significantly increased pain response in children during instillation of the lidocaine lubricant compared with the nonanesthetic lubricant. In addition, there was no difference in parent satisfaction scores between the nonanesthetic lubricant and lidocaine lubricant (Poonai, Li, Langford, et al., 2015).

Apply the Evidence: Nursing Implications

There is moderate-quality evidence with strong recommendations (Guyatt, Oxman, Vist, et al., 2008) for using a lidocaine lubricant to decrease pain associated with urethral catheterization.

Four published research studies were found to support the use of anesthetic before urethral catheterization, one found topical application alone insufficient to reduce pain, and one found no difference in pain response between anesthetic and nonanesthetic application. Several publications support the effectiveness of lidocaine gel lubricant in clinical practice. Topical application followed by one or two transurethral instillations of 2% lidocaine gel before urethral catheterization minimizes distress and reduces pain before urinary catheterization.

Quality and Safety Competencies: Evidence-Based Practice[a]

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe use of lidocaine gel for pain reduction during urethral catheterization.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by using lidocaine gel for pain reduction during urethral catheterization in children.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate the strengths and weakness of evidence for using lidocaine gel for pain reduction during urethral catheterization in children.

[a] Adapted from the Quality and Safety Education for Nurses (QSEN) website at http://www.qsen.org.

In male patients, grasp the penis with the nondominant hand and retract the foreskin. In uncircumcised newborns and infants, the foreskin may be adhered to the shaft; use care when retracting. If the penis is pendulous, place a sterile drape under the penis. Using the sterile hand, swab the glans and meatus three times with povidone-iodine beginning at the meatus and moving outward toward the edge of the glans. If appropriate to use lidocaine lubricant based on the child's age, developmental level, and preference, apply a small amount of lidocaine jelly to the tip of the penis over the urethra. Gently introduce the tip of the lidocaine jelly applicator into the urethra 1 to 2 cm (0.4 to 0.8 inch) so that the lubricant flows only into the urethra; insert 5 to 10 ml 2% lidocaine lubricant into the urethra and hold it in place for 2 to 5 minutes by gently squeezing the distal penis. Lubricate the catheter and insert it into the urethra while gently stretching the penis and lifting it to a 90-degree angle to the body. Resistance may occur when the catheter meets the urethral sphincter. Ask the patient to inhale deeply and advance the catheter. Do not force a catheter that does not easily enter the meatus, particularly if the child has had corrective surgery. For indwelling catheters, after urine is obtained, advance the catheter to the hub, inflate the balloon with sterile water, pull it back gently to test inflation, and connect it to the closed drainage system. Cleanse the glans and meatus and replace the retracted foreskin. If blood is seen at any time during the procedure, discontinue the procedure and notify the provider.

In female patients, place a sterile drape under the buttocks. Use the nondominant hand to gently separate and pull up the labia minora to visualize the meatus. Swab the meatus from front to back three times using a different povidone-iodine swab each time. If appropriate to use lidocaine lubricant based on the child's age, developmental level, and preference, place 1 to 2 ml 2% lidocaine lubricant on the periurethral mucosa and insert the lubricant 1 to 2 ml into the urethral meatus. Delay catheterization for 2 to 5 minutes to maximize absorption of the anesthetic into the periurethral and intraurethral mucosa. Add lubricant to the catheter and gently insert it into the urethra until urine returns; then advance the catheter an additional 2.5 to 5 cm (1 to 2 inches). When using an indwelling Foley catheter, inflate the balloon with sterile water and gently pull back; then connect to a closed drainage system. Cleanse the meatus and labia (see Cultural Considerations box). Because the use of lidocaine jelly can increase the volume of intraurethral lubricant, urine return may not be as rapid as when minimal lubrication is used. For both male and female patients, apply a securement device from the catheter tubing to the patient's thigh to avoid kinks and painful pulling on the catheter. Ensure that the patient can move his or her thigh without pulling on the catheter tubing.

! NURSING ALERT

Do not advance the catheter too far into the bladder to prevent knotting of catheters and tubes within the bladder. Feeding tubes should not be used for urinary catheterization because they are more flexible, longer, and prone to knotting compared with commercially designed urinary catheters.

CULTURAL CONSIDERATIONS

Bladder Catheterization

Parents may be upset when their child is catheterized. Aside from the trauma the child experiences, some parents may fear that the procedure affects their daughter's virginity. To correct this misconception, the family may benefit from a detailed explanation of the genitourinary anatomy, preferably with a model that shows the separate vaginal and urethral openings. The nurse can also indicate that catheterization has no effect on virginity.

Suprapubic aspiration is used mainly when the bladder cannot be accessed through the urethra (e.g., with some congenital urologic birth defects, severe phimosis, or labial adhesions) or to reduce the risk of contamination that may be present when passing a catheter. With the advent of small catheters (5- and 6-Fr straight catheters), the need for suprapubic aspiration has decreased. Access to the bladder via the urethra has a much higher success rate than suprapubic aspiration, in which success depends on the practitioner's skill at assessing the location of the bladder and the amount of urine in the bladder. However, suprapubic aspiration remains a more accurate specimen collection method for urine cultures and should be considered for infants who have unsatisfactory urine collection or inconclusive results (Eliacik, Kanik, Yavascan, et al., 2016).

Suprapubic aspiration involves aspirating bladder contents by inserting a 20- or 21-gauge needle in the midline approximately 1 cm (0.4 inch) above the symphysis pubis and directed vertically downward. The nurse prepares the skin as for any needle insertion, and the bladder should contain an adequate volume of urine. This can be assumed if the infant has not voided for at least 1 hour or the bladder can be palpated above the symphysis pubis or verified via ultrasound. This technique is useful for obtaining sterile specimens from young infants because the bladder is an abdominal organ and is easily accessed. Suprapubic aspiration is painful; therefore pain management during the procedure is important (see Atraumatic Care box).

ATRAUMATIC CARE

Bladder Catheterization or Suprapubic Aspiration

- Use distraction to help the child relax (e.g., blowing bubbles, deep breathing, singing a song).
- Use lidocaine jelly to anesthetize the area before insertion of the catheter. EMLA cream (a eutectic mixture of lidocaine and prilocaine) or LMX cream (lidocaine) may lessen an infant's discomfort as the needle passes through the skin for suprapubic aspiration, but care should be taken that the site is thoroughly cleaned and prepped before the procedure.
- Children often become agitated at being restrained for either procedure. Use comfort measures through touch and voice, both during and after the procedure, to help reduce the child's distress.

STOOL SPECIMENS

Stool specimens are frequently collected from children to identify parasites and other organisms that cause diarrhea, assess gastrointestinal function, and check for occult (hidden) blood. Ideally, stool should be collected without contamination with urine, but in children wearing diapers, this is difficult unless a urine bag is applied. Children who are toilet trained should urinate first, flush the toilet, and then defecate into a bedpan (preferably one that is placed on the toilet to avoid embarrassment) or a commercial potty hat over the toilet. Stool specimens should never be contaminated with toilet water to avoid inaccurate results.

Stool specimens should be large enough to obtain an ample sampling, not merely a fecal fragment. Specimens are placed in an appropriate container, which is covered and labeled. If several specimens are needed, mark the containers with the date and time and keep them in a specimen refrigerator. Exercise care in handling the specimen because of the risk of contamination. If a stool specimen cannot be obtained, some laboratory tests may allow for internal rectal swab.

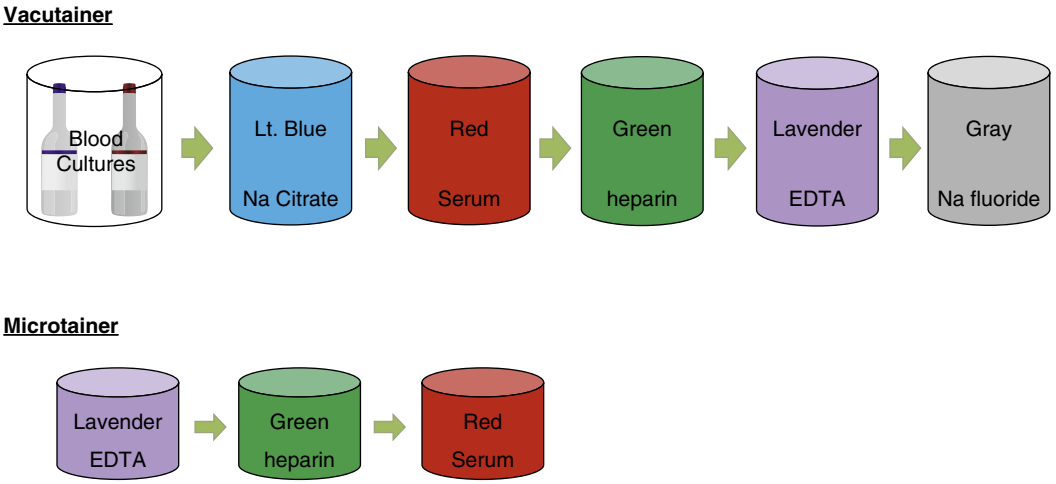

Fig. 20.9 Order of draw for blood collection by vacutainer and microtainer. *EDTA,* Ethylenediaminetetraacetic acid; *Na,* sodium. (Courtesy Cook Children's Medical Center Laboratory.)

NURSING TIP: To obtain a stool specimen, use a tongue depressor or disposable spoon or knife to collect the stool.

BLOOD SPECIMENS

Whether the specimen is collected by the nurse or by others, the nurse is responsible for making certain that specimens, such as serial examinations and fasting specimens, are collected on time and that the proper equipment is available. Collecting, transporting, and storing specimens can have a major impact on laboratory results. For accurate results, blood must be collected in the proper tube for the test. When preparing for blood specimen collection, the nurse should consult the institution's laboratory reference guide to determine appropriate tubes for specimen collection, as well as the volume of blood required for the test, and any special instructions, such as "transport on ice" or "protect from light." Inadequate sample size will result in rejected specimens and may require repeat venipuncture in order to obtain accurate samples, causing additional discomfort for the patient. When multiple blood tests are ordered for a patient and there is concern about the total volume of blood that may be needed, the nurse should be aware that the World Health Organization advises that the maximum volume of blood collected over any 24-hour period should not exceed 3 ml/kg (Clinical Laboratory Standards Institute, 2017; Howie, 2011). When collecting multiple samples via vacutainer system, the order of sample collection also has an impact on test results because the additive from one tube may inadvertently be transferred to subsequent tubes, affecting sample integrity (Clinical Laboratory Standards Institute, 2017). See Fig. 20.9 for proper order of collection. The order of collection is different if collecting blood in capillary tubes or microtainers. Venous blood samples can be obtained by venipuncture or by aspiration from a peripheral or central access device (see Research Focus box). Evidence for best practice supports use of direct venipuncture as the preferred method for venous blood collection because it minimizes risk for hemolysis of the specimen (McCaughey, Vecellio, Lake, et al., 2017). However, when venous access is difficult or repeated specimens are necessary, sampling blood from an indwelling catheter may be warranted. Benefits of sampling blood from an indwelling catheter include decreased anxiety, discomfort, and dissatisfaction associated with venipuncture samples (Infusion Nurses Society, 2016). Withdrawing blood specimens through peripheral lock devices in small peripheral veins has varying degrees of success. Factors influencing successful blood draw through an existing peripheral intravenous (PIV) line include gauge of catheter, location of the PIV catheter, and size of syringe used to obtain the waste sample (Braniff, DeCarlo, Haskamp, & Broome, 2014). When using an IV infusion site for specimen collection, pause the infusion before collecting the blood sample, because the type of fluid being infused may affect test results. For example, a specimen collected for glucose determination would be inaccurate if removed from a catheter through which glucose-containing solution was infusing. Before obtaining laboratory specimens from a PIV catheter, 1 to 2 ml of blood must be withdrawn from the catheter to clear any saline, heparin, or IV fluids from the tubing. Blood cultures should not be obtained through an existing PIV.

RESEARCH FOCUS

Obtaining Blood Samples From Existing Peripheral Intravenous Catheters

Blood specimens collected from existing peripheral intravenous (PIV) catheters in pediatric patients were reviewed for rejected samples. Out of 150 specimens reviewed, successful sample collection occurred in 91.3%. Whether the catheter was heplocked or had fluids infusing did not contribute to sample contamination. There was a low rate of unacceptable specimens (clotted, hemolyzed, insufficient quantity). Only 1.3% of the PIVs were nonfunctional after being used for specimen collection (Braniff et al., 2014).

Central venous catheters can be used to withdraw blood specimens; however, risks include catheter occlusion and catheter-associated bloodstream infection. When collecting blood specimens from a central venous catheter, a small volume of blood must first be withdrawn and discarded to clear the line of any IV fluids, heparin, or other fluids that might erroneously affect test results. The Infusion Nurses Society (2016) recommends withdrawing and discarding 3 ml from the central venous access device (CVAD). Limited research supports using the initial volume obtained as a blood culture specimen (see Research Focus box). The Infusion Nurses Society (2016) recommends not reinfusing the blood obtained as discard sample, due to risk of contamination and clot formation. Some facilities allow reinfusion of the blood initially withdrawn from the CVAD, especially when blood conservation is essential. Another technique that conserves blood is the push-pull

method in which blood is withdrawn into a syringe and reinfused into the CVAD three times. A new sterile syringe is then attached, and the specimen is withdrawn; no blood is discarded (Hess & Decker, 2017). If drawing blood from a multilumen central line, ensure that all lumens are clamped, except for the lumen being used to draw blood.

RESEARCH FOCUS

Central Venous Access Device

In 62 pediatric oncology emergency room patients, the initial 5 ml of blood drawn from a central venous access device (CVAD) was used to inoculate blood culture bottles instead of the usual practice of discarding the first 5 ml of blood. A second specimen was obtained (as per standard of care) and used to inoculate separate blood culture bottles. In the 186 paired blood cultures, 4.8% were positive. In all positive cultures, both specimens contained the same organism. In four pairs, the first specimen that is usually discarded grew organisms earlier than the standard of care specimen, allowing for earlier administration of definitive antibiotic. The results of this study could lead to a change in practice, allowing the first 5 to 10 ml of blood obtained from CVADs to be used for blood cultures, rather than discarding this initial sample (Winokur, Pai, Rutledge, et al., 2014).

When venipuncture is performed, the needed specimens are quickly collected, and after the needle is withdrawn, pressure is applied to the puncture site with dry gauze until bleeding stops (see Atraumatic Care box). When the venipuncture site is in the antecubital fossa, pressure should be applied with the arm extended, not flexed, to reduce bruising. The nurse then covers the site with an adhesive bandage. In young children, adhesive bandages pose an aspiration hazard, so avoid using them or remove the adhesive bandage as soon as the bleeding stops. If bruising or hematoma develops after venipuncture, applying warm compresses to the ecchymotic area increases circulation, helps remove extravasated blood, and decreases pain.

Arterial blood samples are sometimes needed for blood gas measurement, although noninvasive techniques such as transcutaneous oxygen monitoring and pulse oximetry are used frequently. Arterial samples may be obtained by arterial puncture using the radial, brachial, or femoral arteries or from indwelling arterial catheters. Assess adequate circulation before arterial puncture by observing capillary refill or performing the **Allen test**, a procedure that assesses the circulation of the radial, ulnar, or brachial arteries. When collecting a blood sample from an established arterial line, use the in-line sampling port and follow institutional policy. Because unclotted blood is required,

ATRAUMATIC CARE

Guidelines for Skin and Vessel Punctures

To reduce the pain associated with heel, finger, venous, or arterial punctures:

- Apply a lidocaine-based topical cream to the site, if time permits: lidocaine-prilocaine (EMLA) cream should be applied at least 60 minutes prior to venipuncture; lidocaine 4% cream (LMX) requires a 30-minute application time. A dollop of cream is applied to the skin and then covered by a transparent dressing for the application time. To remove the transparent dressing atraumatically, grasp opposite sides of the film and pull the sides away from each other to stretch and loosen the film. After the film begins to loosen, grasp the other two sides of the film and pull. As an alternative, the cream can be covered by a 3- to 4-inch piece of kitchen plastic wrap.
- When unable to wait 30 to 60 minutes for EMLA or LMX products to work, a vapocoolant spray or buffered lidocaine (injected intradermally near the vein with a 30-gauge needle) can be used to numb the skin. Buffered lidocaine can also be administered using a J-tip needleless injection system (Stoltz & Manworren, 2017).
- Use nonpharmacologic methods of pain and anxiety control (e.g., ask the child to take a deep breath when the needle is inserted and again when the needle is withdrawn, to exhale a large breath or blow bubbles to "blow hurt away," or to count slowly and then faster and louder if pain is felt).
- Keep all equipment out of sight until used.
- Enlist parental presence or assistance if they wish.
- Restrain child *only as needed* to perform the procedure safely; use comfort positioning.
- Allow the skin preparation to dry completely before penetrating the skin.
- Use the smallest gauge needle (e.g., 23 to 25 gauge) that permits free flow of blood; for neonates and infants, a 27-gauge needle may be sufficient for obtaining 1 to 1.5 ml of blood and for prominent veins (needle length is only 1.25 cm [0.5 inch]).
- If possible, avoid putting an IV catheter in the dominant hand or the hand the child uses to suck the thumb.
- Use an automatic lancet device for precise puncture depth of the finger or heel; press the device lightly against the skin; avoid steadying the finger against a hard surface.
- Have a "two-try-only" policy to reduce excessive insertion attempts—two operators each have two insertion attempts. If insertion is not successful after four punctures, consider alternative venous access, such as a PICC.
- Have a policy for proactively identifying children with difficult access and appropriate interventions (e.g., most experienced operator for the first attempt, use transilluminator or ultrasonography for insertion guidance).

For Multiple Blood Samples

- Use an intermittent infusion device (saline lock) to collect additional samples from an existing IV line.
- Consider PICC lines early, not as a last resort.
- Coordinate care to allow several tests to be performed on one blood sample; use micromethods of collection whenever possible.
- Anticipate tests (e.g., drug levels, chemistry, immunoglobulin levels) and ask the laboratory to save blood for additional testing.
- Maximum blood collection volumes for any 24-hour period should not exceed 3 ml/kg; limits should be lower for children who are acutely or chronically ill (Clinical Laboratory Standards Institute, 2017; Howie, 2011)

For Heel Lancing in Newborns

- Heelsticks have been shown to be more painful than venipuncture (Shah & Ohlsson, 2011).
- Kangaroo care (placing the diapered newborn against the parent's bare chest in skin-to-skin contact) 10 to 15 minutes before and during heel lance reduces pain. (Gao, Xu, Gao, et al., 2015; Johnston, Campbell-Yeo, Disher, et al., 2017)
- Breastfeeding during a neonatal heel lance is effective in reducing pain and has been found to be more effective than sucrose in some studies (Benoit, Martin-Misener, Latimer, et al., 2017). If breast milk is unavailable, administer sucrose and encourage the newborn to suck a pacifier (Stevens, Yamada, Ohlsson, et al., 2016). When commercially manufactured 24% sucrose solution is unavailable, add 1 teaspoon of table sugar to 4 teaspoons of sterile water. Use this solution to coat the pacifier or administer 2 ml to the tongue 2 minutes before the procedure.
- Although safe for use in preterm infants when applied correctly, EMLA has been found to be no more effective than placebo in preventing pain during heel lancing (Anand & Hall, 2006).

EMLA, Eutectic mixture of local anesthetics; *IV,* intravenous; *LMX,* lidocaine; *PICC,* peripherally inserted central catheter.

Fig. 20.10 Puncture site *(colored stippled area)* on the sole of an infant's foot.

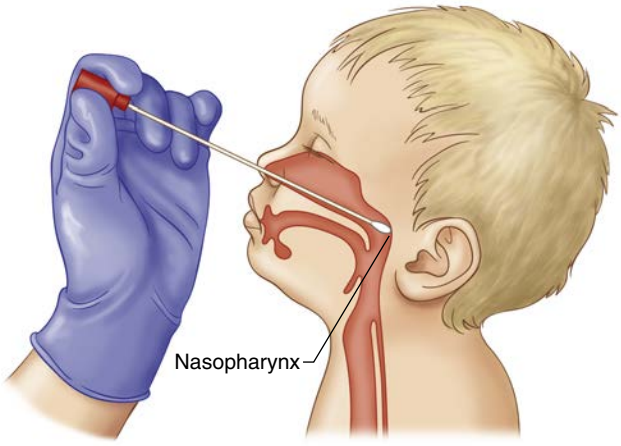

Fig. 20.11 Technique for collecting a nasopharyngeal swab. (From "Standard method for detecting upper respiratory carriage of *Streptococcus pneumonia:* Updated recommendations from the World Health Organization Pneumococcal Carriage Working Group," by C. Satzke, P. Turner, A. Virolainen-Julkunen, P. V. Adrian, M. Antonio, K. M. Hare . . . K. L. O'Brien, 2013, *Vaccine, 32*(1), p. 168. Copyright 2013 by Elsevier Ltd. Reprinted with permission.)

use only heparinized collection tubes or syringes for arterial blood samples. In addition, no air bubbles should enter the collection tube or syringe because they can alter blood gas concentration. Crying, fear, and agitation affect blood gas values; therefore make every effort to comfort the child. Pack arterial blood samples in ice to reduce blood cell metabolism and transport to the laboratory immediately.

Take capillary blood samples from children by fingerstick or heelstick. When using a finger for capillary blood collection, use the second or third finger. Cleanse the area with alcohol or chlorhexidine and allow to dry. After performing the fingerstick, wipe once with dry gauze before beginning collection. Gently massage the entire finger to maintain blood flow. Avoid squeezing just the tip of the finger. Hold the fingerstick site facing downward to facilitate blood collection. A common method for taking peripheral blood samples from infants younger than 6 months old is by heelstick. Before the blood sample is taken, warm the heel for 3 minutes, then cleanse the area with alcohol or chlorhexidine. Holding the infant's foot firmly with the free hand, the nurse then punctures the heel with an automatic lancet device. An automatic device delivers a more precise puncture depth and is less painful than using a lance (Sorrentino, Fumagalli, Milani, et al., 2017). Several studies demonstrate that the automatic lancet is safer and has been shown to require fewer heel punctures, less collection time, and lower recollection rates. Sorrentino and colleagues (2017) reported that certain automated devices were more effective and that a surgical blade of any kind is contraindicated when obtaining blood by heelstick. Although obtaining capillary venous blood gases is a common practice, these measures may not accurately reflect arterial values.

The most serious complications of infant heel puncture are necrotizing osteochondritis from lancet penetration of the underlying calcaneus bone, resulting in infection and abscess of the heel. To avoid osteochondritis, the puncture should be no deeper than 2 mm and should be made at the outer aspect of the heel. The boundaries of the calcaneus can be marked by an imaginary line extending posteriorly from a point between the fourth and fifth toes and running parallel with the lateral aspect of the heel and another line extending posteriorly from the middle of the great toe and running parallel with the medial aspect of the heel (Fig. 20.10). Repeated trauma to the walking surface of the heel can cause fibrosis and scarring that may interfere with locomotion.

Children do not like the discomfort associated with venous, arterial, and capillary punctures. Children have identified these procedures as the most frequent causes of pain during hospitalization. Arterial puncture was identified as one of the most painful of all procedures experienced. Toddlers are most distressed by venipuncture, followed by school-age children and then adolescents. Consequently, nurses should use developmentally appropriate language when preparing a child for venipuncture (see Table 20.1 and Applying Evidence to Practice: Age-Specific Preparation of Children for Procedures Based on Developmental Characteristics) and use developmentally appropriate pain reduction techniques to lessen the discomfort of these procedures. (See Chapter 5, Pain Management.)

RESPIRATORY SECRETION SPECIMENS

Upper respiratory tract infections are common in children, and about 80% of these infections are due to viruses. Laboratory detection of important viruses such as influenza and respiratory syncytial virus (RSV) can be diagnosed from epithelial cells of the nasopharynx. These respiratory specimens are usually collected by nasopharyngeal swab or nasal wash. The choice of collection method depends on laboratory specifications. The nurse is responsible for confirming which collection method is preferred for the test ordered.

For collection by nasopharyngeal swab, ensure that the appropriate swab is used, as specified in the laboratory manual. The swab should be flocked or rayon. Use only swabs with plastic shafts. Do not use cotton swabs or swabs with wooden shafts, as these will result in inadequate specimen. After gathering the necessary supplies, the nurse should don mask and gloves. If the child has a lot of nasal secretions, have him or her blow the nose prior to the procedure (remember that the nurse is collecting epithelial cells and not nasal discharge). The child should be placed in a sitting position. For younger children or children who may have difficulty holding still, a comfort hold by a second caregiver is strongly recommended to avoid injury. With the child in position, tilt the head up slightly, then gently insert the swab into the nose, aiming toward the ear, parallel to the palate, until it reaches the posterior nares (half the distance from the nostril to the opening of the ear) (Fig. 20.11). Gently rotate the swab for 10 to 15 seconds while withdrawing it from the nose. Be aware that the child may sneeze or cough during this procedure. Once the swab is removed, immediately place it in the transport media tube, then snap off the top part of the plastic shaft so that the cap can be closed securely on the transport tube. Specimens for *Bordetella pertussis* are also collected in this manner, but they must be placed in a different transport media.

For collection by nasal wash, gather supplies and don mask and gloves, then place the child supine, with an additional caregiver providing a comfort hold if needed. Using a sterile syringe without a needle, instill 1 to 3 ml of sterile normal saline into one nostril. Then aspirate the contents using a small, sterile bulb syringe and place them in a sterile container. As an alternate method, use a syringe with 5 cm (2 inches) of 18- to 20-gauge tubing attached. Gently insert the tubing into the nostril, then quickly instill the saline and promptly aspirate while withdrawing the tubing to recover the nasal specimen. To prevent any additional discomfort, all equipment should be ready before beginning the procedure.

Specimens from the oropharynx are collected for diagnosis of streptococcal throat infections, *Bordetella*, and other pathogens. With the child in a sitting position and using the appropriate swab, the nurse should swab both tonsils and the posterior pharynx when obtaining a throat culture. Ideally, the swab should not touch the tongue, teeth, or gums. The swab stick should then be inserted into the culture tube, taking care that the swab does not come in contact with the outside of the container or the hands of the nurse collecting the sample. Some culture kits require squeezing an ampule within the transport tube to release the culture medium. Viral testing usually requires that the specimen be place in a container with special transport medium and be kept on ice. The nurse should ensure that the correct container is on hand before obtaining the specimen.

Infections of the lower respiratory tract, such as pneumonia or tuberculosis, may require sputum collection. Because the infectious organisms are in the lungs and lower airways, the sputum specimen must be produced by deep cough, not just spitting oral secretions into a container. Older children and adolescents can cough as directed and supply sputum specimens when given proper directions. The nurse must make it clear to the patient that a coughed specimen is needed, not merely mucus cleared from the throat. It is helpful to demonstrate a deep cough. Infants and small children are unable to follow directions to cough on command, and often swallow any sputum produced; therefore gastric washings (lavage) may be used to collect a sputum specimen. Gastric washing specimens should be collected in early morning for best results. Sometimes a satisfactory specimen can be obtained using a suction device, such as a mucus trap, if the catheter is inserted into the trachea and the cough reflex is elicited. A catheter inserted into the back of the throat is not sufficient. For children with a tracheostomy, a specimen is easily aspirated from the trachea or major bronchi by attaching a collecting device to the suction apparatus. Sputum collection from a young child can be uncomfortable, so the nurse should be sure to provide developmentally appropriate comfort measures.

ADMINISTRATION OF MEDICATION

DETERMINATION OF DRUG DOSAGE

Nurses must understand the safe dosages of medications that they administer to children, as well as the expected actions, possible side effects, and signs of toxicity. Unlike the standardized doses for adult medications, dosing for pediatric medications is usually presented as a recommended dosage range based on the age, weight, and/or body surface area (BSA) of the child. Differences between adult and pediatric dosing of medications are related to physiologic differences. Factors related to growth and maturation significantly alter an individual's capacity to metabolize and excrete drugs. Immaturity or defects in any of the important processes of absorption, distribution, biotransformation, or excretion can significantly alter the pharmacodynamics of a drug, resulting in increased toxicity or inadequate effect. Newborn and premature infants are particularly vulnerable to the harmful effects of drugs because they have immature enzyme systems in the liver (where most drugs are broken down and detoxified), lower concentrations of plasma proteins (necessary for binding with drugs), and immature functioning of kidneys (where most drugs are excreted). Beyond the newborn period, children metabolize many drugs more rapidly than adults. Consequently, children may require larger doses (per weight) than adults and/or more frequent administration to achieve a therapeutic effect. This is particularly important in pain control, when the dosage of analgesics may need to be increased or the interval between doses decreased to obtain a therapeutic effect.

Nurses are accountable for the medications that they administer. An important part of that responsibility is having a working knowledge of drug actions and potential side effects. In addition, nurses should know the safe dose ranges for the drugs with which they work. Before giving any medication, the pediatric nurse must be vigilant to verify that the drug has been dispensed in a dose that is within the recommended range for the child. Pediatric dosages are most often expressed in units of measure per body weight (mg/kg). Some medications, such as chemotherapy, are more precisely dosed using BSA (expressed as mg/m^2), which historically is believed to be a more accurate reflection of metabolic rate and less affected by adipose tissue than weight-based calculations. The ratio of BSA to weight varies inversely with length; therefore an infant who is shorter and weighs less than an older child or adult has relatively more BSA than would be expected from the weight. BSA can be determined using the **West nomogram** or the commonly used Mosteller formula: BSA = the square root of [height (cm) × weight (kg)] divided by 3600. Conversion programs are widely available on the Internet.

Checking Dosage

Administering the correct dosage of a drug is a shared responsibility between the provider who orders the drug and the nurse who carries out that order. Children react with unexpected severity to some drugs, and ill children may be especially sensitive to drugs. When a dose that is outside the usual range is ordered or when there is some question regarding the preparation or the route of administration, the nurse should check with the prescribing provider before proceeding with the administration, because the nurse is legally liable for any drug administered.

Even when given at the correct dosage, many drugs are potentially hazardous or lethal. For this reason, the Institute for Safe Medication Practices has identified a list of "high-alert" medications (see https://www.ismp.org/recommendations/high-alert-medications-acute-list). Most facilities have regulations requiring that these "high-alert" medications be double-checked by another nurse before giving them to the child. Among drugs that require such additional safeguards to reduce risk of error and minimize harm are antiarrhythmics, anticoagulants, chemotherapeutic agents, and insulin. Other high-alert medications include epinephrine, opioids, and sedation agents (Institute for Safe Medication Practices, 2018; Maaskant, Eskes, van Rijn-Bikker, et al., 2013). A misplaced decimal point could result in a 10-fold or greater dosing error. So even if this precaution is not mandatory, nurses are wise to incorporate this safe practice and take the additional time to independently check and recheck drug dose calculations.

Another category of high-alert medications is the "look-alike, sound-alike" drugs that have similar names but significantly different doses and side effects. To emphasize these differences, Tall Man lettering is recommended by the Institute for Safe Medication Practices and the US Food and Drug Administration (Institute for Safe Medication

Practices, 2016). Examples of Tall Man lettering include DOBUTamine and DOPamine, and predniSONE and prednisoLONE.

Identification

Before the administration of any medication, the child must be correctly identified using two identifiers (e.g., name and medical record number or birth date). With an infant, young child, or nonverbal child, the parent or guardian (if present) can verify the child's identity. After verbal verification of the child's identity (by the parent, guardian, or child), the identification band should be verified using two identifiers. Bedside computers and handheld barcode scanners can be used to verify the identification bracelet directly with the patient's electronic record.

Preparing the Parents

Nearly all parents have given some type of medication to their child and can describe the approaches that they have found successful. In some cases, it is less traumatic for the hospitalized child if a parent gives the medication, provided that the nurse prepares the medication and supervises its administration. Children who take daily medications at home are accustomed to the parent functioning in this capacity and may be less likely to fuss than if a stranger administers the medication. Individual decisions need to be made regarding parental presence and participation in other procedures, such as holding the child during injections.

Preparing the Child

Every child requires developmentally appropriate preparation for parenteral administration of medication and supportive care during the procedure (see discussion earlier in the chapter). Even if the child has received previous injections, rarely does a child become accustomed to the discomfort. With every dose of medication, the nurse should be cognizant of the developmental needs of the child, whether it is the first dose or the 200th dose for that child.

ORAL ADMINISTRATION

The oral route is preferred for giving medications to children because of the ease of administration. Oral medications are available in various dosing formulations, including tablets, capsules, chewable tablets, orally dissolving tablets, sprinkles, and oral liquids. Although some children can swallow or chew solid medications at an early age, solid preparations are not recommended for young children because of the danger of aspiration. Determining when a child is old enough to swallow pills depends on the developmental age of the child, the size of the pill, and the child's past experiences with medications. The nurse should ensure that the formulation of any prescribed medication will be appropriate for the child, based on developmental level, swallowing ability, and available formulations of the medication.

Many pediatric medications come in liquid preparations for added ease of administration. Some of these liquids have a slightly unpleasant aftertaste. The taste can be camouflaged when necessary, by mixing the medication with a small amount of juice or applesauce. In the hospital, pharmacies can provide flavored syrup, known as Syrpalta, for this purpose (see Atraumatic Care box).

Preparation

The most accurate means for measuring small amounts of medication is the plastic disposable calibrated oral syringe (Centers for Disease Control and Prevention, 2017; Paul & Yin, 2012; US Food and Drug Administration, 2011). Not only does the syringe provide a reliable measure, but it also serves as a convenient means for transporting and administering the medication. The medication can be placed directly into the child's mouth from the syringe.

Paper cups are totally unsuitable for liquid medications because they collapse easily, are likely to have irregularly shaped or crumpled bottoms, and retain considerable amounts of thick medication. Molded plastic cups with measuring lines are often supplied with over-the-counter medications for cough and fever, but most families in one study could not accurately measure a 5-ml dose within 0.5 ml (Ryu & Lee, 2012; Yin, Parker, Sanders, et al., 2016). Quantities less than 5 ml are impossible to determine accurately with a medicine cup.

The household teaspoon is also an inaccurate measuring device and is subject to error. Household teaspoons vary greatly in capacity, and different persons using the same spoon will pour different amounts, resulting in potentially dangerous dosing errors (Beckett, Tyson, Carroll, et al., 2012; Torres, Parker, Sanders, et al., 2017).

Because of the risk of inaccurate dosing when using medicine cups and teaspoons, a policy statement issued by the American Academy of Pediatrics recommends that all liquid oral medications, over-the-counter and prescription, should be dosed only in milliliters and never in teaspoons or other nonmetric units (American Academy of Pediatrics, Committee on Drugs, 2015). Syringes are the preferred device for dosing accuracy. Measuring cups with metric markings may be used as an alternative. A convenient hollow-handled medicine spoon with calibrations is available to accurately measure and administer the drug. Household spoons, including measuring spoons, should be avoided.

Another unreliable device for measuring liquids is the dropper, which varies to a greater extent than the teaspoon or measuring cup. The volume of a drop varies according to the viscosity (thickness) of

ATRAUMATIC CARE

Encouraging a Child's Acceptance of Oral Medication

- Give the child a flavored ice pop or small ice cube to suck to numb the tongue before giving the drug.
- Mix the drug with a small amount (about 5 ml) of sweet-tasting substance, such as flavored syrups, jam, fruit purees, sherbet, or applesauce; avoid essential food items because the child may later refuse to eat them.
- Wrap bad-tasting pills (i.e., corticosteroids) in a small piece of fruit-flavored candy roll-up.
- Give a "chaser" of water, juice, or child's drink of choice, or ice pop or frozen juice bar after the drug.
- Avoid dairy products with medication administration due to risk of interfering with absorption
- If nausea is a problem, give a carbonated beverage poured over finely crushed ice before or immediately after the medication.
- When medication has an unpleasant taste, have the child pinch the nose and drink the medicine through a straw. Much of what we taste is associated with smell.
- Commercially available flavorings, such as apple, banana, and bubble gum can be added at many local pharmacies for a nominal additional cost. As an alternative, some pharmacies may be able to prepare the drug in a flavored, chewable troche or lozenge. Infants will suck medicine from a needleless syringe or dropper in small increments (0.25 to 0.5 ml) at a time.
- Use a nipple or a special pacifier with a reservoir for the drug.
- Avoid adding a medication to an infant's regular bottle, as the infant may not drink the entire bottle within a time frame appropriate for one dose of medication.

the liquid measured (Bauters, Claus, Willems, et al., 2012). Viscous fluids produce much larger drops than thin liquids. The Institute for Safe Medication Practices (2017) recommends only using droppers that display a metric scale and describe the medication dose in milliliters, not in drops. In addition, the Institute for Safe Medication Practices recommends using an oral syringe to administer the dose, for better accuracy.

Young children and some older children have difficulty swallowing tablets or pills. For these children, if a liquid formulation is not available, tablets may need to be crushed. Commercial devices for crushing pills are available. Simple methods can also be used, such as crushing a pill between two spoons or placing the pill in a plastic sandwich bag and then crushing it with a spoon. Certain pills may easily be dissolved in a small amount of warm water. Crushed tablets can be mixed with applesauce or a small amount of juice for ease of administration. Some drugs, such as medication with an enteric or protective coating or formulated for slow release, should not be crushed because crushing will alter the amount of drug that is absorbed. In some cases, this might result in overdose of medication. The Institute for Safe Medication Practices maintains a list of oral medications that should not be crushed (http://www.ismp.org/tools/DoNotCrush.pdf). In addition, some drugs may be hazardous if the powder becomes aerosolized while being crushed. These drugs should be prepared in a pharmacy, or the pharmacist or drug label should be consulted for recommendations.

When a child needs to take solid oral medication for an extended period, the nurse can teach the child how to swallow tablets or capsules. Training sessions include verbal instruction, demonstration, reinforcement for swallowing progressively larger candy or capsules, no attention for inappropriate behavior, and gradual withdrawal of guidance after children can swallow their medication. Helpful tips for patients of all ages can be found at http://www.pillswallowing.com.

In some situations, pediatric doses may require splitting pills or tablets. The nurse should be vigilant to ensure that the divided dose is accurate. With tablets, only those that are scored can be halved or quartered accurately. If the medication is soluble, the tablet or contents of a capsule can be mixed in a small premeasured amount of liquid and the appropriate portion given (Valizadeh, Rasekhi, Hamishehkar, et al., 2015). For example, if half a dose is required, the tablet is dissolved in 5 ml of water, and 2.5 ml is given.

Administration

Although administering liquids to infants is relatively easy, the nurse must take care to prevent aspiration. While holding the infant in a semireclining position, place the medication in the mouth using an oral syringe. It is best to place the syringe along the side of the infant's tongue and administer the liquid slowly in small amounts, waiting for the child to swallow between increments.

NURSING TIP In infants up to 11 months old and children with neurologic impairments, blowing a small puff of air in the face frequently elicits a swallow reflex.

Allowing the infant to suck the medication that has been placed in an empty nipple or, for breastfeeding infants, inserting the syringe into the side of the mouth, parallel to the nipple, while the infant nurses are other convenient methods for giving liquid medications to infants. Medication is not added to the infant's formula feeding because the child may subsequently refuse the formula. Dispose of any plastic covers that may be on the ends of syringes because these covers are choking hazards.

Children are more likely to take their oral medication willingly if they feel involved in the process (as opposed to being forced). Giving choices to a child helps them feel involved. Although taking the medicine is not a choice, the child can be offered other options such as whether they want to take the medicine before or after a specific activity, what they would like to drink with their medicine, or if they want to help give the medicine. Allowing a child to push the plunger of the syringe of oral medication while the caregiver holds the syringe in the mouth may improve adherence.

Fig. 20.12 A nurse partially restrains a child for easy and comfortable administration of oral medication.

When giving oral liquids from a syringe, it is often helpful to give the dose in several small increments and allow the child to swallow between squirts. Place the tip of the syringe into the pocket formed between the lower teeth and cheek. Aiming at the back of the throat increases the risk of aspiration. Children who refuse to cooperate or who resist consistently despite explanation and encouragement may require physical holding. If holding is necessary, it should be done in a position of comfort, sitting up or semireclining. Make every effort to reassure the child that holding is for his or her well-being and is not a form of punishment. There is always a risk in using even mild forceful techniques. A crying child can aspirate a medication, particularly when lying on the back. If the nurse holds the child in the lap with the child's right arm behind the nurse, the left hand firmly grasped by the nurse's left hand, and the head securely cradled between the nurse's arm and body, the medication can be slowly administered into the mouth (Fig. 20.12).

Because of the natural outward tongue thrust in infancy, medications may need to be retrieved from the lips or chin and refed. If part of a dose of oral medication is lost due to spitting, drooling, or vomiting, the nurse should discuss with a provider before readministering the dose. There are no evidence-based recommendations regarding a specific time frame for repeating a dose of medication after a patient has vomited (Kendrick, Ma, DeZorzi, et al., 2012). Because it is difficult to accurately estimate the amount of dose that was received, giving additional amounts may result in overdose.

INTRAMUSCULAR ADMINISTRATION

Selecting the Syringe and Needle

The volume of medication prescribed for intramuscular (IM) injections in small children necessitates selection of a syringe that can measure small amounts of solution. For volumes less than 1 ml, the

tuberculin syringe, calibrated in 0.01-ml increments, is appropriate. Doses smaller than 0.5 ml may be facilitated by the use of a 0.5-ml, low-dose syringe. These syringes, along with specially constructed needles, minimize the possibility of inadvertently administering incorrect amounts of a drug because of **dead space**, which allows fluid to remain in the syringe and needle after the plunger is pushed completely forward. A minimum of 0.2 ml of solution remains in a standard needle hub; therefore when very small amounts of two drugs are combined in the syringe, such as mixtures of insulin, the ratio of the two drugs can be altered significantly due to dead space. Measures that minimize the effect of dead space are (1) when two drugs are combined in the syringe, always draw them up in the same order to maintain a consistent ratio between the drugs, (2) use the same brand of syringe (dead space may vary between brands), and (3) use one-piece syringe units (needle permanently attached to the syringe).

Dead space is also an important factor to consider when injecting medication because flushing the syringe with an air bubble adds an additional amount of medication to the prescribed dose. This can be hazardous when very small amounts of a drug are given. Consequently, flushing is not recommended, especially when less than 1 ml of medication is given. Syringes are calibrated to deliver a prescribed drug dose, and the amount of medication left in the hub and needle is not part of the syringe barrel calibrations.

Certain drugs (such as iron dextran and diphtheria and tetanus toxoid) may cause irritation if inadvertently tracked into the subcutaneous tissue. To prevent tracking, the Z-track method is recommended to prevent drug leakage (Yilmaz, Khorshid, & Dedeoglu, 2016). The Z-track method is performed by using the nondominant hand to move skin slightly laterally at the injection site just prior to inserting the needle. This action will shift the subcutaneous skin over the muscle below. Maintain the skin in this displaced position while giving the injection, then remove the needle before releasing the skin. The skin and subcutaneous tissue slide back to their original position, creating an interruption in the needle's pathway and minimizing the risk of fluid leaking from the muscle into subcutaneous tissue. Changing the needle after withdrawing the fluid from the vial is another technique to minimize tracking.

The needle length must be sufficient to penetrate the subcutaneous tissue and deliver the medication into the body of the muscle. The needle gauge should be as small as possible to deliver the fluid safely. Smaller-diameter (25- to 30-gauge) needles cause the least discomfort, but larger gauges are needed for viscous medication and prevention of accidental bending of longer needles.

Determining the Site

Factors to consider when selecting a site for an IM injection on an infant or child include:

- The amount and viscosity of the medication to be injected
- The amount and general condition of the muscle mass
- The frequency or number of injections to be given during the course of treatment
- The type of medication being given
- Factors that may impede access to or cause contamination of the site
- The child's ability to assume the required position safely

Older children and adolescents usually pose few problems in selecting a suitable site for IM injections, but infants, with their small and underdeveloped muscles, have fewer available options. It is sometimes difficult to assess the amount of fluid that can be safely injected into a single site. Usually 1 ml is the maximum volume that should be administered in a single site to small children and older infants. The muscles of small infants may not tolerate more than 0.5 ml. As the child approaches adult size, the nurse can use volumes approaching those given to adults. However, the larger the amount of solution, the larger the muscle at the injection site must be.

Injections must be placed in muscles large enough to accommodate the medication, while avoiding major nerves and blood vessels. The IM immunization site recommended by the Centers for Disease Control and Prevention, World Health Organization, and American Academy of Pediatrics for infants is the anterolateral thigh or vastus lateralis (Table 20.5). Additional studies have shown that injections at the ventrogluteal site are suitable for children and infants as young as 2 months old (Atay, Kurt, Akkaya, et al., 2017; Yapucu, Ceylan, & Bayindir, 2016). Cook and Murtagh (2006) also found fewer systemic reactions (irritability and persistent crying or screaming) and greater

TABLE 20.5 Intramuscular Injection Sites in Children

Site	DISCUSSION
Vastus Lateralis	
	***Location***[a] Palpate to find greater trochanter and knee joints; divide vertical distance between these two landmarks into thirds; inject into middle third ***Needle Insertion and Size*** Insert needle perpendicular to knee in infants and young children or perpendicular to thigh or slightly angled toward anterior thigh 22 to 25 gauge (⅝ to 1 inch) ***Advantages*** Large, well-developed muscle that can tolerate larger quantities of fluid (0.5 ml [infant] to 2.0 ml [child]) Easily accessible if child is supine, side lying, or sitting ***Disadvantages*** Thrombosis of femoral artery from injection in midthigh area Sciatic nerve damage from long needle injected posteriorly and medially into small extremity More painful than deltoid or gluteal sites

TABLE 20.5 Intramuscular Injection Sites in Children—cont'd

Site	DISCUSSION
Ventrogluteal  Ventrogluteal site of injection	***Location***[a] Palpate to locate greater trochanter, anterior superior iliac tubercle (found by flexing thigh at hip and measuring up to 1 to 2 cm [0.4 to 0.8 inch] above crease formed in groin), and posterior iliac crest; place palm of hand over greater trochanter, index finger over anterior superior iliac tubercle, and middle finger along crest of ileum posteriorly as far as possible; inject into center of V formed by fingers ***Needle Insertion and Size*** Insert needle perpendicular to site but angled slightly toward iliac crest 22 to 25 gauge (½ to 1 inch) ***Advantages*** Free of important nerves and vascular structures Easily identified by prominent bony landmarks Thinner layer of subcutaneous tissue than in dorsogluteal site, thus less chance of depositing drug subcutaneously rather than intramuscularly Can accommodate larger quantities of fluid (0.5 ml [infant] to 2.0 ml [child]) Easily accessible if child is supine, prone, or side lying Less painful than vastus lateralis ***Disadvantages*** Health professionals' unfamiliarity with site
Deltoid  	***Location***[a] Locate acromion process; inject only into upper third of muscle that begins about two fingerbreadths below acromion ***Needle Insertion and Size*** Insert needle perpendicular to site but angled slightly toward shoulder 22 to 25 gauge (½ to 1 inch) ***Advantages*** Faster absorption rates than gluteal sites Easily accessible with minimal removal of clothing Less pain and fewer local side effects from vaccines compared with vastus lateralis ***Disadvantages*** Small muscle mass; only limited amounts of drug can be injected (0.5 to 1.0 ml) Small margins of safety with possible damage to radial nerve and axillary nerve (not shown; lies under deltoid at head of humerus)

[a]Locations are indicated by asterisks (*) on illustrations.

parental acceptance for the ventrogluteal site. The ventrogluteal site is relatively free of major nerves and blood vessels, is a relatively large muscle with less subcutaneous tissue than the dorsal site, has well-defined landmarks for safe site location, and is easily accessible in several positions. Distraction and prevention of unexpected movement may be more easily achieved by placing the child supine on a parent's lap for ventrogluteal site use (Cook & Murtagh, 2006). The deltoid muscle, a small muscle near the axillary and radial nerves, can be used for small volumes of fluid in children as young as 18 months old. Its advantages are less pain and fewer side effects from the injectate (as observed with immunizations), compared with the vastus lateralis. Table 20.5 summarizes the three major injection sites and the location of the preferred IM injection sites for children.

Administration

Although injections that are executed with care seldom cause trauma to children, there have been reports of serious disability related to IM injections in children. Repeated use of a single site has been associated with fibrosis of the muscle with subsequent muscle contracture. Injections close to large nerves, such as the sciatic nerve, have been responsible for permanent disability, especially when potentially neurotoxic drugs are administered. For this reason, the dorsogluteal muscle (buttocks) is no longer recommended as a site for IM injections for children under the age of 10 years (Brown, Gillespie, & Chard, 2015).

Aspiration prior to injection of IM medications is no longer universally recommended. Traditionally, the absence of blood during aspiration is intended to confirm that the medication is being delivered intramuscularly and not inadvertently being injected into a vein. However, there is insufficient evidence to show that significant adverse reactions have occurred when aspiration has not been performed (Sepah, Samad, Alrag, et al., 2017). In addition, studies have shown that aspiration can increase the pain associated with injection. Aspiration during IM vaccine administration is no longer recommended by the Centers for Disease Control and Prevention, World Health Organization, American Academy of Pediatrics, or Immunization Action Coalition (Ezeanolue, Harriman, Hunter, et al., 2019; Sisson, 2015; Thomas, Mraz, & Rajcan, 2016). Aspiration for routine injections into deltoid or vastus lateralis is not indicated because there are no large blood vessels in these locations. Aspiration may still be indicated before injection of medications such as penicillin into larger muscle groups such as the ventrogluteal site (Crawford & Johnson, 2012). Aspiration should also be considered if the medication has a high risk of adverse effects if administered intravenously (Sepah et al., 2017).

IM injections should be delivered with the needle perpendicular to the surface of the skin (Ezeanolue et al., 2019). One classic study of IM injection techniques revealed that the straighter the path of needle insertion (e.g., 90-degree angle), the less displacement and shear to tissue, causing less discomfort (Katsma & Smith, 1997).

When preparing medication from a glass ampule, a reported potential hazard is the inadvertent creation of glass particles that fall into the medication solution when the ampule is broken open. When the medication is withdrawn into the syringe, the glass particles may also be withdrawn and subsequently injected into the patient. As a precaution, medication from glass ampules must be withdrawn through a needle with a filter.

Most children are unpredictable, and few are totally cooperative when receiving an injection. Even children who appear to be relaxed and constrained can become nervous under the stress of the procedure and find it difficult to sit still for an injection. It is advisable to have someone available to help hold the child during an injection, if needed. Because children often jerk or pull away unexpectedly, the nurse should carry an extra needle to exchange for the contaminated one so that delay is minimal. The child, even a small one, is told that he or she is receiving an injection (preferably using a phrase such as "putting the medicine under the skin"), and then the procedure is carried out as quickly and skillfully as possible to avoid prolonging the stressful experience. Invasive procedures such as injections are especially anxiety provoking in young children, who may associate any painful procedure, especially one that requires being held tightly, with punishment. Because injections are painful, the nurse should use excellent injection techniques and developmentally appropriate pain reduction measures to reduce discomfort (see Nursing Care Guidelines box).

NURSING CARE GUIDELINES

Intramuscular Administration of Medication

- Apply EMLA (a eutectic mix of lidocaine and prilocaine) or LMX cream (lidocaine) topically over injection site if time permits. (See Chapter 5, Pain Management.)
- Prepare medication.
  - Select appropriate-size needle and syringe.
  - If withdrawing medication from an ampule, use a needle equipped with a filter that removes glass particles; then change to a new, nonfilter needle for injection.
  - Maximum volume to be administered in a single site is 1 ml for older infants and small children and 2 ml for older children and adolescents.
  - Have medication at room temperature before injection.
- Determine site of injection (see Table 20.5); make certain that the muscle is large enough to accommodate volume and type of medication.
  - For infants and small or debilitated children, use the vastus lateralis or ventrogluteal muscles; for school-age children and adolescents, use the deltoid or ventrogluteal muscle.
- Obtain sufficient help for restraining child, if needed.
- Explain briefly what is to be done and, if appropriate, what the child can do to help.
- Expose injection site area for unobstructed view of landmarks.
- Select a site where skin is free of irritation and danger of infection; palpate for and avoid sensitive or hardened areas.
- With multiple injections, rotate sites. When giving multiple injections at the same time (e.g., immunizations), the Centers for Disease Control and Prevention recommends that injection sites in the same muscle group must be at least 1 inch apart (Ezeanolue et al., 2019).
- Place child in a lying or sitting position; child is not allowed to stand because landmarks are more difficult to assess, restraint is more difficult, and the child may faint and fall.
  - **Ventrogluteal:** On side with upper leg flexed and placed in front of lower leg
  - **Vastus lateralis:** Supine, lying on side, or sitting
- Use a new, sharp needle (not one that has pierced rubber stopper on vial) with smallest diameter that permits free flow of the medication.
- Grasp muscle firmly between thumb and fingers to isolate and stabilize muscle for deposition of drug in its deepest part; in obese children, spread skin with thumb and index finger to displace subcutaneous tissue and grasp muscle deeply on each side.
- Allow skin preparation to dry completely before penetrating skin.
- Decrease perception of pain.

NURSING CARE GUIDELINES—cont'd

Intramuscular Administration of Medication

- Distract child with conversation.
- Give child something on which to concentrate (e.g., squeezing a hand or side rail, pinching own nose, humming, counting, yelling "Ouch!").
- Spray vapocoolant on site before injection, place a cold compress or wrapped ice cube on site about 1 minute before injection, or apply cold to contralateral site.
- Studies have shown that applying manual pressure to the injection site for 10 seconds before injection can reduce postinjection pain (Derya, Ukke, Taner, et al., 2015; Öztürk, Baykara, Karadag, et al., 2017).
- Have child hold a small adhesive bandage and place it on puncture site after IM injection is given.
- Insert needle quickly using a dart-like motion at a 90-degree angle, unless contraindicated.
- Aspirate for blood return only if indicated.
- Avoid tracking any medication through superficial tissues:
  - Change needle after withdrawing medication from vial.
  - Use the Z-track or air-bubble technique as indicated.
  - Avoid any depression of the plunger during insertion of the needle.
- Administer the medication, then remove the needle quickly; hold gauze firmly against skin near needle when removing it to avoid pulling on tissue.
- Apply firm pressure to site after injection; massage site to hasten absorption unless contraindicated (e.g., if patient has a bleeding disorder or is receiving anticoagulation therapy).
- Place a small adhesive bandage on puncture site; with young children, decorate it by drawing a smiling face or other symbol of acceptance. Remind parents to remove the bandage as soon as bleeding has stopped, because bandages are a choking hazard in younger children.
- Hold and cuddle young child and encourage parents to comfort child; praise older child.
- Allow expression of feelings.
- Discard syringe and uncapped, uncut needle in puncture-resistant container located near site of use.
- Record time of injection, drug, dose, and injection site.

EMLA, Eutectic mixture of local anesthetics; *IM,* intramuscular; *LMX,* lidocaine.

Fig. 20.13 Holding a small child for intramuscular injection. Note how the nurse isolates and stabilizes the muscle.

Small infants usually can be positioned without assistance. A larger infant's body can be securely restrained between the nurse's arm and body. To inject into the body of a muscle, the nurse firmly grasps the muscle mass between the thumb and fingers to isolate and stabilize the site (Fig. 20.13). However, in obese children, it is preferable to first spread the skin with the thumb and index finger to displace subcutaneous tissue and then grasp the muscle deeply on each side.

If medication is given around the clock, the nurse must wake the child. Although it may seem easier to surprise the sleeping child and do it quickly, this can cause the child to fear going back to sleep. When awakened first, children will know that nothing will be done to them unless they are forewarned. The Nursing Care Guidelines box summarizes administration techniques that maximize safety and minimize the discomfort often associated with injections.

SUBCUTANEOUS AND INTRADERMAL ADMINISTRATION

Subcutaneous and intradermal injections are frequently administered to children, but the technique differs little from the method used with adults. Examples of **subcutaneous injections** include insulin, hormone replacement, allergy desensitization, and some vaccines. Tuberculin testing, local anesthesia, and allergy testing are examples of frequently administered **intradermal injections**.

Techniques to minimize the pain associated with these injections include changing the needle if it pierced a rubber stopper on a vial, using 26- to 30-gauge needles (only to inject the solution), and injecting small volumes (≤0.5 ml). The angle of the needle for the subcutaneous injection is typically 90 degrees. In children with little subcutaneous tissue, some practitioners insert the needle at a 45-degree angle. However, the benefit of using the 45-degree angle rather than the 90-degree angle remains controversial.

Although subcutaneous injections can be given anywhere there is subcutaneous tissue, common sites include the center third of the lateral aspect of the upper arm, the abdomen, and the center third of the anterior thigh. Some practitioners believe it is not necessary to aspirate before injecting subcutaneously; for example, this is an accepted practice in the administration of insulin. Automatic injector devices do not aspirate before injecting.

When giving an intradermal injection into the volar surface of the forearm, the nurse should avoid the medial side of the arm, where the skin is more sensitive.

NURSING TIP Families often need to learn injection techniques to administer medications, such as insulin, at home. Begin teaching as early as possible to allow the family the maximum amount of practice time.

INTRAVENOUS ADMINISTRATION

The IV route for administering medications is frequently used in pediatric therapy. For some drugs, it is the only effective route. This method is used for giving drugs to children who:

- Have poor absorption as a result of diarrhea, vomiting, or dehydration
- Need a high serum concentration of a drug
- Have resistant infections that require parenteral medication over an extended time
- Need continuous pain relief
- Require emergency treatment

Intravenous Line Placement

The nurse needs to consider several factors in relation to IV medication. When a drug is administered intravenously, the effect is almost instantaneous and further control is limited. Most drugs for IV administration require a specified minimum dilution, rate of flow, or both, and many drugs are highly irritating or toxic to tissues outside the vascular system. In addition to the precautions and nursing observations commonly related to IV therapy, factors to consider when preparing and administering drugs to infants and children by the IV route include:

- Amount of drug to be administered
- Minimum dilution of drug and whether child is fluid restricted
- Type of solution in which drug can be diluted
- Length of time over which drug can be safely administered
- Rate limitations of child, vascular system, and infusion equipment
- Time that this or another drug is to be administered
- Compatibility of all drugs that child is receiving intravenously
- Compatibility with infusion fluids

Before any IV infusion, check the site of insertion for patency, which includes a brisk blood return and flushing easily without resistance. Never flush against resistance and if encountered, the integrity of the access should be further evaluated (Infusion Nurses Society, 2016). Never administer medications into the same IV tubing with blood products. Only one antibiotic should be administered at a time. Extra fluids needed to administer IV medications can be problematic for infants and fluid-restricted children. Syringe pumps are often used to deliver IV medication because they minimize fluid requirements and more precisely deliver small volumes of medication compared with large-volume infusion pumps. Regardless of the technique, the nurse must know the minimum dilutions for safe administration of IV medications to infants and children.

Peripheral Intermittent Infusion Device

When prolonged access to a vein is required without the need for continuous fluid, a **peripheral lock**, also known as an **intermittent infusion device** or **saline** or **heparin lock**, is an alternative. The peripheral lock allows a child more freedom than being connected to a continuous IV infusion. It is most frequently used for intermittent infusion of medication, such as antibiotics, via peripheral venous route. A short, flexible catheter is used as the lock device, and a site where there will be minimal movement, such as the forearm, is selected. The catheter is inserted and secured in the same manner as for any IV infusion device, but an injection cap or needleless connector is attached to the hub. When it is time for medication administration, the needleless connector is disinfected, the lock is flushed to ensure patency, and then IV tubing, primed with either normal saline or medication, is connected.

The type of device used may vary, and the care and use of the peripheral lock are carried out according to the policy of the institution or unit. However, the general concept is the same. The catheter remains in place and is flushed with saline before and after infusion of the medication. See the Translating Evidence Into Practice box and Table 20.6 on flushing with normal saline or heparin.

TRANSLATING EVIDENCE INTO PRACTICE

Normal Saline or Heparinized Saline Flush Solution in Pediatric Intravenous Lines

Ask the Question

PICOT Question

Is there a significant difference in the longevity of intravenous (IV) intermittent infusion locks in children when normal saline (NS) is used as a flush instead a heparinized saline (HS) solution?

Search for the Evidence

Search Strategies

Selection criteria included evidence during the years 2006 to 2017 with the following terms: saline versus heparin intermittent flush, children's heparin lock flush, heparin lock patency, peripheral venous catheter in children.

Databases Used

CINAHL, PubMed

Critical Appraisal of the Evidence

- No differences in patency were established in a double-blind prospective randomized study in neonates. NS was deemed preferable to HS in peripheral intravenous (PIV) locks in neonates, in consideration of complications associated with heparin (Arnts, Heijnen, Wilbers, et al., 2011).
- Infusion devices flushed with NS lasted longer than those flushed with HS (Cook, Bellini, & Cusson, 2011).
- Peripheral catheters flushed with heparin remained patent longer but were also more likely to develop phlebitis (Tripathi, Kaushik, & Singh, 2008).
- A randomized trial in neonates demonstrated that use of HS for flushing before and after IV antibiotics significantly increased the duration of PIVs when compared to NS flushes (Upadhyay, Verma, Lal, et al., 2015).
- A systematic review of 10 randomized controlled trials in pediatrics found minimal benefit to use of HS as intermittent flush of peripheral catheters compared to NS. The difference was not statistically significant (Kumar, Vandermeer, Bassler, et al., 2013).
- Peripheral catheters in children, ages 1 to 17 years, flushed once every 24 hours with NS did not affect patency when compared to flushing with NS every 12 hours (Schreiber, Zanchi, Ronfani, et al., 2015).
- Either HS or preservative-free NS may be used to flush a PIV line (Arnts et al., 2011; Bellini, 2012; Cook et al., 2011; Infusion Nurses Society, 2016; White, Crawley, Rennie, et al., 2011).
- After each catheter use, peripheral catheters should be locked with either HS (0.5 to 10 units/ml) or preservative-free NS, since outcome data remain equivocal (Infusion Nurses Society, 2016).
- Intermittent flushing with NS results in fewer complications, lower cost, and less time compared with continuous infusion (Stok & Wieringa, 2016).
- The Centers for Disease Control and Prevention recommends use of NS for intermittent flushing to avoid complications (O'Grady, Alexander, Burns, et al., 2011).
- Switching from HS to NS involves educational and administrative interventions (Cook et al., 2011; Thamlikitkul & Indranoi, 2006).
- NS is more cost effective (Thamlikitkul & Indranoi, 2006).
- NS flush has fewer side effects. HS can be associated with anticoagulation, thrombocytopenia, drug interactions, and hypersensitivity (Arnts et al., 2011).
- NS flushes once a day maintained patency of pediatric PIV locks, resulting in reduced costs and increased patient satisfaction (Schreiber et al., 2015).
- Nurses in Italy tend to use HS with smaller-gauge (24-gauge) catheters when access is less frequent (12 hours or more between doses) and when patients are on specific units (hematology/oncology, pediatric surgery, and short-stay units) (Bisogni, Guisti, Ciofi, et al., 2014).

Apply the Evidence: Nursing Implications

There is **low-quality evidence with a weak recommendation** (Guyatt, Oxman, Vist, et al., 2008) for using NS versus HS flush solution in pediatric IV lines. Further research is needed with larger samples of children, especially preterm neonates, using small-gauge catheters (24 gauge) and other gauge catheters flushed with NS

TRANSLATING EVIDENCE INTO PRACTICE—cont'd

Normal Saline or Heparinized Saline Flush Solution in Pediatric Intravenous Lines

and HS as intermittent infusion devices only (no continuous infusions). Variables to be considered include catheter dwell time; medications administered; period between regular flushing and flushing associated with medication administration; pain, erythema, and other localized complications; concentration and amount of HS used; type of needleless connector used (negative pressure, positive pressure, or neutral pressure); flush method (positive-pressure technique vs. no specific technique); reason for IV device removal; and complications associated with either solution. NS is a safe alternative to HS flush in infants and children with intermittent IV locks larger than 24 gauge; smaller neonates may benefit from HS flush (longer dwell time), but the evidence is inconclusive for all weight ranges and gestational ages. Neonates may benefit from a continuous infusion of NS at 5 ml/h to maintain patency.

Quality and Safety Competencies: Evidence-Based Practice[a]

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe methods for using NS or HS flush solution in pediatric IV lines.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice on NS or HS flush solution in pediatric IV lines.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate the strength and weakness of evidence for NS or HS flush solution in pediatric IV lines.

TABLE 20.6 Intravenous Catheter Flushes for Lines Without Continuous Fluid Infusions

Peripheral lines (Hep-Lock or saline locks)	NS[a] after medications or every 8 hours for dormant lines; instill 2½ times tubing volume 24-g catheters: NS[a] or heparin 2 units/ml
Midline	Heparin 10 units/ml; 3 ml in a 10-ml syringe[b] after medications or every 8 hours if dormant Newborns: heparin 1-2 units/ml to run continuously at ordered rate
External central line (nonimplanted, nontunneled, tunneled, or PICC)	Heparin 10 units/ml; 3 ml in a 10-ml syringe[b] after medications or once daily if dormant Newborns: heparin 2 units/ml; 2-3 ml after medications or to check line patency OR heparin 1-2 units/ml to run continuously at ordered rate
Totally implanted central line (TIVAS, implanted port)	Heparin 10 units/ml; 5 ml after medications or once daily if dormant and accessed; if not accessed, heparin 100 units/ml; 5 ml every month
Arterial and central venous pressure continuous monitored lines	Heparin 2 units/ml in 55-ml syringe to run continuously at 1 ml/h

[a]Use 5% dextrose in water when medication is incompatible with saline.
[b]Smaller syringes may be used when flush is delivered by a pump.*NS,* Normal saline; *PICC,* peripherally inserted central catheter; *TIVAS,* totally implantable venous access device.

Children who require medications on a short-term basis may be discharged from the hospital with a peripheral lock in place to continue receiving IV medications at home under the care of a home health infusion company. When IV therapy is needed for more than 6 days, use of a midline catheter or peripherally inserted central catheter is recommended (O'Grady, Alexander, Burns, et al., 2011). Midline catheters are peripheral catheters that are placed in one of the larger veins of the upper arm, with the catheter tip terminating below the axilla. Midline catheters are appropriate for short-term use, usually lasting 2 to 6 weeks (Adams, Little, Vinsant, et al., 2016). A midline catheter is not considered a central venous catheter, so total parenteral nutrition (TPN) or any other drug known to irritate a peripheral vein (e.g., chemotherapy drugs) should not be administered through it. The high concentration of glucose in TPN is irritating to the interior lining of the blood vessel; therefore TPN should always be infused through a central catheter.

Central Venous Access Device

Children with acute or chronic illnesses who require repeated blood sampling or medications, long-term chemotherapy, intensive care, or frequent hyperalimentation or antibiotic therapy are best managed with a central venous catheter. Because the large central veins (such as the subclavian, femoral, or superior vena cava) allow more rapid diffusion of fluids and medications, they offer a more durable venous access than PIV catheters. However, central venous catheters also have a greater risk of bloodstream infection.

Short-term or **nontunneled catheters** are used in acute care, emergency, and intensive care units. These catheters are made of polyurethane and are placed in large veins, such as the subclavian, femoral, or jugular. Insertion is by surgical incision or large percutaneous threading. A chest radiograph should be taken to verify that the catheter tip is properly located in a large central vein before administration of fluids or medications.

Peripherally inserted central catheters (PICCs) can be used for short-term to moderate-length therapy. These catheters consist of silicone or polymer material and are placed by specially trained nurses, physicians, or interventional radiologists. The most common insertion site is above the antecubital area using the median, cephalic, or basilic vein. The catheter is threaded either with or without a guidewire into the superior vena cava.

The decision to insert a PICC needs to be made before several attempts at IV insertion are done. When the antecubital veins have been punctured repeatedly, they are not considered candidates for this type of catheter. Because this catheter is the least costly and has less chance of complications than other CVADs, it is an excellent choice for many pediatric patients who require IV therapies for weeks or months.

Children with chronic illnesses who require long-term venous access, for months or years, are best managed with a CVAD. CVADs have several different characteristics. They can be tunneled or nontunneled, external or internal, inserted peripherally or centrally. Factors that influence selection of the type of CVAD for a child include the reason for placement of the catheter (diagnosis), length of therapy, risk to the patient in placement of the catheter, and availability of resources to assist the family in maintaining the catheter.

! NURSING ALERT

Most peripherally inserted central catheter (PICC) lines are not sutured into place, so great care is needed when changing the dressing to avoid accidental catheter dislodgment.

Long-term CVADs include tunneled catheters and implanted infusion ports (Table 20.7 and Fig. 20.14). They may have single, double, or triple lumens. Several lumens (multilumen) catheters allow more than one therapy to be administered at the same time. Reasons for placement of multilumen catheters include repeated blood sampling, TPN administration, frequent administration of blood products, frequent infusion of large quantities or concentrations of fluids, administration of incompatible drugs or fluids at the same time (through different lumens), and central venous pressure monitoring.

TABLE 20.7 Comparison of Long-Term Central Venous Access Devices

Description	Benefits	Care Considerations
Tunneled Catheter (e.g., Hickman or Broviac Catheter)		
Silicone, radiopaque, flexible catheter with open ends or VitaCuffs (biosynthetic material impregnated with silver ions) on catheter(s) enhances tissue ingrowth May have more than one lumen	Reduced risk of bacterial migration after tissue adheres to cuff One or two Dacron cuffs Easy to use for self-administered infusions Removal requires pulling catheter from site (nonsurgical procedure)	Requires daily heparin flushes Requires semipermeable dressing over exit site at all times; dressing must be changed regularly and whenever it becomes wet or loose Must be clamped or have clamp nearby at all times Must keep exit site dry Heavy activity restricted until tissue adheres to cuff Water sports may be restricted (risk of infection) Risk of infection still present Protrudes outside body; susceptible to damage from sharp instruments and may be pulled out; may affect body image More difficult to repair Patient or family must learn catheter care
Implanted Ports (e.g., Port-a-Cath, Infuse-a-Port, Mediport, NorPort, Groshong Port)		
Totally implantable metal or plastic device that consists of self-sealing injection port with preconnected or attachable silicone catheter that is placed in large blood vessel	Reduced risk of infection Placed completely under the skin and therefore much less likely to be pulled out or damaged No maintenance care and reduced cost for family Heparinized monthly and after each infusion to maintain patency No limitations on regular physical activity, including swimming Dressing needed only when port accessed with Huber needle that is not removed No or only slight change in body appearance (slight bulge on chest)	Must pierce skin for access; pain with insertion of needle; can use local anesthetic (EMLA, LMX) or intradermal buffered lidocaine before accessing port Special noncoring needle (Huber) with straight or angled design must be used to inject into port Skin cleansing preparation needed before injection Difficult to manipulate for self-administered infusions Catheter may migrate internally, especially if child "plays" with port site (twiddler syndrome) Vigorous contact sports generally not allowed Removal requires surgical procedure

EMLA, Eutectic mix of local anesthetics; *LMX,* lidocaine.

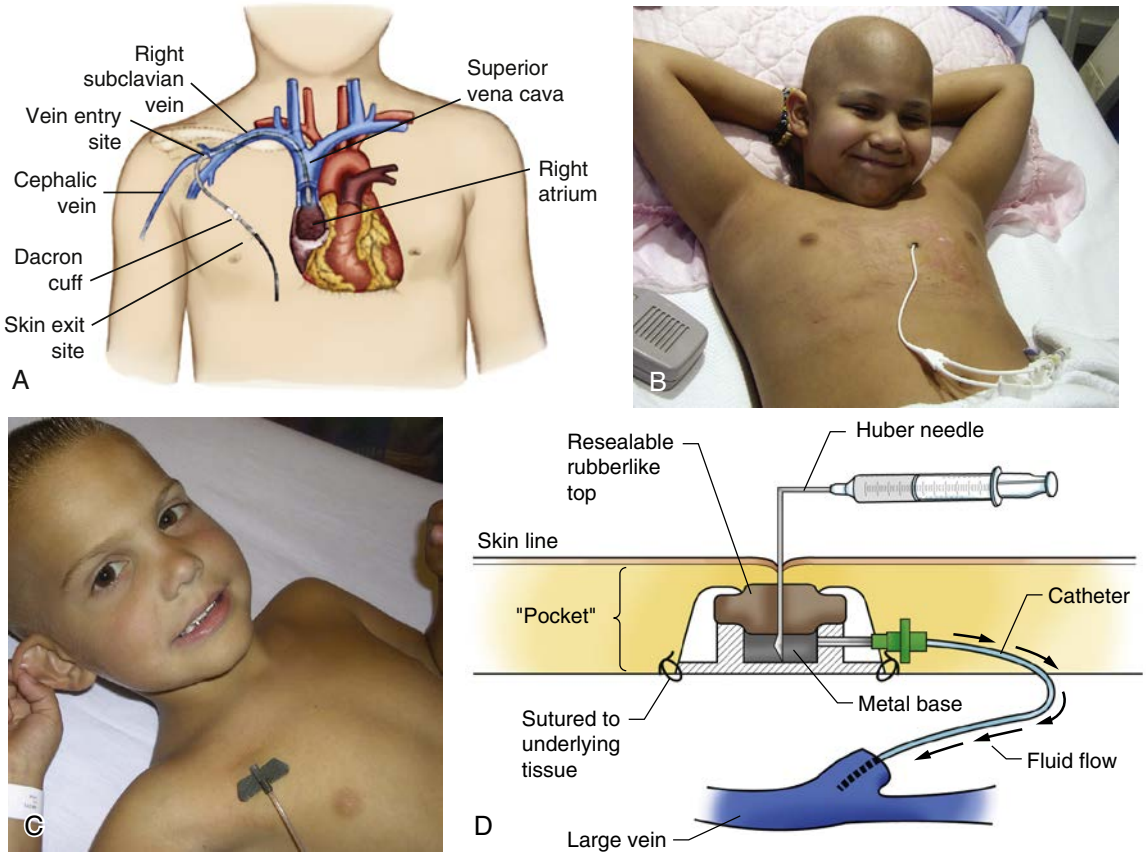

Fig. 20.14 Venous access devices. **A,** External central venous catheter insertion and exit site. **B,** Child with an external central venous catheter (dressing removed for photo). **C,** Child with an implanted port with a Huber needle in place (dressing removed for photo). **D,** Side view of an implanted port.

Maintenance of the catheter includes dressing changes, flushing to maintain patency, and prevention of occlusion or dislodgment.

NURSING ALERT

When working with tunneled catheters, peripherally inserted central catheters (PICCs), and peripheral intravenous (PIV) lines, avoid the use of any scissors around the tubing or dressing. Removal is best accomplished using fingers and much patience. If a tunneled catheter is cut, use a padded clamp to occlude the catheter between the exit site and the site of damage to avoid blood loss. Repair kits are available, which may save the catheter and avoid surgery to replace a damaged catheter.

To access the implanted CVAD, the port must be palpated for placement and stabilized. The overlying skin should be cleansed. The port should be accessed only with a special noncoring Huber needle. The needle is inserted through the diaphragm of the port, which is usually located on the top of the device. If the port needs to be accessed for several days, a special infusion set with a Huber needle and extension tubing with a Luer connection can be inserted and an occlusive dressing applied to keep the needle in place. When the infusion set is used, the procedure for administration of fluids and medications is the same as for an intermittent infusion device or a central venous catheter. To prevent infection, meticulous aseptic technique must be used any time the CVAD is entered, including instillation of heparin or saline to prevent clotting. Huber needles are changed at established intervals, usually 5 to 7 days (see Research Focus box).

NURSING TIP A pocket sewn on the inside of a T-shirt provides a place in which to coil the catheter line while the child is at play if a dressing is not used.

Infection and catheter occlusion are two of the most common complications of central venous catheters. They require treatment with antibiotics for infection and a fibrinolytic agent, such as alteplase, for thrombus formation (Anderson, Pesaturo, Casavant, & Ramsey, 2013). When the line is not in use, the catheter should be flushed with heparin, then clamped.

Parents are cautioned to keep scissors away from the child with an external central venous catheter, to prevent accidental cutting of the tubing. If the catheter leaks, the parents are instructed to tape it above the leak and then clamp the catheter at the taped site. The child should be taken to the hospital or clinic as soon as possible to prevent infection or clotting after a catheter leak (see Research Focus box).

RESEARCH FOCUS

Dressing Changes

Semipermeable transparent dressings should be changed at least every 5 to 7 days; the interval depends on the dressing material, age, and condition of the patient; infection rate reported by the organization; environmental conditions; and manufacturer labeled uses and directions (Infusion Nurses Society, 2016). In children older than 2 months of age, use of chlorhexidine-impregnated dressing (i.e., BioPatch) should be considered as an extra prevention measure for catheter-related bloodstream infection (Infusion Nurses Society, 2016).

NURSING ALERT

If a central venous catheter is accidentally removed, apply pressure to the skin overlying the location of vein entry, not the exit site on the skin.

The children and parents are taught the procedure for care of the CVAD before discharge from the hospital, including preparation and injection of the prescribed medication, the flush, and dressing changes. A protective wrap may be recommended for some active children to prevent their accidentally dislodging the needle. Older children and adolescents may take responsibility for preparing and administering medications. Both verbal and written step-by-step instructions are provided for the learners.

Intraosseous Infusion

Situations may occur in which rapid establishment of systemic access is vital and venous access is complicated by peripheral circulatory collapse, hypovolemic shock (secondary to vomiting or diarrhea, burns, or trauma), cardiopulmonary arrest, or other conditions. The American Heart Association recommends that intraosseous access be obtained if venous access cannot be readily achieved after three unsuccessful attempts or 90 seconds in a pediatric resuscitation (de Caen, Berg, Chameides, et al., 2015). **Intraosseous infusion** provides a rapid, safe, and life-saving alternate route for administration of fluids and medications until intravascular access is possible. Health care providers, including physicians, nurses, and paramedics, can secure intraosseous cannulation within 30 to 60 seconds. Some hospitals recommend pediatric advanced life support training before performing this procedure. This procedure is usually reserved for children who are unconscious or for those receiving analgesia because the procedure is painful. Local anesthesia should be used for a semiconscious patient. Contraindications for placement of an intraosseous catheter include concurrent problems involving that extremity, such as previous intraosseous attempt, skin rash, bone fracture, osteogenesis imperfecta, or osteosarcoma.

A large-bore rigid needle, such as an intraosseous needle (e.g., Cook) or a bone marrow aspiration needle (e.g., Jamshidi), is inserted into the medullary cavity of a long bone. The anteromedial aspect of the tibia—1 to 3 cm (0.4 to 1.2 inch) below the tibial tuberosity—is the preferred site for children of all ages because it is flat and has a large marrow cavity. In newborns, the distal third of the femur may be used. The distal tibia is an alternative site. Local anesthesia should be used for semiconscious patients. Spring-loaded and battery-powered intraosseous needle drivers are available for use (Bielski, Szarpak, Smereka, et al., 2017).

Once the bone marrow needle is in place, the needle should stand alone and feel secure. The needle should be stabilized and secured with tape and gauze. If a bone marrow aspirate needle is used, gauze should be built up around the needle to provide support and prevent trauma or dislodgment (Lewis, Crapo, & Williams, 2013). Drugs may be pushed and fluids delivered via an infusion pump. The intraosseous line may be discontinued after IV access has been achieved, typically within 24 to 48 hours.

Once established, the intraosseous route can be used during resuscitation to administer the same medications that could be given through the IV route. During infusion through an intraosseous needle, monitor the extremity closely for swelling or oozing of fluid at the insertion site. Give particular attention to the dependent tissue of the leg. Extravasation of fluid from the bone marrow may be hidden under the leg. Check for swelling of the entire lower leg when the intraosseous bone marrow needle is in the tibia or ankle, and check the entire upper leg when the intraosseous needle is in the femur. Compartment syndrome has resulted from an infiltrated intraosseous line. Other complications, although rare, include fractures, fat embolism, skin necrosis, osteomyelitis, and cellulitis (Lewis et al., 2013).

MAINTAINING FLUID BALANCE

MEASUREMENT OF INTAKE AND OUTPUT

Accurate measurements of fluid intake and output (I&O) are essential to the assessment of fluid balance. Measurements from all sources—including gastrointestinal, parenteral, urine, stools, vomitus, fistulas, NG suction, sweat, and drainage from wounds—must be included in assessment of fluid balance. Although the provider usually indicates when I&O measurements are to be recorded, it is a nursing responsibility to keep an accurate I&O record on certain children, including those with any of the following:

- Current IV therapy
- Recent major surgery
- Medications that include diuretic or corticosteroid therapy
- Severe thermal burns or injuries
- Renal disease or damage
- Congestive heart failure
- Dehydration
- Diabetes mellitus
- Oliguria
- Respiratory distress
- Chronic lung disease

Wet diapers or pads should be carefully weighed to ascertain the amount of fluid lost. This includes liquid stool, vomitus, and other losses. The applicaton of a collection bag may be useful for monitoring urine output in diapered infants and small children who have bowel movements with every void. The volume of fluid in milliliters is equivalent to the weight of the fluid measured in grams. The specific gravity as a measure of urine osmolality assists in assessing the degree of hydration.

NURSING TIP 1 g of wet diaper weight = 1 ml of urine

In infants with diapers, weigh all dry diapers to be used and note in an indelible marker the dry weight of the diaper; when there is fluid (urine or liquid stool) in the diaper, the amount of output can be approximated by subtracting the weight of the dry diaper from the weighed amount of the wet diaper.

Disadvantages of the weighed-diaper method of fluid measurement include (1) an inability to differentiate one type of loss from another because of admixture, (2) loss of urine or liquid stool from leakage or evaporation (especially for infants under a radiant warmer), and (3) additional fluid in the diaper (superabsorbent disposable type) from absorption of atmospheric moisture (in high-humidity incubators).

Special Needs When the Child Is Not Permitted to Take Fluids by Mouth

Infants or children who are unable or not permitted to take fluids by mouth (NPO) have special needs. To ensure that they do not receive fluids, a sign can be placed in some obvious place, such as over their beds or on their shirts, to alert caregivers and other hospital personnel to the NPO status. To prevent the temptation to drink, fluids should not be left at the bedside. Older children may try to sneak a drink when out of sight of caregivers, so nurses would be wise to keep an eye on

NPO children if they go into bathrooms or other locations where they are not easily observed.

Oral hygiene, a part of routine hygienic care, is especially important when fluids are restricted or withheld. For young children who cannot brush their teeth or rinse their mouth without swallowing fluid, the mouth and teeth can be cleaned and kept moist by swabbing with saline-moistened gauze.

NURSING TIP To keep the mouth feeling moist when the child is not permitted to take fluids by mouth, give ice chips (if this is permitted by the provider) or spray the mouth from an atomizer. To meet the need to suck, infants are provided with a safe commercial pacifier.

The child who is fluid restricted presents an equal challenge. Limiting fluids is often more difficult for the child than being NPO, especially when IV fluids are also eliminated. To make certain the child does not drink the entire amount allowed early in the day, the daily amount is calculated, then divided to provide fluids at periodic intervals throughout the child's waking hours. Serving the fluids in small containers gives the illusion of larger servings. No extra liquid is left at the bedside.

PARENTERAL FLUID THERAPY

Site and Equipment

The site selected for PIV infusion depends on accessibility and convenience. Current evidence also supports choosing the site that is most likely to last the duration of time needed (Infusion Nurses Society, 2016). The child's developmental, cognitive, and mobility needs must be considered when selecting a site. Ideally, in older children, the superficial veins of the forearm should be used, leaving the hands free. An older child can help select the site and thereby maintain some measure of control. For veins in the extremities, it is best to start with the most distal site and avoid the child's favored hand to reduce the temporary disability created by having an IV in the hand. Avoid placing peripheral IVs over joints (wrist, antecubital fossa, ankle), if possible, as these are areas of flexion and are more prone to accidental dislodgement, infiltration, and phlebitis (Infusion Nurses Society, 2016). In small infants, a superficial vein of the hand, wrist, forearm, foot, or ankle is usually most convenient and most easily stabilized (Fig. 20.15). Foot veins should be avoided in children learning to walk and in children already walking. Superficial veins of the scalp have no valves, are easily accessed, and can be used in infants up to about 9 months old, but they should be used only after attempts at other sites have failed.

The Infusion Nurses Society (2016) recommends use of vein-locating devices for assistance in starting PIVs on infants and children with difficult venous access. Vein-locating devices include ultrasound, transilluminators, and near-infrared light technology. Although not as powerful as ultrasound, a transilluminator requires minimal training and experience to use (Bahl, Pandurangadu, Tucker, et al., 2016). Small veins that may not be visible or palpable (especially in infants and toddlers) are often more readily visualized using a transilluminator. The cephalic vein in the proximal forearm may be the optimal vein for ultrasound-guided placement (Takeshita, Nakayama, Nakajima, et al., 2015). Because veins stand out so clearly with transillumination, they appear more superficial than they really are. Although visualization of veins is improved with transillumination, an increase in successful venipuncture is not guaranteed (Rothbart, Yu, Müller-Lobeck, et al., 2015). Some devices require assistance to hold in place. Commercial devices have not caused burns in infants

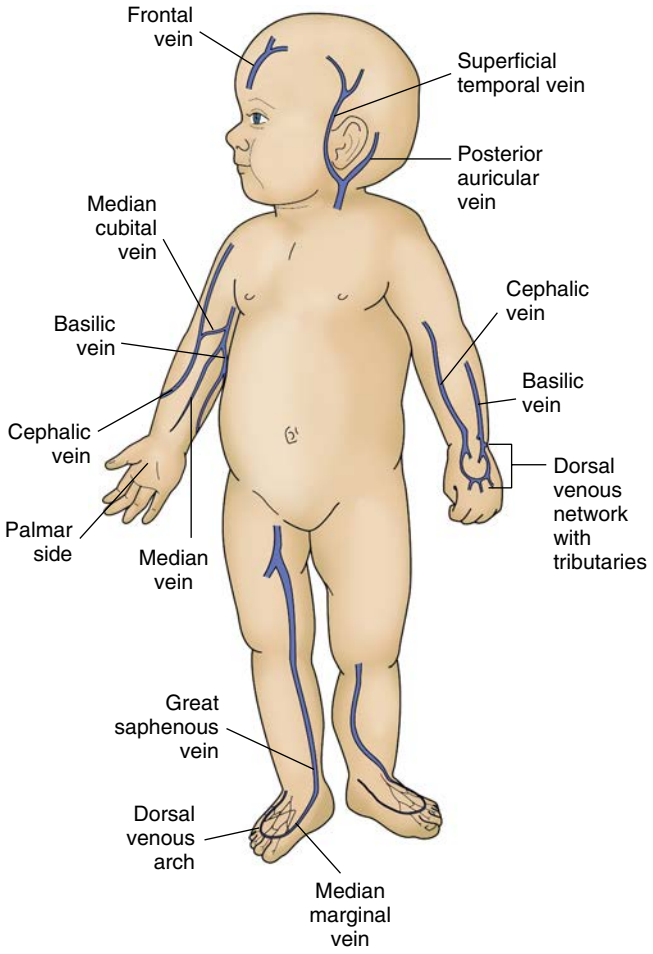

Fig. 20.15 Preferred sites for venous access in infants.

or children. Practice in this technique is necessary for optimal outcomes (Stolz, Cappa, Minckler, et al., 2016).

Selection of a scalp vein may require clipping the hair in the area around the site to better visualize the vein and provide a smoother surface on which to tape the catheter hub and tubing. Clipping a portion of the infant's hair may be upsetting to parents; therefore they should be told what to expect and be reassured that the hair will grow back. Remove as little as possible directly over the insertion site and taping surface. Save the clipped hair because parents often wish to keep it. A rubber band slipped onto the head from brow to occiput will usually suffice as a tourniquet, although if the vein is visible, a tourniquet may not be necessary.

NURSING TIP A tab of tape should be placed on the rubber band to help grasp it when removing it from the infant's head. The rubber band should be cut to avoid accidentally dislodging the catheter when moving the rubber band over the IV insertion site. The tape tab will lift the rubber band and allow it to be cut. Hold the rubber band in two places and cut between these areas to prevent the rubber band from snapping on the head.

For most IV infusions in children, a 20- to 24-gauge catheter may be used if therapy is expected to last 6 days or less. The smallest gauge and shortest length catheter that will accommodate the prescribed therapy should be chosen. The length of the catheter may be directly related to infection or embolus formation; the shorter the catheter, the fewer the complications. The gauge of the catheter should be sufficient

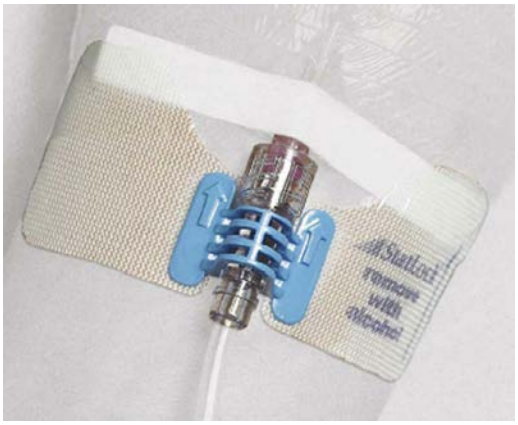

Fig. 20.16 StatLock securement devices enhance peripheral intravenous line dwell time and decrease phlebitis.

to maintain adequate flow of the IV fluids into the cannulated vein, while allowing adequate blood flow around the catheter walls to promote proper hemodilution of the fluid being infused.

Determining the best catheter for the patient early in the therapy provides the best chance of avoiding catheter-related complications. As the duration of therapy increases, decisions regarding the type of infusion device (short peripheral, midline, PICC, or central venous catheter) should be explored. Guidelines such as flow charts and algorithms are available to help in these decisions (Sou, McManus, Mifflin, et al., 2017).

SECUREMENT OF A PERIPHERAL INTRAVENOUS LINE

Catheters must be stabilized for easy monitoring and evaluation of the access site; to promote delivery of therapy; and to prevent damage, dislodgement, or migration of the catheter (Infusion Nurses Society, 2016)

To maintain the integrity of the IV line, adequate protection of the site is required. The catheter hub is firmly secured at the puncture site with a transparent dressing and commercial securement device (e.g., StatLock; Fig. 20.16) or clear nonallergenic tape. Transparent dressings are ideal because the insertion site is easily observed. Minimal tape should be used at the puncture site and on about 1 to 2 inches of skin beyond the site to avoid obscuring the insertion site for early detection of infiltration. The catheter insertion site and 1 to 2 inches along the vein proximal to the site should be readily visible so that the area can be monitored for signs of infiltration, irritation, or leakage.

Current guidelines recommend minimal use of additional tape or securement methods at the PIV site (Infusion Nurses Society, 2016). Plastic site protectors, improvised or commercial, are not recommended. These devices can lead to catheter dislodgement and can cause injury to patients.

It is important to safely secure the IV tubing to prevent infants and children from becoming entangled in the tubing and from accidentally pulling out the catheter or needle. Taping of the IV tubing should not obscure visibility of the catheter site.

Finger and toe areas are left unconcealed by dressings or tape to allow for assessment of circulation. The thumb is never immobilized because of the danger of contractures with prolonged limitation of movement. An extremity should never be encircled with tape, as this can become an unintentional tourniquet if the IV infiltrates. The use of roll gauze, self-adhering stretch bandages (Coban), and ACE bandages is not recommended because these can cause constriction and hide signs of infiltration.

! NURSING ALERT

Opaque covering should be avoided; however, if any type of opaque covering is used to secure the IV line, the insertion site and extremity distal to the site should be visible to detect an infiltration. If these sites are not visible, they must be checked frequently to detect problems early.

Traditionally, padded boards and splints have been used to partially immobilize the joint nearest to the PIV site. Padded boards and splints and restraints were appropriate when metal needles were used for venous access, in order to prevent the sharp tip of the needle from puncturing the vessel, especially at a joint. With the more recent use of soft, pliable catheters, arm or leg boards may not be necessary and have several disadvantages. They obscure the IV site, can constrict the extremity, may excoriate the underlying tissue and promote infection, can cause a contracture of a joint, restrict useful movement of the extremity, and are generally uncomfortable. No research has been conducted to demonstrate the proposed benefit of increasing dwell time and maintaining patency of the IV line. Adequate securement should eliminate the need for padded boards in most circumstances. Older children who are alert and cooperative can usually be trusted to protect the IV site.

SAFETY CATHETERS AND NEEDLELESS SYSTEMS

Needlestick injuries are a serious risk for nurses and other health care professionals who provide IV therapy to their patients. Current technologies, including safety catheters and needleless systems, have minimized the risk of exposure to bloodborne pathogens by needlestick injury. Safety catheters use retractable needle mechanisms to prevent accidental needlesticks when inserting over-the-needle PIV catheters.

Needleless IV systems are designed to prevent needlestick injuries during administration of IV push medications and IV piggyback medications. Needleless IV systems rely on connectors that function as caps. These connectors maintain a closed system until activated by insertion of a syringe or IV tubing set, which opens the fluid pathway. The needleless connectors of most needleless systems have an internal mechanical valve that controls how fluid flows through the connector when IV tubing or syringe is attached. There are three general types of needleless systems, based on how fluid is displaced within the connector. Each system has benefits and risks (Hadaway, 2012):

- Negative displacement systems (including blunt-tip cannulas for use with pre-slit injection caps)—fluid flows straight through the middle of the connector (Fig. 20.17A); these systems can allow a reflux or backflow of blood from the IV catheter when a syringe or IV tubing is disconnected, creating a potential for catheter occlusion.
- Positive displacement systems—the mechanical valve within the connector keeps a small amount of IV fluid in a tiny reservoir separate from the fluid pathway; when disconnecting the syringe or IV tubing, this reserve fluid is automatically released into the connector housing to prevent backflow of blood (see Fig. 20.17B). This action prevents inadvertent catheter occlusion but may allow trace amounts of incompatible fluids to remain within the connector.
- Neutral displacement systems—the mechanical valve within the connector is designed to prevent backflow of blood without the need for a fluid reservoir within the connector (see Fig. 20.17C).

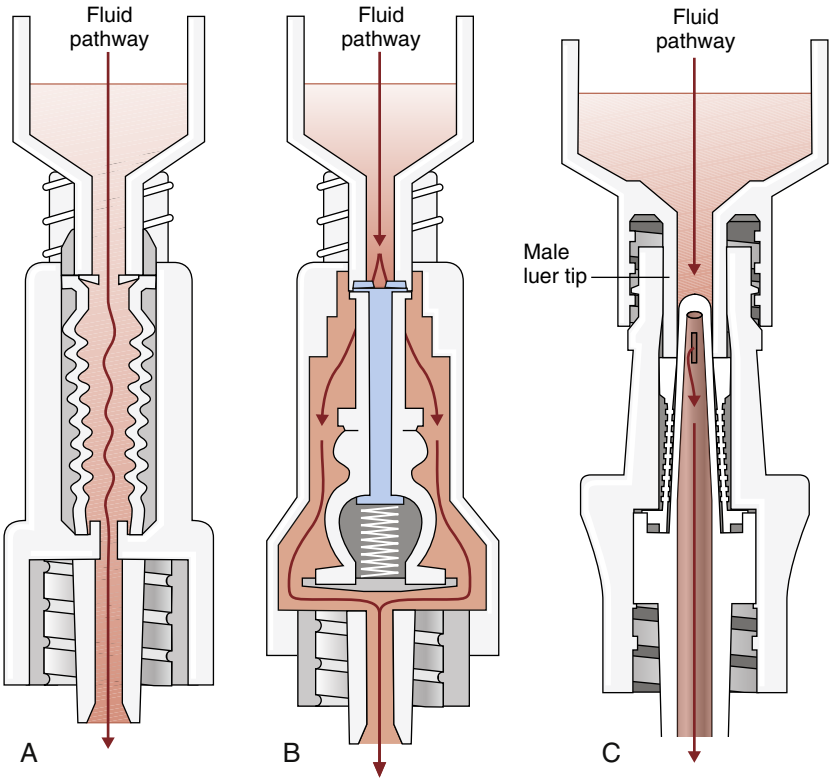

Fig. 20.17 Fluid pathways of needleless connectors. **A,** Negative displacement. **B,** Positive displacement. **C,** Neutral displacement. (**A** and **B,** Copyright by Becton, Dickinson, and Company. Used with permission. **C,** From Hadaway, L. [2012]. Needleless connectors for IV catheters. *American Journal of Nursing, 112*[11], 32–44. Courtesy Lynn Hadaway Associates, Inc.)

Flushing and disconnection procedures are different for each type of system. There is no way to know which type of mechanism is used by simply looking at the connectors. Therefore the nurse must understand the mechanics of the system in use at the institution. Some needleless devices can be used with any tubing, but others require use of an entire brand-specific IV delivery system for compatibility.

! NURSING ALERT

Misconnections of tubing have occurred, resulting in patient deaths. Many needleless IV systems allow other types of tubing, such as blood pressure and oxygen tubing, to connect and instill air directly into the IV line. Before tubing is connected or reconnected to a patient, trace it completely from the patient to the point of origin for verification.

An important potential risk of needleless systems, especially those with mechanical valves, is the possibility of contamination, either on the connector surface or by colonization of the internal valve mechanism. Disinfection of the needleless connector should occur prior to connecting any syringe or IV tubing. Chlorhexidine, 70% isopropyl alcohol, or combination products are all acceptable agents for decontamination, although the time required to adequately disinfect connector surfaces varies between agents. Disinfection is a two-step process: scrubbing the hub, followed by allowing the agent to dry for an appropriate length of time. The time involved in each step of the process depends on the agent used. Nurses should practice strict adherence to their institutional policy for cleansing the connector prior to attaching any syringe or IV tubing. Passive cleansing caps, impregnated with chlorhexidine or 70% isopropyl alcohol, can be applied to needleless connectors when not in use to provide continuous passive disinfection of catheter connectors between uses (Moureau & Flynn, 2015).

INFUSION PUMPS

In infants and children, most IV infusions are delivered via infusion pump in order to accurately administer fluids and medication and minimize the possibility of overloading the circulation. It is important to calculate the amount to be infused in a given length of time, set the infusion rate, and monitor the apparatus frequently (at least every 1 to 2 hours) to make certain that the desired rate is maintained, the integrity of the system remains intact, the venous access site remains intact (free of redness, edema, infiltration, or irritation), and the infusion does not stop.

Smart infusion pump technology provides built-in safety features that can alert nurses when pump settings are outside of programmed parameters, thereby reducing infusion errors and improving patient safety. Smart pump software within the infusion pump is preprogrammed with dose and infusion rate information for commonly used drugs. The smart pump can recognize drug information in its database, check dosing, calculate infusions rates, monitor line pressure, and report errors back to nursing. However, programming the pump for an infusion is a multistep process. The nurse must take great care in ensuring that the pump is properly programmed, especially if the set-up involves secondary infusions or multiple agents (Guiliano, 2018). A hastily programmed pump, bypassed drug libraries, or overridden alerts can result in potential patient safety issues or medication errors. After the pump is programmed, careful periodic reassessments should be performed by the nurse.

MAINTENANCE

Nurses play a significant role in the care and maintenance of IV devices, both peripheral and central. Nurses must be vigilant in monitoring and maintaining the integrity of each patient's venous access site and all associated supplies and equipment in order to prevent IV therapy–related harm, including infection, infiltration, phlebitis, and pain. The occurrence of IV-related bloodstream infections is of particular concern because of the added harm that it can cause to the already hospitalized patient. Many professional organizations have published evidence-based guidelines for the prevention of IV-related morbidity, especially hospital-acquired infections. Health care organizations also establish care guidelines, called bundles, with the goal of preventing IV therapy–related infections and other adverse events. Although most care bundles are unique to the organization, they are always evidence-based and include some common components (Hugull, 2017):

- Decision to insert a device or not
- Device selection considering, for example, patient characteristics, intended purpose, and duration of therapy
- Good hand hygiene for all caregivers
- Skin asepsis before needle or catheter insertion
- Aseptic nontouch techniques for insertion, use, site and line access, and removal
- Effective stabilization, securement, and dressing of the device
- Actions to maintain antisepsis during use and access
- Decisions about removing PIVs and temporary IV lines as soon as they are no longer needed
- Monitoring of the integrity of the device and side effects of use
- Audit of and feedback on essential components of compliance to individuals and teams

There is growing evidence that care bundles are effective in preventing infections, and the nurse should incorporate institutional bundles into daily practice.

COMPLICATIONS

The same precautions regarding maintenance of asepsis, prevention of infection, and observation for infiltration are carried out with patients of any age. However, infiltration may be more difficult to detect in infants and small children than in adults. The increased amount of subcutaneous fat and the amount of tape used to secure the catheter often obscure the early signs of infiltration. When the fluid appears to be infusing too slowly or ceases to infuse, the usual assessment for obstruction within the apparatus—tubing kinks, roller clamps, shutoff valve, and positioning interference (e.g., a bent elbow)—often locates the difficulty. When these actions fail to detect the problem, it may be necessary to carefully remove some of the dressing to obtain a clear view of the venipuncture site. Dependent areas, such as the palm and undersides of the extremity or the occiput and behind the ears, should be examined because infiltrations in these areas may not be readily visible.

Whenever possible, the hospital identification (ID) bracelet should not be placed on the same extremity where a peripheral IV is located. If the ID band fits too snugly, it can act like a tourniquet, preventing adequate venous return, resulting in serious circulatory impairment. To check for return blood flow through the catheter, the tubing is removed from the infusion pump, and the bag is lowered below the level of the infusion site. Using this maneuver, a backflash of blood can usually be observed at the catheter site, if the IV is patent. A good blood return, or lack thereof, is not always an indicator of infiltration in small infants or in smaller-gauge catheters. Flushing the catheter and observing for edema, redness, or streaking along the vein are also appropriate methods for assessment of IV patency. Resistance during flushing or resistance during aspiration for blood return may indicate that the IV infusion may have infiltrated surrounding tissue.

IV therapy in pediatrics can be difficult to maintain because of mechanical factors such as vascular trauma resulting from the catheter, the insertion site, vessel size, vessel fragility, pump pressure, the patient's activity level, operator skill and insertion technique, forceful administration of boluses of fluid, and infusion of irritants or vesicants through a small vessel. These factors increase the risk of infiltration and extravasation injuries. **Infiltration** is defined as inadvertent administration of a nonvesicant solution or medication into surrounding tissue. **Extravasation** is defined as inadvertent administration of vesicant solution or medication into surrounding tissue (Infusion Nurses Society, 2016). A **vesicant** or **sclerosing agent** causes varying degrees of cellular damage when even minute amounts escape into surrounding tissue. Guidelines are available for determining the severity of tissue injury by staging characteristics, such as the amount of redness, blanching, the amount of swelling, pain, the quality of pulses below infiltration, capillary refill, and warmth or coolness of the area (Nickel, 2019).

Treatment of infiltration or extravasation varies according to the type of vesicant. Guidelines outlining nursing management of infiltration or extravasation, including antidotes that could be used in specific situations, are available from the Infusion Nurses Society (Doellman, Hadaway, Bowe-Geddes, et al., 2009).

! NURSING ALERT

When infiltration or extravasation is observed (signs include erythema, pain, edema, blanching, streaking on the skin along the vein, and darkened area at the insertion site), immediately stop the infusion, elevate the extremity, notify the provider, and initiate the ordered treatment as soon as possible. Remove the intravenous (IV) line when it is no longer needed (e.g., after infusing an antidote).

Phlebitis, or inflammation of the vessel wall, may also develop in children receiving IV therapy. There are three types of phlebitis: mechanical (caused by rapid infusion rate, manipulation of the IV), chemical (caused by medications), and bacterial (caused by staphylococcal organisms). The initial sign of phlebitis is erythema (redness) at the insertion site. Pain may or may not be present. Incidence of phlebitis can be minimized by use of conscientious asepsis at site of PIV placement, adequate securement of site to minimize mechanical phlebitis, awareness of medications prone to causing phlebitis and adjusting infusion rates accordingly, and monitoring PIV sites for early signs of phlebitis (Higginson, 2011).

! NURSING ALERT

The most effective ways to prevent infection of an intravenous (IV) site are to cleanse hands between each patient, wear gloves when inserting a catheter, and closely inspect the insertion site and physical condition of the dressing. Proper education of the patient and family regarding signs and symptoms of an infected site can help prevent infections from going unnoticed.

REMOVAL OF A PERIPHERAL INTRAVENOUS LINE

When the time comes to discontinue an IV infusion, many children are distressed by the thought of catheter removal. Therefore they need a careful explanation of the process and suggestions for helping. Encouraging children to remove or help remove the tape from the site provides them with a measure of control and often fosters

their cooperation. The procedure consists of turning off any pump apparatus, occluding the IV tubing, removing the tape, pulling the catheter out of the vessel in the opposite direction of insertion, and exerting firm pressure at the site. A dry dressing (adhesive bandage strip) is placed over the puncture site. The use of adhesive-removal pads can decrease the pain of tape removal, but the skin should be washed after use to avoid irritation. To remove transparent dressings (e.g., OpSite, Tegaderm), pull the opposing edges parallel to the skin to loosen the bond. Hand sanitizer can also be applied over the top of the transparent dressing to help loosen the adhesive and allow the dressing to come off more easily. Inspect the catheter tip after removal, to ensure that the catheter is intact and that no portion remains in the vein.

When removing the needle from an implanted port, the line should be flushed with 5 ml of heparin, 100 units/ml, before removal of the needle, to ensure patency during the interim between accesses.

Nontunneled central lines can be removed by specially trained nurses with orders by the provider. Tunneled lines and implanted ports should be removed by the surgical team.

! NURSING ALERT

Consider the child's age, development, and neurologic status, as well as the predictability of the child (how the child responds to painful treatments), when determining the need for assistance to maintain safety. Manual removal of tape is the preferred method. Only if absolutely necessary should a small cut be made in the tape, using bandage scissors, to facilitate its removal. Before cutting the tape:

- Ensure that all digits are visible.
- Remove any barrier that hinders visibility, such as a protective covering.
- Protect the child's skin and digits by sliding own finger(s) between the tape and the child's skin so that the scissors do not touch the patient.
- Cut the tape on the medial aspect (thumb side) of the extremity.

RECTAL ADMINISTRATION

The rectal route for administration of medications is useful when a child is unable to take oral medications due to vomiting, altered gastrointestinal motility, or altered mental status. Advantages to medication administration via the rectal route include no need to coax a child to swallow unpleasant-tasting medications and relative ease of accessibility for giving medications during an emergency if the patient is unconscious or vomiting and there is no venous access. If the patient is neutropenic, immunosuppressed, or thrombocytopenic, the rectal route may be contraindicated due to the risk of introducing bacteria into the bloodstream.

Some of the drugs available in suppository form are acetaminophen, aspirin, sedatives, analgesics (morphine), antiemetics, and laxatives. Absorption by rectal mucosa is dependent on several factors, including gut motility, amount of time the drug remains in the rectum, and amount of stool present at time of drug administration. The difficulty in using the rectal route is that unless the rectum is empty at the time of insertion, the absorption of the drug may be delayed, diminished, or prevented by the presence of feces. Sometimes the drug is later evacuated, securely surrounded by stool.

When preparing to administer medication by the rectal route, first remove the wrapping on the suppository and lubricate the suppository with warm water (water-soluble jelly may affect medication absorption). Have the child lie on the side with top leg flexed; alternatively, the child can lie prone. Provide developmentally appropriate distraction for the child during the procedure. Rectal suppositories are traditionally inserted with the apex (pointed end) foremost. Reverse contractions or the pressure gradient of the anal canal may help the suppository slip higher into the canal. Using a glove or finger cot, quickly but gently insert the suppository into the rectum beyond both of the rectal sphincters. Then hold the buttocks together firmly to relieve pressure on the anal sphincter until the urge to expel the suppository has passed, which occurs within 5 to 10 minutes. Sometimes the amount of drug ordered is less than the dose available. The irregular shape of most suppositories makes the process of dividing them into a desired dose difficult if not dangerous. If it must be halved, the suppository should be cut lengthwise. However, there is no guarantee that the drug is evenly dispersed throughout the glycerin base.

If medication is administered via a retention enema, the same procedure is used. Drugs given by enema are diluted in the smallest amount of solution possible to minimize the likelihood of being evacuated.

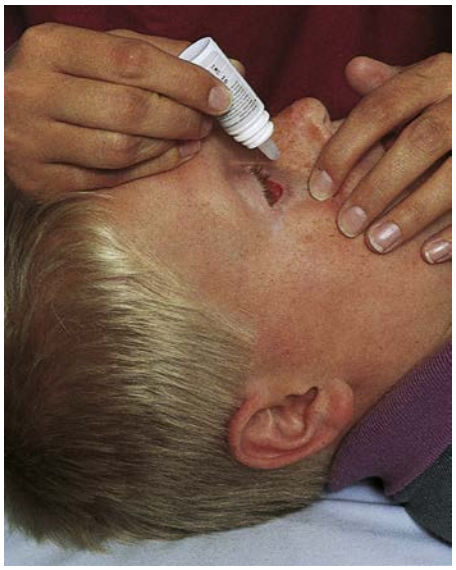

Fig. 20.18 Administering eye drops.

OPTIC, OTIC, AND NASAL ADMINISTRATION

There are few differences in administering eye, ear, and nose medication to children and to adults. The major difficulty is in gaining the child's cooperation. Older children need only an explanation and direction. Although the administration of optic, otic, and nasal medication is not painful, these drugs can cause unpleasant sensations, which can be eliminated with various techniques.

To instill eye medication, place the child supine or sitting with the head extended and ask the child to look up. Use one hand to pull the lower eyelid downward; the hand that holds the dropper rests on the head so that it may move synchronously with the child's head, thus reducing the possibility of trauma to a moving child or dropping medication on the face (Fig. 20.18). When the lower eyelid is pulled down, a small conjunctival sac is formed; apply the solution or ointment to this area, rather than directly on the eyeball. If applying an ointment, start at the inner canthus and move outward. Another effective technique is to pull the lower eyelid down and out to form a cup effect, into which the medication is dropped. Take care not to touch the tip of the dropper to the eyeball. Gently close the eyelids to prevent expression of the medication. Wipe excess medication from the inner canthus outward to prevent contamination to the contralateral eye.

NURSING TIP To reduce unpleasant sensations when administering medications:

- **Eye:** Apply finger pressure to the lacrimal punctum at the inner aspect of the eyelid for 1 minute to prevent drainage of medication to the nasopharynx and the unpleasant "tasting" of the drug.
- **Ear:** Allow medications stored in the refrigerator to warm to room temperature before instillation.
- **Nose:** Position the child with the head hyperextended to prevent strangling sensations caused by medication trickling into the throat rather than up into the nasal passages.

Instilling eye drops in infants can be difficult because they often clench the eyelids tightly closed. One approach is to place the drops in the nasal corner where the eyelids meet. The medication pools in this area, and when the child opens the eyelids, the medication flows onto the conjunctiva. For young children, playing a game can be helpful, such as instructing the child to keep the eyes closed to the count of three and then open them, at which time the drops are quickly instilled. Ointment can be applied by gently pulling down the lower eyelid and placing the ointment in the lower conjunctival sac.

DRUG ALERT

If both eye ointment and drops are ordered, give drops first, wait 3 minutes, and then apply the ointment to allow each drug to work. When possible, administer eye ointments before bedtime or naptime because the child's vision will be blurred temporarily.

Ear drops are instilled with the child in the prone or supine position and the head turned to the appropriate side. To avoid uncomfortable stimulation of vertigo, ensure that ear medications are at room temperature before instilling. For children younger than 3 years old, the external auditory canal is straightened by gently pulling the pinna downward and straight back. The pinna is pulled upward and back in children older than 3 years old. To place the drops deep into the ear canal without contaminating the tip of the dropper, place a disposable ear speculum in the canal and administer the drops through the speculum. Position the dropper so that the drops fall against the side of the ear canal. After instillation, the child should remain lying on the unaffected side for a few minutes. Gentle massage of the area immediately anterior to the ear facilitates the entry of drops into the ear canal. The use of cotton pledgets prevents medication from flowing out of the external canal. However, they should be loose enough to allow any discharge to exit from the ear. Premoistening the cotton with a few drops of medication prevents the wicking action from absorbing the medication instilled in the ear.

The intranasal route can be used for administration of steroids for local relief of the inflammation associated with rhinosinusitis. This route is also being used in emergency departments and in palliative care for the systemic administration of fentanyl for pain, midazolam and ketamine for sedation, lorazepam for seizures, and naloxone for drug overdose (Tucker, Tucker, & Brown, 2018). The intranasal route allows quick absorption of medications across the nasal mucosa, with fairly painless patient preparation and rapid onset of action (Del Pizzo & Callahan, 2014). Intranasal delivery systems include nose drops (low volume, low pressure), intranasal sprays, and atomizers (low volume, high pressure). Nose drops are instilled in the same manner as in the adult patient. Remove mucus from the nose with a clean tissue or a washcloth. Unpleasant sensations associated with medicated nose drops are minimized when care is taken

Fig. 20.19 Proper position for instilling nose drops.

to position the child with the head extended well over the edge of the bed or pillow (Fig. 20.19). Depending on size, infants can be positioned in the football hold (see Fig. 20.3B), in the nurse's arm with the head extended and stabilized between the nurse's body and elbow and the arms and hands immobilized with the nurse's hands, or with the head extended over the edge of the bed or a pillow. When administering a nasal spray, the patient can be either sitting up or lying down. Insert the nasal spray dispenser into the nostril, aiming toward the top of the ear to direct the medication away from the nasal septum and toward the turbinates for rapid absorption. Quickly squeeze the pump sprayer to instill the medication. The patient should inhale slightly as the medication is being delivered. If the patient sniffs, instead of slowly inhaling, the medication will bypass the intended turbinates and end up in the back if the throat, likely resulting in a bad taste and slower absorption. After instillation of the drops or spray, the child should remain in position for 1 minute to allow the medication to come in contact with the nasal surfaces. For intranasal medication administration using an atomizer, the patient can be sitting up or lying down. The atomizer device is attached to the syringe of medication. Maximum volume for intranasal administration is 1 ml per nostril (Tucker et al., 2018). The procedure for administration is similar to that for intranasal spray.

AEROSOL THERAPY

Aerosol therapy can be an effective method for administering medication directly into the lower airway (trachea, bronchi, bronchioles). Bronchodilators, steroids, mucolytics, and antibiotics, suspended in particulate form, can be inhaled so that the medication reaches the small airways. This route of administration can be useful in avoiding the systemic side effects of certain drugs and in reducing the amount of drug necessary to achieve the desired effect. Aerosol therapy is particularly challenging in children who are too young to cooperate with controlling the rate and depth of breathing. Administration of this therapy requires skill, patience, and creativity. Because many children with airway diseases, such as asthma, use aerosol therapies on a regular basis, it is important for families to understand the home plan of care, including drugs to use for maintenance and drugs to use for rescue.

DRUG ALERT

Medications can be aerosolized or nebulized with air or with oxygen-enriched gas. Delivery systems include the metered-dose inhaler (MDI) and the nebulizer. The MDI is a self-contained, handheld device that allows for intermittent delivery of a specified amount of medication. Many bronchodilators are available in this form and are successfully used by children with asthma. A spacer device attached to the MDI can help with coordination of breathing and aerosol delivery. It also allows the aerosolized particles to remain in suspension longer. For nebulized administration, a handheld nebulizer discharges a medicated mist through a mouthpiece or a small plastic mask that the child holds over the nose and mouth. To avoid particle deposition in the nose and pharynx, the child is instructed to take slow, deep breaths through an open mouth during the treatment. For home use, an air compressor is necessary to force air through the liquid medication to form the aerosol. Compact, portable units can be obtained from health equipment companies.

Breath sounds and work of breathing should be assessed before and after treatments. Young children who become upset by having a mask held close to the face may become fatigued with fighting the procedure and may appear worse during and immediately after the therapy. It may be necessary to spend a few minutes calming the child after the procedure and allowing the vital signs to return to baseline to accurately assess changes in breath sounds and work of breathing.

FAMILY TEACHING AND HOME CARE

The nurse usually assumes responsibility for preparing families to administer medications at home. The family should understand why the child is receiving the medication and the effects that might be expected, as well as the amount, frequency, and length of time the drug is to be administered. Instruction should be carried out in an unhurried, relaxed manner, preferably in an area away from a busy ward or office.

Instruct the caregiver carefully regarding the correct dosage. Some persons have difficulty understanding medical terminology, and just because they nod or otherwise indicate that they understand, the nurse should not assume that the message is clear. It is important to be certain that they have acceptable devices for measuring the drug. If the drug is packaged with a dropper, syringe, or plastic cup, the nurse should show or mark the point on the device that indicates the prescribed dose and demonstrate how the dose is drawn up into a dropper or syringe, measured, and the bubbles eliminated. To allow an opportunity to demonstrate their understanding of the skills required, caregivers should always perform return demonstration before returning home. This is essential when the drug has potentially serious consequences from incorrect dosage, such as insulin or digoxin, or when more complex administration is required, such as parenteral injections. When teaching a parent to give an injection, the nurse must allot adequate time for instruction and practice.

Home modifications are often necessary because the availability of equipment or assistance can differ from the hospital setting. For example, the parent may need guidance in devising methods that allow one person to hold the child and safely give the drug.

NURSING TIP To administer oral, nasal, or optic medication when only one person is available to hold the child and the child is unable to cooperate, use the following procedure:

- Place child supine on a flat surface (bed, couch, floor).
- Sit facing child so child's head is between operator's thighs and child's arms are under operator's legs.
- Place lower legs over child's legs to restrain lower body, if necessary.
- To administer oral medication, place a small pillow under child's head to reduce risk of aspiration.
- To administer nasal medication, place a small pillow under child's shoulders to aid flow of liquid through nasal passages.

The nurse should clarify with parents the time that the drug is to be administered. For instance, when a drug is prescribed in association with meals, the number of meals that the family is accustomed to eating influences the amount of drug the child receives. Does the family have meals twice a day or five times a day? When a drug is to be given several times during the day, together the nurse and parents can work out a schedule that accommodates the family's routine. This is particularly significant if a drug must be given at equal intervals throughout a 24-hour period. For example, telling parents that the child needs 5 ml of medicine four times a day is subject to misinterpretation, because the parents may routinely schedule the doses at incorrect times. Instead, a preplanned schedule based on 6-hour intervals should be set up with the number of days required for the therapeutic dosage listed. Modification should also be made to accommodate sleep schedules. Written instructions should accompany all drug prescriptions.

NURSING TIP If parents have difficulty reading or if there is a language barrier, use colors and/or pictures to convey instructions. For example, mark each drug with a color and place the appropriate color on a calendar chart or on a drawing of a clock to identify when the drug needs to be given. If a liquid medication and syringe are used, also mark the syringe at the place the plunger needs to be with color-coded tape. Several websites and phone applications are available to help create patient-specific medication calendars.

ALTERNATIVE FEEDING TECHNIQUES

Some children are unable to take nourishment by mouth because of anomalies of the throat, esophagus, or bowel; impaired swallowing capacity; severe debilitation; respiratory distress; or unconsciousness. These children are frequently fed by way of a tube inserted orally or nasally into the stomach (**orogastric [OG]** or **NG gavage**) or duodenum-jejunum (**enteral gavage**) or by a tube inserted directly into the stomach (**gastrostomy**) or jejunum (**jejunostomy**). Such feedings may be intermittent or by continuous drip. Feeding resistance, a problem that may result from any long-term feeding method that bypasses the mouth, is discussed in Chapter 8. During gavage or gastrostomy feedings, infants are given a pacifier. Nonnutritive sucking has several advantages, such as increased weight gain and decreased crying. However, only pacifiers with a safe design can be used to prevent the possibility of aspiration. Using improvised pacifiers made from bottle nipples is not a safe practice.

When a child is concurrently receiving both continuous gastroenteral feedings and parenteral (IV) therapy, the potential exists for inadvertent administration of the enteral formula through the circulatory system. The possibility for harmful error increases when the parenteral solution is a fat emulsion, a milky-appearing substance. Safeguards to prevent this potentially serious error include:

- Be sure that the feeding bag and all enteral tubings are cleaned on a regular basis, according to the manufacturer's recommendations.
- Use enteral-specific connectors (ENFit) that are not compatible with Luer Lock or needleless connections used for IV tubing (Guenter & Lyman, 2016).
- Use a separate, specifically designed enteral feeding pump mounted on a separate pole for continuous-feeding solutions.
- Use specifically designed enteral feeding bags instead of parenteral equipment, such as a burette, to contain the feeding solutions.
- Label all enteral feeding tubing with brightly colored tape or labels.
- Whenever access or connections are made, trace the tubing all the way from the patient to the bag to ensure that the correct tubing source is selected.

NASOGASTRIC, OROGASTRIC, AND GASTROSTOMY ADMINISTRATION

When a child has an indwelling feeding tube or a gastrostomy, oral medications are usually given via that route. An advantage of this method is the ability to administer oral medications around the clock without disturbing the child. A disadvantage is the risk of occluding, or clogging, the tube, especially when giving viscous or incompatible solutions through small-bore feeding tubes. The most important measure to prevent enteral tube occlusions is adequate flushing before and after any medication is instilled (see Nursing Care Guidelines box).

NURSING CARE GUIDELINES

Nasogastric, Orogastric, or Gastrostomy Medication Administration in Children

Use only syringes compatible with the enteral feeding tube; avoid using syringes with Luer Locks, designed for intravenous (IV) medications

Confirm with pharmacist that the medication is suitable to be given through an enteral feeding tube (a drug that is inappropriately given via enteral tube can lead to occluded tubes, decreased drug effect, and increased drug toxicity) (American Society for Parenteral and Enteral Nutrition, 2017):

- Extended-release and enteric-coated medications should not be administered via enteral tube because they may result in inadvertent overdose.
- Some medications, such as lansoprazole delayed-release oral suspension packets, ursodiol, and bulk-forming laxatives cannot be given via enteral feeding route.
- Some medications (i.e., esomeprazole granules) must be administered promptly after they are mixed in water because they deteriorate after only a few minutes and will not be effective.
- Avoid oily medications (e.g., tacrolimus) because they tend to cling to side of tube.
- Some drugs, such as oral iron, warfarin, phenytoin, and digoxin may not be properly absorbed if given through jejunal feeding tubes.
- Medications with high osmolality can cause diarrhea if given via jejunal feeding tube, if not adequately diluted (European Society of Paediatric Gastroenterology, Hepatology, and Nutrition, 2010). Check with pharmacist.

Use elixir or suspension (rather than tablet) preparations of medication whenever possible.

Dilute viscous medication or syrup with a small amount of water if possible.

If administering tablets, crush tablet to a fine powder and dissolve drug in a small amount of warm water. Enteral tubes are easily clogged by incompletely crushed or incompletely dissolved medication.

Never crush enteric-coated or sustained-release tablets or capsules.

Tubing should be flushed with clear water before and after each medication.

Do not add medication directly to the enteral feeding bag.

When administering a medication via nasogastric (NG) tube that is used intermittently (i.e., clamped):

- Check for correct placement of NG or orogastric (OG) tube (see Translating Evidence Into Practice box).
- Flush the NG tube with clear water prior to giving medication.
- Attach medication-filled syringe to the tube and administer the medication.
- Follow the medication with clear water to flush the medication from the tubing, then remove syringe and clamp tubing.

When administering a medication via NG tube with enteral feeding infusing continuously:

- Pause the pump.
- If the feeding tube has medication side port, use this port for administration of medication and any flushes; if the tube does not have a medication port, disconnect the feeding from the NG tube.
- Check for correct placement of NG or OG tube (see Translating Evidence Into Practice box).
- If the medication is not compatible with the enteral formula, attach a syringe filled with clear water and flush the NG tube to remove the formula from the tubing.
- Attach medication-filled syringe to tube and administer the medication.
- Follow the medication with clear water to flush the medication from the tubing before resuming the continuous enteral feeding.

When flushing enteral tubing:

- Always flush with clear water (bottled water, purified water, or tap water, depending on degree of contaminants) (American Society for Parenteral and Enteral Nutrition, 2017).
- Amount of water depends on length and gauge of tubing.
- Before administering any medication, determine amount of water needed by using a syringe to fill completely an unused NG or OG tube with water. Amount of flush solution is usually 1.5 times this volume.
- With certain drug preparations (e.g., suspensions), more fluid may be needed.

If administering more than one drug at the same time, flush tube with clear water between each medication.

GAVAGE FEEDING

Infants and children can be fed simply and safely by a tube passed into the stomach through either the nares or the mouth. The tube can be left in place or inserted and removed with each feeding. In older children, it is usually less traumatic to tape the tube securely to the cheek between feedings. For long-term enteral tube feedings, the tube should be removed and replaced with a new tube at specified intervals according to hospital policy, manufacturer recommendations, specific orders, and the type of tube used. Meticulous hand washing is practiced during the procedure to prevent bacterial contamination of the feeding, especially during continuous feedings.

Preparations

The equipment needed for gavage feeding includes:

- A suitable feeding tube, selected according to the child's size, the viscosity of the solution being fed, and anticipated duration of treatment
- A receptacle for the fluid to be administered; for small amounts, a 10- to 30-ml syringe barrel or Asepto syringe is satisfactory; for

larger amounts, a 60-ml syringe with a catheter tip is more convenient
- A 10-ml syringe to aspirate stomach contents after the tube has been placed
- Water or water-soluble lubricant to lubricate the tube; sterile water is used for infants
- Paper or nonallergenic tape to mark the tube and to attach the tube to the infant's or child's cheek
- pH paper to determine the correct placement in the stomach
- The solution for feeding

Not all feeding tubes are the same. Polyethylene and polyvinylchloride types lose their flexibility and need to be replaced frequently, usually every 3 or 4 days. Polyurethane and silicone tubes remain flexible, so they can remain in place for up to 30 days. Advantages of small-bore tubes include a reduced incidence of pharyngitis, otitis media, aspiration, and discomfort. Disadvantages include difficulty during insertion (may require a stylet or metal guidewire), collapse of the tube during aspiration of gastric contents to test for correct placement, dislodgment during forceful coughing, migration out of position, knotting, occlusion, and unsuitability for thick feedings.

Procedure

Infants are easier to control if they are first wrapped in a mummy restraint (see Fig. 20.4A). Even tiny infants with random movements can grasp and dislodge the tube. Preterm infants do not ordinarily require restraint, but if they do, a small blanket folded across the chest and secured beneath the shoulders is usually sufficient. Be careful that breathing is not compromised.

Whenever possible, the infant should be held and provided with a means for nonnutritive sucking during the procedure to associate the comfort of physical contact with the feeding. When this is not possible, gavage feeding is carried out with the infant or child lying supine or on the right side; the head and chest should be elevated. Feeding the child in a sitting position helps maintain placement of the tube in the lowest position, thus increasing the likelihood of correct placement in the stomach.

Although the most accurate method for testing tube placement is radiography, this practice is not always possible before each feeding. Research indicates that bedside assessment of gastrointestinal aspirate color and pH is useful in predicting feeding tube placement (see Translating Evidence Into Practice box). If doubt exists regarding correct placement, consult the provider. The Nursing Care Guidelines box describes the procedure for gavage feeding.

TRANSLATING EVIDENCE INTO PRACTICE

Confirming Nasogastric Tube Placement in Pediatric Patients

Ask the Question

PICOT Question

In children, how should correct placement of nasogastric (NG) tubes be assessed during hospitalization?

Search for the Evidence

Search Strategies

Search selection criteria included English-language, research-based articles and children and adolescents requiring NG tube placement. Search areas included aspirate, auscultation and radiology methods, NG tube length prediction methods, age-related height-based methods, and accurate NG tube placement. Searches excluded newborns and preterm infants.

Databases Used

PubMed, Cochrane Collaboration, MDConsult, Joanna Briggs Institute, Agency for Healthcare Research and Quality National Guideline Clearinghouse, TRIP Database Plus, PedsCCM, BestBETS

Critical Appraisal of the Evidence

Studies compared various methods used to evaluate correct placement of the NG tube.

Accurate Nasogastric Tube Length Measurement

- Children 8 years, 4 months old or younger: Use age-related height-based equation for NG length predictions.
- Children older than 8 years, 4 months old, short stature, or when you cannot obtain accurate height: Use nose-ear–midway to umbilicus (NEMU) (Beckstrand, Cirgin Ellett, & McDaniel, 2007).
- Use of the nose-ear-xyphoid (NEX) method resulted in increased risk of misplaced tubes (Irving, Rempel, Lyman, et al., 2018).

Radiographs

- Although abdominal x-ray provides confirmation of enteral tube location, the results can sometimes be equivocal. In addition, this method cannot be used for ongoing, frequent placement verification basis due to the risk of radiation exposure to the child (Irving, Lyman, Northington, et al., 2014). Alternate methods of verification have evidence-based support in the literature (Cincinnati Children's Hospital Medical Center, 2011; Emergency Nurses Association, 2019).

Nonradiologic Verification Methods

- A pH of 5 or less supports that the tip of the tube is in the gastric location (Ellett, Croffie, Cohen, et al., 2005; Gilbertson, Rogers, & Ukoumunne, 2011; Nyqvist, Sorell, & Ewald, 2005; Society of Pediatric Nurses Clinical Practice Committee, Society of Pediatric Nurses Research Committee, & Longo, 2011).
- A pH greater than 5 does not reliably predict correct distal tip location. This may indicate respiratory or esophageal placement or the presence of medications to suppress acid secretion. Gastric aspirate pH means are statistically significantly lower compared with means from intestinal and respiratory pH aspirates (Ellett et al., 2005; Gilbertson et al, 2011; Society of Pediatric Nurses Clinical Practice Committee et al., 2011).

Visual Inspection of Aspirate

- Visual inspection is less accurate than pH to confirm placement. Aspirate colors are specific to the intended placement location. Gastric contents are clear, off-white, or tan or may be brown-tinged if blood is present. Respiratory secretions may look the same. Intestinal contents are often bile stained, light to dark yellow, or greenish-brown (Society of Pediatric Nurses Clinical Practice Committee et al., 2011).

Enzyme Testing

- Aspirate testing of enzyme levels for bilirubin, pepsin, and trypsin is highly accurate but limited to laboratory assessment (Ellett et al., 2005).

Carbon Dioxide Monitoring

- Carbon dioxide (CO_2) monitoring (capnography or colorimetric capnometry) is as reliable as radiograph for confirmation of gastrointenstinal (GI) versus respiratory placement of NG tubes but cannot distinguish between gastric and duodenal placement (Erzincanli, Zaybak, & Guler, 2017; Miller, 2013).

Continued

TRANSLATING EVIDENCE INTO PRACTICE—cont'd

Confirming Nasogastric Tube Placement in Pediatric Patients

Gastric Auscultation

- Auscultation as a verification tool is not reliable and should not be used without additional methods (Boeykens, Steeman, & Duysburgh, 2014).
- Although evidence shows auscultation alone is not a reliable confirmatory test, it is still widely used by nurses for evaluation of enteral tube placement (Bourgault, Heath, Hooper, et al., 2015; Lyman, Kemper, Northington, et al., 2016; Metheny, Stewart, & Mills, 2012; Northington, Lyman, Guenter, et al., 2017).
- Using aspirate and nonaspirate NG tube placement verification methods in combination increases the likelihood for accurate NG tube placement to 97% to 99%, similar to the chest radiography gold standard of 99% (Ellett et al., 2005; Society of Pediatric Nurses Clinical Practice Committee et al., 2011).

Electromagnetic Device

- An electromagnetic tracing device demonstrated more than 94% accuracy in enteral feeding tubes in a study of both adults and children (Powers, Luebbehusen, Aguirre, et al., 2018); however, the device requires special training and considerable expertise for proper use (Metheny & Meert, 2017) and cannot detect enteral tubes smaller than 8 French (Bourgault et al., 2015; Bryant, Phang, &Abrams, 2015).

Apply the Evidence: Nursing Implications

There is **good evidence** with **strong recommendations** (Guyatt, Oxman, Vist, et al., 2008) that a combination of verification methods to confirm NG tube placement will reduce the required number of x-rays in children (Society of Pediatric Nurses Clinical Practice Committee et al., 2011). These methods include pH testing and visual inspection of the pH aspirate. There is also good evidence that improving the accuracy of predicting NG tube length before insertion will enhance the precision of successful NG tube placement. Auscultation is used in combination with other NG tube verification methods. Further investigation of additional noninvasive, user-friendly, portable verification methods, including ultrasound and electromagnetic tracer, is warranted (Irving et al., 2018; Powers, Luebbehusen, Spitzer, et al., 2011).

Quality and Safety Competencies: Evidence-Based Practice[a]

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe the various verification methods to confirm NG tube placement.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by using the techniques for NG and orogastric (OG) tube placement verification in clinical care.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate the strengths and weakness of evidence for confirming NG tube placement.

NURSING CARE GUIDELINES

Nasogastric Tube Feedings in Children

Place child supine with head slightly hyperflexed or in a sniffing position (nose pointed toward ceiling).

Measure the tube for approximate length of insertion and mark the point with a small piece of tape.

Consider using lidocaine nasal spray to numb the nostril before tube insertion.

Insert a tube that has been lubricated with sterile water or water-soluble lubricant through either the mouth or one of the nares to the predetermined mark. Because most young infants are obligatory nose breathers, insertion through the mouth causes less distress and helps stimulate sucking. In older infants and children, the tube is passed through the nose and alternated between nostrils. An indwelling tube is almost always placed through the nose.

- When using the nose, slip the tube along the base of the nose and direct it straight back toward the occiput.
- When entering through the mouth, direct the tube toward the back of the throat (see Fig. 20.20B).
- If the child can swallow on command, synchronize passing the tube with swallowing.

Confirm placement (see Translating Evidence Into Practice: Confirming Nasogastric Tube Placement in Pediatric Patients box).

Stabilize the tube by holding or taping it to the cheek, not to the forehead, because of possible damage to the nostril. To maintain correct placement, measure and record the amount of tubing extending from the nose or mouth to the distal port when the tube is first positioned. Recheck this measurement before each feeding.

Warm the formula to room temperature. Do not microwave!

For bolus feeds: pour formula into the barrel of the syringe attached to the feeding tube. To start the flow, give a gentle push with the plunger but then remove the plunger and allow the fluid to flow into the stomach by gravity. The rate of flow should not exceed 5 ml every 5 to 10 minutes in premature and very small infants and 10 ml/min in older infants and children to prevent nausea and regurgitation. The rate is determined by the diameter of the tubing and the height of the reservoir containing the feeding and is regulated by adjusting the height of the syringe. A usual feeding may take 15 to 30 minutes to complete.

Flush the tube with sterile water (1 or 2 ml for small tubes to 5 to 15 ml or more for large ones) to clear it of formula, or see discussion of flushing for administering medication through nasogastric (NG) tubes in the Nursing Care Guidelines box earlier in this chapter.

Cap or clamp indwelling tubes to prevent loss of feeding.

If the tube is to be removed, first pinch it firmly to prevent escape of fluid as the tube is withdrawn. Withdraw the tube quickly.

Position the child with the head elevated 30 to 45 degrees or on the right side for 30 to 60 minutes in the same manner as after any infant feeding to minimize the possibility of regurgitation and aspiration. If the child's condition permits, burp the youngster after the feeding.

Record the feeding, including the type and amount of residual, the type and amount of formula, and how it was tolerated.

For most infant feedings, any amount of residual fluid aspirated from the stomach is re-fed to prevent electrolyte imbalance, and the amount is subtracted from the prescribed amount of feeding. For example, if the infant is to receive 30 ml and 10 ml is aspirated from the stomach before the feeding, the 10 ml of aspirated stomach contents is re-fed along with 20 ml of feeding. Another method can be used in children. If residual fluid is more than one-fourth of the last feeding, return the aspirate and recheck in 30 to 60 minutes. When residual fluid is less than one-fourth of the last feeding, give the scheduled feeding. If large amounts of aspirated fluid persist and the child is due for another feeding, notify the practitioner.

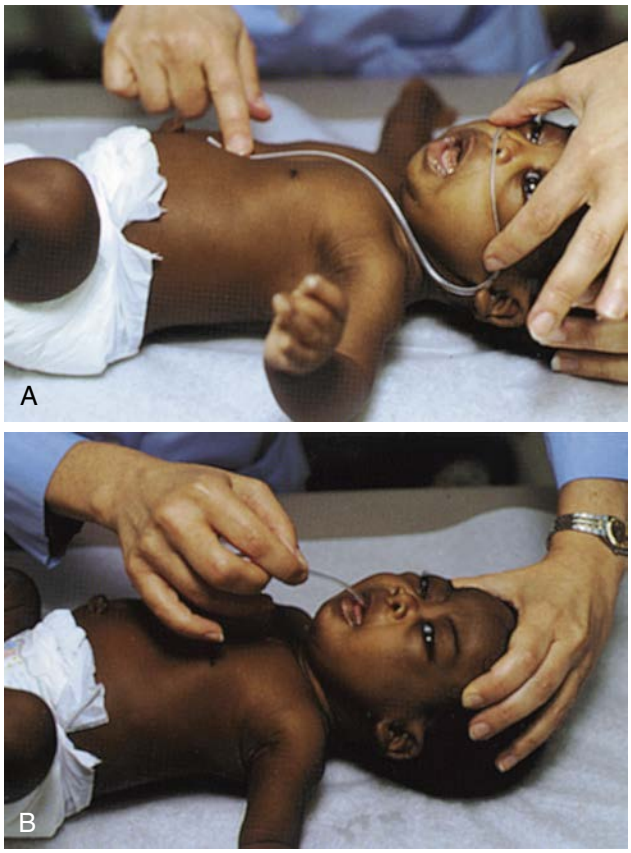

Fig. 20.20 Gavage feeding. **A,** Measuring the tube for orogastric feeding from the tip of the nose to the earlobe and to the midpoint between the end of the xiphoid process and the umbilicus. **B,** Inserting the tube.

Most NG tubes are placed at the bedside by nurses. Proper placement of the tube is essential, and incorrectly placed tubes can result in significant harm to the patient. Correct determination of the length of the tube is a crucial step in the placement procedure. Studies evaluating NG and OG tube length in infants and children found that age-specific methods for predicting the distance based on height is a more accurate estimate of internal distance to the stomach (Beckstrand, Cirgin Ellett, & McDaniel, 2007; Ellett, Cohen, Perkins, et al., 2012), but the calculations are complex and not readily accessible. A convenient and reliable morphologic measurement, the nose-ear–midway to umbilicus (NEMU) span, approached the accuracy of the age-specific prediction equations and is easy to use in a clinical setting (Ellett et al., 2012) (Fig. 20.20A) (see Nursing Care Guidelines box). Research supports radiographs as the gold standard for confirmation of enteral tube placement. Additional methods to check placement, all of which can be done at the bedside, include visual confirmation of aspirate and pH testing of aspirate. Although auscultation is still widely used, multiple sources have documented that it is not an accurate method to confirm enteral tube placement.

NURSING TIP: Enteral feeding tubes may become occluded by debris from medications and/or formulas. Best practice guidelines are aimed at preventing occlusions by adequately flushing between medications and before and after feedings. However, when a feeding tube does become clogged, research shows that warm water is the best choice for initial attempts to unclog (American Society for Parenteral and Enteral Nutrition, 2017). If initial attempts to unclog using water are unsuccessful, a solution of pancreatic enzymes (such as Creon) or commercially available enzyme declogging kits are recommended as a second-line option. Carbonated drinks and cranberry juice are not recommended because these liquids can change the pH of the clogging debris and worsen the occlusion (American Society for Parenteral and Enteral Nutrition, 2017).

GASTROSTOMY FEEDING

Feeding by way of gastrostomy tube, or G-tube, is often used for children in whom passage of a tube through the mouth, pharynx, esophagus, and cardiac sphincter of the stomach is contraindicated or impossible. It is also used to avoid the constant irritation of an NG tube in children who require tube feeding over an extended period. A gastrostomy tube may be placed with the child under general anesthesia or percutaneously using an endoscope with the patient sedated and under local anesthesia (percutaneous endoscopic gastrostomy [PEG]). The tube is inserted through the abdominal wall into the stomach about midway along the greater curvature and secured by a purse-string suture. The stomach is anchored to the peritoneum at the operative site. The gastrostomy tube can be a Foley, wingtip, or mushroom catheter. Immediately after surgery, the catheter may be left open and attached to gravity drainage for 24 hours or more.

Postoperative care of the wound site is directed toward prevention of infection and irritation. Cleanse the area with soap and water, then dry thoroughly, at least daily or as often as needed to keep the area free of drainage. After healing, meticulous care is needed to keep the area surrounding the tube clean and dry to prevent excoriation and infection. Exercise care to prevent excessive tension on the catheter that might cause widening of the opening and subsequent leakage of highly irritating gastric juices. Use barrier ointments such as zinc oxide, and alcohol-free skin barrier film to control leakage; add absorptive powders and pectin-based skin barrier wafers if skin irritation is present (Townley, Wincentak, Krog, et al., 2018). Secure the tube to the abdomen using a commercial stabilizer, polyurethane foam, or the H tape method and leave a small loop of tubing at the exit site to prevent tension on the site.

Granulation tissue may grow around a gastrostomy site (Fig. 20.21). This moist, beefy red tissue is not a sign of infection. However, if it continues to grow, the excess moisture can irritate the surrounding skin. Recommendations for management of hypergranulation include using triamcinolone cream (0.5%) three times daily, applying silver nitrate, stabilizing the tube, and keeping the peristomal area dry by applying polyurethane foam (Fuchs, 2017; Townley et al., 2018). Hydrogen peroxide should not be used because it may dry the tissue too much, leading to additional damage.

For children who require long-term enteral feeding, a low-profile, **skin-level** gastrostomy device (e.g., MIC-KEY, Bard Button) offers several advantages. The small, flexible silicone device protrudes slightly from the abdomen, is cosmetically pleasing, affords increased comfort and mobility to the child, is easy to care for, and is fully immersible in water. The one-way valve at the proximal end minimizes reflux and eliminates the need for clamping. However, the skin-level device requires a well-established gastrostomy site and is more expensive than the conventional tube (Hueschkel, Gottrand, Devarajan, et al., 2015). In addition, the valve may become clogged. When functioning, the valve prevents air from escaping; therefore the child may require frequent bubbling. Some skin-level devices require a special tube to be able to decompress the stomach (to check residual or release air). With some devices, during feedings, the child must remain still, because the tubing easily disconnects from the opening if the child moves. With other devices, extension tubing can be securely attached to the opening (Fig. 20.22). The feeding is instilled at the other end of the tubing in a manner similar to that for a regular gastrostomy. The extension tubing may also have a separate medication port. Both the feeding and the medication ports have plugs attached.

Feeding of water, formula, or pureed foods is carried out in the same manner and rate as for gavage feeding. A mechanical pump may be used to regulate the volume and rate of feeding. After feedings, the infant or child is positioned on the right side or in the Fowler position, and the tube may be clamped or left open and suspended between feedings, depending on the child's condition. A clamped tube allows more mobility but is appropriate only if the child can tolerate intermittent feedings without vomiting or prolonged backup of feeding into the tube. Sometimes a Y tube is used to allow for simultaneous decompression during feeding. If a Foley catheter is used as the gastrostomy tube, apply very slight tension. The tube is securely taped to maintain the balloon at the gastrostomy opening and prevent leakage of gastric contents and the tube's progression toward the pyloric sphincter, where it may occlude the stomach outlet. As a precaution, the length of the tube is measured postoperatively and then remeasured each shift to be certain it has not slipped. The nurse can make a mark above the skin level to further ensure its placement. When the gastrostomy tube is no longer needed, it is removed; the skin opening usually closes spontaneously by contracture.

NASODUODENAL AND NASOJEJUNAL TUBES

Children at high risk for regurgitation or aspiration such as those with gastroparesis, mechanical ventilation, or brain injuries may require placement of a postpyloric feeding tube. A trained provider inserts the nasoduodenal or nasojejunal tube because of the risk of misplacement and potential for perforation in tubes requiring a stylet. Accurate placement is verified by radiography. Small-bore tubes may clog easily. Flush the tube when feeding is interrupted, before and after medication administration, and routinely every 4 hours or as directed by

Fig. 20.21 Appearance of healthy granulation tissue around a stoma.

Fig. 20.22 Child with a low-profile gastrostomy device (MIC-KEY), which provides for secure attachment of extension tubing to the gastrostomy opening.

institutional policy. Tube replacement should be considered monthly to ensure optimal tube patency. Continuous feedings are delivered by a mechanical pump to regulate their volume and rate. Bolus feeds are contraindicated. Tube displacement is suspected in children showing signs of feeding intolerance, such as vomiting. In these cases, stop the feedings and notify the provider. Some medications cannot be administered via postpyloric feeding tubes because they will not be absorbed in the duodenum or jejunum.

TOTAL PARENTERAL NUTRITION

TPN provides for the nutritional needs of infants and children whose lives are threatened because feeding by way of the gastrointestinal tract is impossible, inadequate, or hazardous.

TPN therapy involves IV infusion of highly concentrated solutions of protein, glucose, and other nutrients. The solution is infused through conventional IV tubing with a special filter attached to remove particulate matter or microorganisms that may have contaminated the solution. The highly concentrated solutions require infusion into a central vein with sufficient volume and turbulence to allow for rapid dilution. The wide-diameter vessels selected are the superior vena cava and innominate or intrathoracic subclavian veins, approached by way of the external or internal jugular veins. The highly irritating nature of concentrated glucose precludes the use of the small peripheral veins in most instances. However, dilute glucose–protein hydrolysates that are appropriate for infusing into peripheral veins are being used with increasing frequency. When peripheral veins are used, soybean oil (Intralipid) becomes the major calorie source. For long-term alimentation, central venous catheters are usually used.

The major nursing responsibilities are the same as for any IV therapy and include control of sepsis, monitoring of the infusion rate, and assessment of the patient. The TPN solution must be prepared under rigid aseptic conditions, which is best accomplished by specially trained pharmacists and technicians.

Nurses should change the TPN, lipids, and tubing on a frequent basis. More frequent tubing changes are required for TPN and lipids because these solutions can increase the risk of microbial growth. Meticulous aseptic precautions should be used whenever the line is entered or changed. In most institutions, this is a nursing responsibility, and the procedure is carried out according to hospital protocol.

The TPN infusion is maintained at a constant rate by means of an infusion pump to ensure the proper concentrations of glucose and amino acids. Accurate calculation of the rate is required to deliver a measured amount in a given length of time. Because alterations in flow rate are relatively common, the infusion should be checked frequently to ensure an even, continuous administration. The TPN infusion rate should not be increased or decreased without the provider being informed because alterations can cause hyperglycemia or hypoglycemia.

General assessments, such as vital signs, input and output measurements, and checking results of laboratory tests, facilitate early detection of infection or fluid and electrolyte imbalance. Additional amounts of potassium and sodium chloride are often required in hyperalimentation; therefore observation for signs of potassium or sodium deficit or excess is part of nursing care. This is rarely a problem except in children with reduced renal function or metabolic defects. Hyperglycemia may occur during the first day or two as the child adapts to the high-glucose load of the hyperalimentation solution. Although hyperglycemia occurs infrequently, insulin may be required to help the body adjust. When this occurs, nursing responsibilities include blood glucose testing. To prevent hypoglycemia when the hyperalimentation is discontinued, the rate of the infusion and the amount of insulin are decreased gradually.

FAMILY TEACHING AND HOME CARE

When alternative feedings are needed for an extended period, the family needs to learn how to feed the child with an NG, gastrostomy, or TPN feeding regimen. The same principles apply as discussed earlier in this chapter for compliance, especially in terms of education, and in Chapter 19 for discharge planning and home care. Plan ample time for the family to learn and perform the procedures under supervision before they assume full responsibility for the child's care. Refer the family to community agencies that provide support and practical assistance. The Oley Foundation (http://www.oley.org) is a nonprofit research and education organization that assists persons receiving enteral nutrition and home TPN.

PROCEDURES RELATED TO ELIMINATION

ENEMA

Although not common in pediatrics, enemas are sometimes performed in children: as therapeutic treatment for constipation that has not responded to other measures, for administration of barium contrast during radiologic evaluation of the colon, and occasionally for reduction of intussusception. The procedure for giving an enema to an infant or child does not differ essentially from that for an adult except for the type and amount of fluid administered and the distance for inserting the tube into the rectum (Table 20.8). Depending on the volume, use a syringe with rubber tubing, an enema bottle, or an enema bag.

An isotonic solution is used in children. Plain water is not used because, being hypotonic, it can cause rapid fluid shift and fluid overload. The Fleet enema (pediatric or adult size) is not advised for children because of the harsh action of its ingredients (sodium biphosphate and sodium phosphate). Commercial enemas can be dangerous to patients with megacolon and to dehydrated or azotemic children. The osmotic effect of the Fleet enema may produce diarrhea, which can lead to metabolic acidosis. Other potential complications are extreme hyperphosphatemia, hypernatremia, and hypocalcemia, which may lead to neuromuscular irritability and coma.

NURSING TIP: If prepared saline is not available, the nurse can make some by adding 1 tsp of table salt to 500 ml (1 pint) of tap water.

Because infants and young children are unable to retain the solution after it is administered, the buttocks must be held together for a short time to retain the fluid. The enema is administered and expelled

TABLE 20.8 Administration of Enemas to Children

Age	Amount (ml)	Insertion Distance
Infant	120-240	2.5 cm (1 inch)
2-4 years	240-360	5 cm (2 inches)
4-10 years	360-480	7.5 cm (3 inches)
11 years	480-720	10 cm (4 inches)

while the child is lying with the buttocks over the bedpan and with the head and back supported by pillows. Older children are ordinarily able to hold the solution if they understand what to do and if they are not expected to hold it for too long. The nurse should have the bedpan handy or, for ambulatory children, ensure that the bathroom is available before beginning the procedure. An enema is an intrusive procedure and thus threatening to preschool children; therefore a careful explanation is especially important to ease possible fear.

Antegrade continence enemas (ACEs) are used in the treatment of refractory functional constipation or fecal incontinence. After surgical placement of a cecostomy (an ostomy near the cecum at the proximal end of the large bowel), enema solutions can be administered through the cecostomy, stimulating the bowels to empty "from the top down."

A preoperative bowel preparation solution given orally or through an NG tube is increasingly being used instead of an enema. The polyethylene glycol–electrolyte lavage solution (GoLYTELY) mechanically flushes the bowel without significant absorption, thereby avoiding potential fluid and electrolyte imbalances. NuLYTELY, a modification of GoLYTELY, has the same therapeutic advantages as GoLYTELY and was developed to improve on the taste. Another effective oral cathartic is magnesium citrate solution.

OSTOMIES

Children may require stomas for various health problems. The most frequent causes in infants are necrotizing enterocolitis and imperforate anus and, less often, Hirschsprung disease. In older children, the most frequent causes are inflammatory bowel disease, especially Crohn disease (regional enteritis), and ureterostomies for distal ureter or bladder defects.

Care and management of ostomies in older children differ little from the care of ostomies in adult patients. The major emphasis in pediatric care is preparing the child for the procedure and teaching care of the ostomy to the child and family. The basic principles of preparation are the same as for any procedure (see earlier in the chapter). Simple, straightforward language is most effective together with the use of illustrations and a replica model (e.g., drawing a picture of a child with a stoma on the abdomen and explaining it as "another opening where bowel movements [or any other term the child uses] will come out"). At another time, the nurse can draw a pouch over the opening to demonstrate how the contents are collected. Using a doll to demonstrate the process is an excellent teaching strategy, and special books are available.

Children with ileostomies are fitted immediately after surgery with an appliance to protect the skin from the proteolytic enzymes in the liquid stool. Infants may not be fitted with a pouch in the immediate postoperative period. When stomal drainage is minimal, as is often the case in small or preterm infants, gauze dressing will suffice. Give the parents a choice of caring for the colostomy with or without an appliance. Pediatric appliances are available in a variety of sizes to ensure an adequate fit. Several helpful online resources for parents and children exist through websites of the major ostomy supply companies.

Ostomy equipment consists of a one- or two-piece system with a hypoallergenic skin barrier to maintain peristomal skin integrity. The pouch should be large enough to contain a moderate amount of stool and flatus but not so large as to overwhelm the infant or child. A hydrocolloid backing helps minimize the risk of skin breakdown from moisture trapped between the skin and pouch. Avoid small clips and rubber bands to prevent choking in young children.

Protection of the peristomal skin is a major aspect of stoma care. Well-fitting appliances are important to prevent leakage of contents. Before putting on the appliance, prepare the skin with a skin sealant that is allowed to dry. Then apply stoma paste around the base of the stoma or to the back of the wafer. The sealant and paste work together to prevent peristomal skin breakdown.

In infants with a colostomy left unpouched, skin care is similar to that for any diapered child. However, protect the peristomal skin with a barrier substance (e.g., zinc oxide–based ointment [Sensi-Care] or a mixture of zinc oxide ointment and stoma powder [Stomahesive]). A diaper larger than the one usually worn may be needed to extend upward over the stoma and absorb drainage. If the skin becomes inflamed, denuded, or infected, the care is similar to the interventions used for diaper dermatitis. A zinc-based product helps protect healthy skin, heal excoriated skin, and minimize pain associated with skin breakdown. The skin protectant adheres to denuded, weeping skin. The nurse can apply zinc-based products over topical antifungal and antibacterial agents if infection is present. No-sting barrier film is a skin sealant that has no alcohol base and can be used on open skin without stinging.

With young children, preventing them from pulling off the pouch is also an important consideration. One-piece outfits keep exploring hands from reaching the pouch, and the loose waist avoids any pressure on the appliance. Keeping the child occupied with toys during the pouch change is also helpful. As children mature, encourage their participation in ostomy care. Even preschoolers can assist by holding supplies, pulling paper backings from the appliance, and helping clean the stoma area. Toilet training for bladder control needs to begin at the appropriate time as for any other child.

Older children and adolescents should eventually have total responsibility for ostomy care just as they would for usual bowel function. During adolescence, concerns for body image and the ostomy's impact on intimacy and sexuality emerge. The nurse should stress to teenagers that the presence of a stoma need not interfere with their activities. These youngsters can choose which ostomy equipment is best suited to their needs. Attractively designed and decorated pouch covers are well liked by teenagers.

Children with familial adenomatous polyposis may require a colectomy with ileoanal reservoir to prevent or treat carcinoma of the colon. Peristomal skin care for these children is particularly challenging because of increased liquid stools, increased digestive enzymes that may cause skin breakdown, and the stoma being at skin level rather than raised. Additional care with this condition includes close monitoring of fluid and electrolyte status and increased incidence of bowel obstruction.

An enterostomal therapy nurse specialist is an important member of the health care team and will have additional suggestions and assistance with skin care information and ostomy pouching options. The nurse can obtain further information by contacting the Wound, Ostomy and Continence Nurses Society.[d]

FAMILY TEACHING AND HOME CARE

Because these children are almost always discharged with a functioning colostomy, preparation of the family should begin as early as possible in the hospital. The nurse instructs the family in the application of the device (if used), care of the skin, and appropriate action in case skin problems develop. Early evidence of skin breakdown or stomal complications (such as ribbonlike stools, excessive diarrhea, bleeding, prolapse, or failure to pass flatus or stool) is brought to the attention of the physician, nurse, or stoma specialist. The same principles are applied as discussed earlier in this chapter for compliance, especially in terms of education, and in Chapter 19 for discharge planning and home care.

[d]888-224-9626; http://www.wocn.org.

PROCEDURES FOR MAINTAINING RESPIRATORY FUNCTION

INHALATION THERAPY

Oxygen Therapy

Oxygen is administered for hypoxemia and may be delivered by mask, nasal cannula, face tent, hood, face mask, or ventilator. Oxygen therapy is essential in many pediatric cases, yet unnecessary oxygen delivery can increase hospitalization time and cost (Walsh & Smallwood, 2017). The mode of delivery is selected based on the concentration needed and the child's ability to cooperate in its use. Oxygen therapy is frequently administered in the hospital, although increasing numbers of children are receiving oxygen in the home. Oxygen is dry and therefore must be humidified to prevent damage to the mucosa and dehydration.

Although use is becoming infrequent, oxygen delivered to infants is well tolerated by using a **plastic hood**. At least 7 L/min of flow is necessary to maintain oxygen concentrations and remove the exhaled carbon dioxide. The humidified oxygen should not be blown directly into the infant's face. Older, cooperative infants and children can use a **nasal cannula** or **prongs**, which can supply a concentration of oxygen of about 50%. High-flow nasal cannula (2 to 8 L/min for neonates and 4 to 70 L/min for children) can provide specific oxygen concentration with flow rates capable of meeting the child's inspiratory demand (Walsh & Smallwood, 2017). High-flow nasal cannula may be used to avoid intubation, postextubation, in palliative care, and as a mode of ventilatory support in very low-birth-weight infants. Care with prong size, placement, and maintenance is important to prevent breakdown of the nasal alae.

Oxygen masks are available in pediatric sizes but may not be well tolerated in children, because a snug fit is required to ensure adequate oxygen delivery. Several variations are available with specific flow rates and oxygen concentrations as indicated for patient need. **Oxygen tents** (croup tents) are rarely used today in developed countries. Oxygen concentration is difficult to control, and the child's clothing can become saturated with water from the humidification and cause hypothermia. **Blow-by** oxygen is occasionally attempted for young children who are not able to tolerate a directly applied oxygen delivery device. However, blow-by oxygen therapy provides low, and frequently inconsistent, concentrations of oxygen and should be used only for patients with short-term or intermittent oxygen needs (Walsh & Smallwood, 2017). **Continuous positive airway pressure (CPAP)** systems provides noninvasive mechanical respiratory support through nasal canula or a variety of mask devices for neonates and children in respiratory distress without the need for emergency intubation. CPAP provides regulated, constant pressure to keep airways open and prevent obstruction. **Bilevel positive airway pressure (BiPAP)** provides similar respiratory support but with two different pressure settings for inspiration and expiration. Both CPAP and BiPAP systems can be used during inhaler or nebulizer treatments (Behnke, Lemyre, Czernik, et al., 2019).

DRUG ALERT

Oxygen Toxicity

Prolonged exposure to high oxygen tensions can damage some body tissues and functions. The organs most vulnerable to the adverse effects of excessive oxygenation are the retinas of extremely preterm infants and the lungs of persons at any age.

NURSING ALERT

Inspect all toys for safety and suitability (e.g., vinyl or plastic, not stuffed items that absorb moisture and are difficult to keep dry). The high-level oxygen environment makes any source of sparks (e.g., mechanical or electrical toys) a potential fire hazard.

Oxygen-induced carbon dioxide narcosis is a physiologic hazard of oxygen therapy that may occur in persons with chronic pulmonary disease, such as cystic fibrosis. In these patients, the respiratory center has adapted to the continuously higher arterial carbon dioxide ($PaCO_2$) tension levels, and therefore hypoxia becomes the more powerful stimulus for respiration. When the arterial oxygen (PaO_2) tension level is elevated during oxygen administration, the hypoxic drive is removed, causing progressive hypoventilation and increased $PaCO_2$ levels, and the child rapidly becomes unconscious. Carbon dioxide narcosis can also be induced by the administration of sedation in these patients.

Monitoring Oxygen Therapy

In addition to a patient's respiratory effort and color, **pulse oximetry** is a continuous, noninvasive method of determining arterial oxygen saturation (SaO_2) to guide oxygen therapy. A sensor composed of a light-emitting diode (LED) and a photodetector is placed in opposition around a foot, hand, finger, toe, or earlobe, with the LED placed on top of the nail when digits are used (Fig. 20.23). The diode emits red and infrared lights that pass through the skin to the photodetector. The photodetector measures the amount of each type of light absorbed by functional hemoglobin. Hemoglobin saturated with oxygen (oxyhemoglobin) absorbs more infrared light than does hemoglobin not saturated with oxygen (deoxyhemoglobin). Pulsatile blood flow is the primary physiologic factor that influences accuracy of the pulse oximeter. Reposition the probe at least every 4 to 8 hours to prevent pressure necrosis; poor perfusion and very sensitive skin may necessitate more frequent repositioning.

Another noninvasive method is **transcutaneous monitoring (TCM)**, which provides continuous monitoring of transcutaneous partial pressure of oxygen in arterial blood ($tcPaO_2$) and, with some devices, of transcutaneous partial pressure of carbon dioxide in arterial blood ($tcPaCO_2$). An electrode is attached to the warmed skin to facilitate arterialization of cutaneous capillaries. Because the site of the

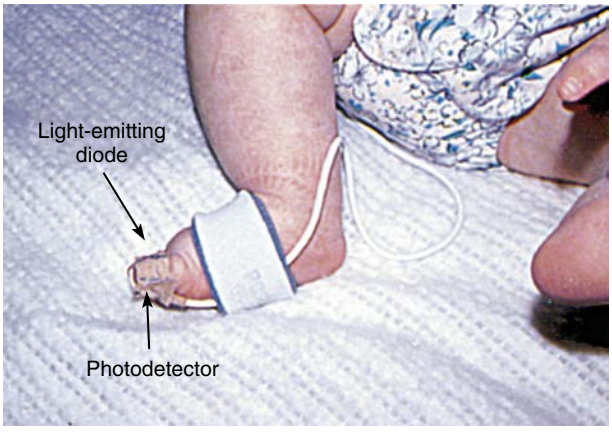

Fig. 20.23 Oximeter sensor on the great toe. Note that the sensor is positioned with a light-emitting diode (LED) opposite the photodetector. The cord is secured to the foot to minimize movement of the sensor.

electrode must be changed every 3 to 4 hours to avoid burning the skin and the machine must be calibrated with every site change, TCM has diminished in use.

Oximetry is insensitive to hyperoxia because hemoglobin approaches 100% saturation for all PaO_2 readings greater than approximately 100 mm Hg, which is a dangerous situation for preterm infants at risk for developing retinopathy of prematurity (see Chapter 8). Therefore preterm infants being monitored with oximetry should have their upper limits identified, such as 90% to 95%, and a protocol should be established for decreasing oxygen when saturations are high.

! NURSING ALERT

It is important to make certain that sensor connectors and oximeters are compatible. Wiring that is incompatible can generate considerable heat at the tip of the sensor, causing second- and third-degree burns under the sensors. Pressure necrosis can also occur from sensors attached too tightly. Therefore inspect the skin under the sensor frequently.

Applying the sensor correctly is essential for accurate SaO_2 measurements. Because the sensor must identify every pulse beat to calculate the SaO_2, movement can interfere with sensing. Some devices synchronize the SaO_2 reading with the heartbeat, thereby reducing the interference caused by motion. Sensors are not placed on extremities used for blood pressure monitoring or with indwelling arterial catheters because pulsatile blood flow may be affected.

NURSING TIP

Infant: Secure the sensor to the great toe and tape the wire to the sole of the foot (or use a commercial holder that fastens with a self-adhering closure). Place a snugly fitting sock over the foot but check the site frequently for color, temperature, and pulse.

Child: Secure the sensor securely to the index finger and tape the wire to the back of the hand.

Ambient light from ceiling lights and phototherapy, as well as high-intensity heat and light from radiant warmers, can interfere with readings. Therefore the sensor should be covered to block these light sources. IV dyes; green, purple, or black nail polish; nonopaque synthetic nails; and possibly ink used for footprinting can also cause inaccurate SaO_2 measurements. The dyes should be removed, or in the case of porcelain nails, a different area should be used for the sensor. Skin color, thickness, and edema do not affect the readings.

Blood gas measurements are sensitive indicators of change in respiratory status in acutely ill patients. They provide valuable information on lung function, lung adequacy, and tissue perfusion. The pH, $PaCO_2$, bicarbonate (HCO_3), and PaO_2 levels can provide information about whether the child is compensating and guide critical treatment decisions.

END-TIDAL CARBON DIOXIDE MONITORING

End-tidal carbon dioxide ($ETCO_2$) monitoring measures exhaled carbon dioxide noninvasively. Capnometry provides a numeric display, and capnography provides a graph over time. Continuous capnometry is available in many bedside physiologic monitors, as well as standalone monitors. $ETCO_2$ differs from pulse oximetry in that it is more sensitive to the mechanics of ventilation rather than oxygenation. Hypoxic episodes can be prevented through the early detection of hypoventilation, apnea, or airway obstruction.

Children who are experiencing an asthma exacerbation, receiving procedural sedation, or are mechanically ventilated may have $ETCO_2$ monitoring. Special sampling cannulas are used for nonintubated patients, and a small device is placed between the endotracheal (ET) tube and the ventilator tubing in intubated patients. Although $ETCO_2$ monitoring is not a substitute for arterial blood gases, it does have the information of providing ventilation information continuously and noninvasively. Normal $ETCO_2$ values are 30 to 43 mm Hg, which is slightly lower than normal partial pressure of carbon dioxide (PCO_2) of 35 to 45 mm Hg. During cardiopulmonary resuscitation (CPR), $ETCO_2$ values consistently below 15 mm Hg indicate ineffective compressions or excessive ventilation. Changes in waveform and numeric display follow changes in ventilation by very few seconds and precede changes in respiratory rate, skin color, and pulse oximetry values.

For years, disposable colorimetric $ETCO_2$ detectors have been used to assess ET tube placement. A color change with each exhaled breath when there is adequate systemic perfusion indicates that the tube is in the lungs. These devices do not provide numbers or graphic representation and do not provide the same early detection of hypoventilation as the continuous quantitative monitors.

Additional uses of $ETCO_2$ monitoring include early detection of opioid-induced respiratory depression, effectiveness of CPR, and severity of asthma exacerbation (Siobal, 2016).

When there is a change in the $ETCO_2$ value or waveform, assess the patient quickly for adequate airway, breathing, and circulation. Sedated patients may be hypoventilating and need stimulation. Intubated patients may need suctioning, have self-extubated or dislodged the tube, or have equipment failure or disconnection. Patients with asthma may have a worsening condition. Problems with the $ETCO_2$ monitoring system can include a kink in the sample line or disconnection. In general, check the patient first and then check the equipment.

BRONCHIAL (POSTURAL) DRAINAGE

Bronchial drainage is indicated whenever excessive fluid or mucus in the bronchi is not being removed by normal ciliary activity and cough. Positioning the child to take maximum advantage of gravity facilitates removal of secretions from the lobes to the larger airways to be expelled. Postural drainage can be effective in children with chronic lung disease characterized by thick mucus, such as cystic fibrosis.

Postural drainage is carried out two to four times daily and is more effective when it follows other respiratory therapy, such as bronchodilator or nebulization medication. Bronchial drainage is generally performed before meals (or 1 to 1½ hours after meals) to minimize the chance of vomiting and is repeated at bedtime. The duration of treatment depends on the child's condition and tolerance; it usually lasts 20 to 40 minutes. Several positions facilitate drainage from all major lung segments. When the child is in each position, the caregiver cups a hand and claps on the chest wall. The child then is encouraged to cough or huff forcefully to move the mucus up and out of the lungs (Cystic Fibrosis Foundation, 2012).

CHEST PHYSICAL THERAPY

Chest physical therapy (CPT) usually refers to the use of postural drainage in combination with adjunctive techniques that are thought to

enhance the clearance of mucus from the airway. These techniques include manual percussion, vibration, and squeezing of the chest; cough; forceful expiration; and breathing exercises. Special mechanical devices are also currently used to perform CPT (e.g., vest-type percussors). Postural drainage in combination with forced expiration has been shown to be beneficial.

Common techniques used in association with postural drainage include manual percussion of the chest wall and percussion with mechanical devices, such as a high-frequency handheld chest compression device. A "popping," hollow sound, not a slapping sound, should be the result. The procedure should be done over the rib cage only and should be painless. Percussion can be performed with a soft circular mask (adapted to maintain air trapping) or a percussion cup marketed especially for the purpose of aiding in loosening secretions. CPT is contraindicated when patients have pulmonary hemorrhage, pulmonary embolism, end-stage renal disease, increased intracranial pressure, osteogenesis imperfecta, or minimal cardiac reserves. To enhance patient comfort during CPT, the patient should wear light clothing without zippers, buttons, or pins. CPT should not be painful, and the caregiver should remove watches and rings to minimize discomfort (Cystic Fibrosis Foundation, 2012).

INTUBATION

Rapid-sequence intubation (RSI) is commonly performed in pediatric and neonatal patients to induce an unconscious, neuromuscular blocked condition in order to intubate quickly and reduce complications (Groth, Acquisto, & Khadem, 2018). Atropine, etomidate, midazolam, ketamine, diazepam, propofol, and fentanyl are commonly used to induce sedation while vecuronium, rocuronium, and succinylcholine are used as paralytic agents during RSI (Groth et al., 2018; Pallin, Dwyer, Walls, et al., 2016).

Indications for intubation include:

- Respiratory failure or arrest, agonal or gasping respirations, apnea
- Upper airway obstruction
- Significant increase in work of breathing, use of accessory muscles
- Potential for developing partial or complete airway obstruction—respiratory effort with no breath sounds, facial trauma, and inhalation injuries
- Potential for or actual loss of airway protection, increased risk for aspiration
- Anticipated need for mechanical ventilation related to chest trauma, shock, increased intracranial pressure
- Hypoxemia despite supplemental oxygen
- Inadequate ventilation

In preparation for intubation, the child should be preoxygenated with 100% oxygen using an appropriate-size bag and mask. Historically, uncuffed ET tubes were used in young children to avoid the risk of postintubation stridor and tracheal mucosal injury. However, current literature suggests that there is no significant difference in postintubation stridor, potential trachea mucosa damage, intubation duration, and the need for reintubation between uncuffed and cuffed ET tubes (Shi, Xiao, Xiong, et al., 2016). Air or gas delivered directly to the trachea must be humidified. During intubation, the cardiac rhythm, heart rate, and oxygen saturation should be monitored continuously with audible tones. Video laryngoscopy is a technique increasing in use that can assist the provider in accurately visualizing the airway and is associated with increased first attempt success (Pallin et al., 2016). ET tube placement should be verified by at least one clinical sign and at least one confirmatory technology:

- Visualization of bilateral chest expansion
- Auscultation over the epigastrium (breath sounds should not be heard) and the lung fields bilaterally in the axillary region (breath sounds should be equal and adequate)
- Color change on $ETCO_2$ detector during exhalation after at least three to six breaths or waveform/value verification with continuous capnography
- Chest radiography

Apply a protective skin barrier and secure the ET tube with tape or a securement device. An NG tube is typically inserted after intubation.

MECHANICAL VENTILATION

ET intubation can be accomplished by the nasal (nasotracheal), oral (orotracheal), or direct tracheal (tracheostomy) routes. Although it is more difficult to place and infrequently practiced, nasotracheal intubation is preferred to orotracheal intubation because it facilitates oral hygiene and provides more stable fixation, which reduces the complication of tracheal erosion and the danger of accidental extubation.

Basic ongoing assessment of the mechanically ventilated patient includes observing the chest rise and fall for symmetry, bilateral breath sounds equal or unchanged from last assessment, level of consciousness, capillary refill and skin color, and vital signs. A heart rate that is too fast or too slow is a possible indication of hypoxemia, air leak, or low cardiac output. Pulse oximetry and $ETCO_2$ monitoring is also routine along with periodic arterial blood gas analysis. If sudden deterioration of an intubated patient occurs, the American Heart Association recommends considering the following etiologies:

- DOPE (de Caen et al., 2015)
  - Displacement: the tube is not in the trachea or has moved into a bronchus (right mainstem most common)
  - Obstruction: secretions or kinking of the tube
  - Pneumothorax: chest trauma, barotraumas, or noncompliant lung disease
  - Equipment failure: check the oxygen source, Ambu bag, and ventilator
- Verify placement again during each transport and when patients are moved to different beds

To maintain skin integrity in the mechanically ventilated patient, reposition the patient at least every 2 hours as the patient's condition tolerates. Apply a hydrocolloid barrier to protect the facial cheeks. Place gel pillows under pressure points, such as occiput, heels, elbows, and shoulders. Allow no tubes, lines, wires, or wrinkles in bedding under the patient. Provide meticulous skin care.

Provide analgesia and sedation as needed. Use a system for communication that includes sign boards, pointing, and opening and closing eyes. To maintain safety, use soft restraints if necessary to maintain a critical airway.

Ventilator-associated pneumonia (VAP) is a complication that can be prevented through the use of aggressive hand hygiene, wearing gloves to handle respiratory secretions or contaminated objects, use of closed suctioning systems, routine oral care, elevation of the head of the bed between 30 and 45 degrees (unless contraindicated), and discontinuing the ventilator as soon as possible (Centers for Disease Control and Prevention, 2019). Enteral nutrition is often provided to decrease the risk of bacterial translocation. Routinely assess the patient's intestinal motility (e.g., by auscultating for bowel sounds and measuring residual gastric volume or abdominal girth) and adjust the rate and volume of enteral feeding to avoid regurgitation. In high-risk

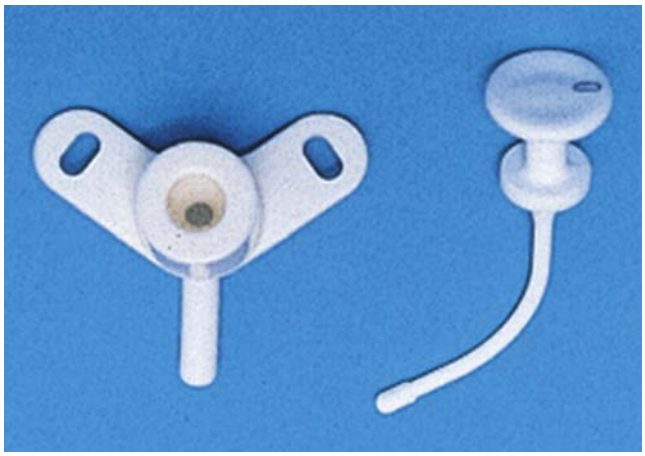

Fig. 20.24 Silastic pediatric tracheostomy tube and obturator.

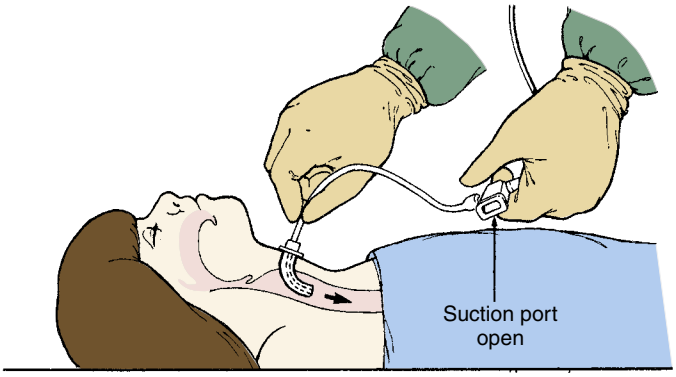

Fig. 20.25 Tracheostomy suction catheter insertion. Note that the catheter is inserted just to the end of the tracheostomy tube.

patients (decreased gag reflex, delayed gastric emptying, gastroesophageal reflux, severe bronchospasm), postpyloric (duodenal or jejunal) feeding tubes are often used. To prevent the aspiration of pooled secretions, suction the hypopharynx before suctioning the ET tube, before repositioning the ET tube, and before repositioning the patient. Prevent ventilator circuits' condensate from entering the ET tube or in-line medication nebulizers.

Assess readiness to extubate daily. Indications that a child is ready to be extubated include an improvement in underlying condition, hemodynamic stability, and mechanical support no longer being necessary. Assess level of consciousness and ability to maintain a patent airway by mobilizing pulmonary secretions through effective coughing. Maintain NPO status 4 hours before extubation. After extubation, monitor for respiratory distress, which may develop within minutes or hours. Signs of postintubation respiratory distress include stridor, hoarseness, increased work of breathing, unstable vital signs, and desaturations.

Tracheostomy

A tracheostomy is a surgical opening in the trachea; the procedure may be done on an emergency basis or may be an elective one, and it may be combined with mechanical ventilation. Indications for tracheostomy placement include upper-airway obstruction or abnormalities, the need for chronic ventilatory support, abnormal ventilatory drive, or neuromuscular conditions affecting ventilation (Watters, 2017). Pediatric tracheostomy tubes are usually made of plastic or silastic (Fig. 20.24). The most common types are the Bivona, Shiley, Tracoe, Arcadia, and Hollinger tubes. These tubes are constructed with a more acute angle than adult tubes, and they soften at body temperature, conforming to the contours of the trachea. Because these materials resist the formation of crusted respiratory secretions, they are made without an inner cannula.

Children who have undergone a tracheostomy must be closely monitored for complications, such as hemorrhage, edema, aspiration, accidental decannulation, tube obstruction, pulmonary infections, skin breakdown, and the entrance of free air into the pleural cavity. The focuses of nursing care are maintaining a patent airway, facilitating the removal of pulmonary secretions, providing humidified air or oxygen, cleansing the stoma, monitoring the child's ability to swallow, and teaching while simultaneously preventing complications.

Because the child may be unable to signal for help, direct observation and use of respiratory and cardiac monitors are essential in the early postoperative period. Respiratory assessments include breath sounds and work of breathing, vital signs, tightness of the tracheostomy ties, skin assessment around the device, and the type and amount of secretions. Large amounts of bloody secretions are uncommon and should be considered a sign of hemorrhage. The practitioner should be notified immediately if this occurs.

The child is positioned with the head of the bed raised or in the position most comfortable to the child with the call light easily available. Suction catheters, suction source, oxygen, bag valve mask, gloves, water-based lubricant, sterile gauze for wiping away secretions, scissors, an extra tracheostomy tube of the same size with ties already attached, another tracheostomy tube one size smaller, and the obturator are kept at the bedside. A source of humidification is provided because the normal humidification and filtering functions of the airway have been bypassed. IV fluids ensure adequate hydration until the child can swallow sufficient amounts of fluids.

Suctioning

The airway must remain patent and may require frequent suctioning to remove mucus plugs and excessive secretions. Proper vacuum pressure and suction catheter size are important to prevent tissue damage, atelectasis, and decrease hypoxia from the suctioning procedure. Vacuum pressure should range from 60 to 80 mm Hg for neonates, 80 to 100 mm Hg for infants and children, and 80 to 120 mm Hg for adolescents (Boroughs & Dougherty, 2015). Unless secretions are thick and tenacious, the lower range of negative pressure is recommended. Tracheal suction catheters are available in a variety of sizes. The catheter selected should be the largest size possible that will fit inside the tracheostomy tube. The catheter should have multiple holes at its distal end to increase secretion removal. Historically, applying suction only when removing the catheter by covering the port with the thumb was the standard recommendation (Fig. 20.25). However, one study found that applying suction while inserting and removing the catheter resulted in fewer secretions by patients over the next 90 minutes when compared to patients suctioned using the traditional method (McClean, 2012). The catheter is inserted just to the end of the tracheostomy tube. Suctioning duration should not last more than 5 seconds. Twisting or twirling the catheter between fingers and thumb rather than stirring can assist in removing secretions (Boroughs & Dougherty, 2015). The practice of instilling sterile saline in the tracheostomy tube before suctioning is not supported by research and is no longer recommended (see Translating Evidence Into Practice box).

TRANSLATING EVIDENCE INTO PRACTICE

Normal Saline Instillation Before Endotracheal or Tracheostomy Suctioning: Helpful or Harmful?

Ask the Question

PICOT Question

In intubated children and those with tracheostomy, is normal saline (NS) instillation before suctioning helpful or harmful?

Critically Analyze the Evidence

There is **moderate evidence** with a **strong recommendation** (Balshem, Helfand, Schunemann, et al., 2011).

- Instillation of NS before endotracheal (ET) tube suctioning has been used for years to loosen and dilute secretions, lubricate the suction catheter, and promote cough. In recent years, the possible adverse effects of this procedure have been explored. Adult studies have found decreased oxygen saturation, increased frequency of nosocomial pneumonia, and increased intracranial pressure after instillation of NS before suctioning (Ackerman, 1993; Ackerman & Gugerty, 1990; Bostick & Wendelgass, 1987; Hagler & Traver, 1994; Kinlock, 1999; O'Neal, Grap, Thompson, et al., 2001; Reynolds, Hoffman, Schlichtig, et al., 1990).
- Two of the first research studies evaluating the effect of NS instillation before suctioning in neonates found no deleterious effects. Shorten, Byrne, and Jones (1991) found no significant differences in oxygenation, heart rate, or blood pressure before or after suctioning in a group of 27 intubated neonates.
- In a second study of nine neonates acting as their own controls, no adverse effects on lung mechanics were found after NS instillation and suctioning (Beeram & Dhanireddy, 1992).
- A study evaluating the effects of NS instillation before suctioning in children found results similar to those in the previously published adult studies. Ridling, Martin, and Bratton (2003) evaluated the effects of NS instillation before suctioning in a group of 24 critically ill children, ages 10 weeks to 14 years old (level 1 evidence). A total of 104 suctioning episodes were analyzed. Children experienced significantly greater oxygen desaturation after suctioning if NS was instilled. Sedigheh and Hossein (2011) also found that instillation of NS before suctioning can cause an adverse effect on oxygen saturation. Another study by Zahran and Abd El-Razik (2011) found a significant increase in arterial carbon dioxide ($PaCO_2$) after suctioning and a reduction in oxygen tension and arterial oxygen saturation (SaO_2) 5 minutes after suctioning. The authors advocate to educate caregivers to avoid using saline to liquefy secretions before suctioning and recommend adequate hydration and humidification, as well as the use of mucolytics.
- The American Thoracic Society states that routine use of NS is not recommended and that adequate humidification should be maintained (Sherman, Davis, Albamonte-Petrick, et al., 2000).
- Gardner and Shirland (2009) evaluated 10 studies on the effects of instilling NS in intubated neonates and concluded that the evidence does not support routine instillation of NS; however, the evidence indicating adverse effect of NS instillation is abundant. Morrow and Argent (2008) suggest that despite evidence indicating the detriment of the use of saline for suctioning in adults, evidence is lacking in the pediatric population. They conclude, however, that saline should not be routinely used for suctioning infants and children.
- Wang and colleagues (2017) evaluated 5 studies on the effects of instilling NS before suctioning in 337 intubated pediatric patients in the intensive care unit. Oxygen saturations remained significantly higher in groups without NS instillation, whereas blood pressure and heart rate did not significantly vary. Overall, the authors conclude that there is no benefit to instilling NS prior to suctioning for pediatric patients.

Apply the Evidence: Nursing Implications

Studies support the contention that the adverse effects of NS instillation before suctioning in children are similar to those found for adults. This technique causes a significant reduction in oxygen saturation that can last up to 2 minutes after suctioning. The evidence does not support the use of NS instillation before ET suctioning in children.

NURSING TIP In a closed suction system, a suction catheter is attached directly to the ventilator tubing. This system has several advantages. First, there is no need to disconnect the patient from the ventilator, which allows for better oxygenation. Second, the suction catheter is enclosed in a plastic sheath, which reduces the risk that the nurse will be exposed to the patient's secretions.

! NURSING ALERT

Suctioning is carried out only as often as needed to keep the tube patent. Signs of mucus partially occluding the airway include an increased heart rate, a rise in respiratory effort, a drop in oxygen saturation, cyanosis, or an increase in the positive inspiratory pressure on the ventilator. If the patient has no signs of secretions, the patient should be suctioned at least in the morning and at night.

The child is allowed to rest for 30 to 60 seconds after each aspiration to allow oxygen saturation to return to normal; then the process is repeated until the trachea is clear. Suctioning should be limited to about three aspirations in one period. If secretions are unable to be cleared after three attempts, the nurse should consider the presence of a mucus plug and possibly perform a tracheostomy tube change. Oximetry is used to monitor suctioning and prevent hypoxia.

In the acute care setting, aseptic technique is used during care of the tracheostomy. Secondary infection is a major concern because the air entering the lower airway bypasses the natural defenses of the upper airway. Gloves are worn during the aspiration procedure, although a sterile glove is needed only on the hand touching the catheter. A new tube, gloves, and sterile saline solution are used each time.

Routine Care

The tracheostomy stoma requires care twice per day. Assessments of the stoma area include observations for signs of infection and breakdown of the skin. The skin is kept clean and dry, and crusted secretions around the stoma may be gently removed with mild soap and water or half-strength hydrogen peroxide. Hydrogen peroxide should not be used with sterling silver tracheostomy tubes, because it tends to pit and stain the silver surface. The nurse should be aware of wet tracheostomy dressings, which can predispose the peristomal area to skin breakdown. Several products are available to prevent or treat excoriation. The Allevyn tracheostomy dressing is a hydrophilic sponge with a polyurethane back that is highly absorptive. Other possible barriers to help maintain skin integrity include the use of hydrocolloid wafers (e.g., DuoDERM CGF, Hollister Restore, Mepilex Lite) under the tracheostomy flanges, as well as extra-thin hydrocolloid wafers under the chin.

The tracheostomy tube is held in place with tracheostomy ties made of a durable, nonfraying material. The ties are changed daily and when soiled. A self-adhering Velcro collar is commonly used. The collar or ties should be tight enough to allow just a fingertip to be inserted between the ties and the neck (Fig. 20.26). It is easier to ensure a snug fit if the child's head is flexed rather than extended while the ties are being secured.

Routine tracheostomy tube changes are usually carried out weekly after a tract has been formed to minimize the formation of granulation tissue. The first change is usually performed by the surgeon; subsequent changes are performed by the nurse or respiratory therapist and, if the child is discharged home with the tracheostomy, by either a parent or a visiting nurse. Ideally, two caregivers participate in the procedure to assist with positioning the child.

Fig. 20.26 Tracheostomy ties are snug but allow one finger to be inserted.

Changing the tracheostomy tube is accomplished using strict aseptic technique. A gown and eye protection should be worn to change the tracheostomy. Sterile gloves may be worn for insertion of the sterile tracheostomy tube, but clean gloves may be used for tubes that are cleansed and reused. Tube changes should occur before meals or 2 hours after the last meal. Continuous feedings should be turned off at least 1 hour before a tube change. The new sterile tube is prepared by inserting the obturator, applying water-based lubricant, and attaching new ties. The child may be suctioned if necessary, before the procedure and positioned with the neck slightly extended. One caregiver removes the old ties and removes the tube from the stoma. The new tube is inserted gently into the stoma (using a downward and forward motion that follows the curve of the trachea), the obturator is removed, and the ties are secured. Assess for airway placement and adequacy of ventilation to ensure that the tube is not inserted into the soft tissue surrounding the trachea.

Supplemental oxygen is always delivered with a humidification system to prevent drying of the respiratory mucosa. Humidification of room air for an established tracheostomy can be intermittent if secretions remain thin enough to be coughed or suctioned from the tracheostomy. Direct humidification via a heat and moisture exchanger (HME) can be provided to promote thin secretions and improve speech quality. HMEs may not be suitable for all patients, as they can increase the work of breathing or increase the difficulty of clearing large amounts of secretions (Watters, 2017). HMEs are not used routinely at night in order to allow the patient to rest comfortably without increased work of breathing. A tracheostomy collar is another alternative to provide humidification for patients unable to tolerate HMEs and is also the preferred humidification method for use while sleeping. Room humidifiers are also used successfully.

If present, the inner cannula, should be removed twice daily, cleaned per manufacturer guidelines, dried thoroughly, and reinserted. In some cases, the inner cannula is disposable and replaced with each change.

Current literature supports the use of speaking valves to promote language development in infants and children, improve swallowing skills, and provide earlier decannulation (Watters, 2017). One-way speaking valves allow expiratory flow to pass through the vocal cords, resulting in the ability to speak. Speaking valves should be ordered by the provider and initiated through a trial period. The speaking valve should be removed if the patient exhibits any signs of distress. Speech therapy is a key member of the multidisciplinary team when evaluating the patient's tolerance of the speaking valve.

Emergency Care: Tube Occlusion and Accidental Decannulation

Occlusion of the tracheostomy tube is life threatening, and infants and children are at greater risk than adults because of the smaller diameter of the tube. Maintaining patency of the tube is accomplished with suctioning and routine tube changes to prevent the formation of crusts that can occlude the tube.

! NURSING ALERT

Hyperventilating the child with 100% oxygen before and after suctioning (using a bag valve mask or increasing the fraction of inspired oxygen [FiO_2] concentration ventilator setting) may be performed to prevent hypoxia. Closed tracheal suctioning systems that allow for uninterrupted oxygen delivery may also be used.

Accidental decannulation also requires immediate tube replacement. Some children have a rigid trachea, so the airway remains partially open when the tube is removed. However, others have malformed or flexible tracheal cartilage, which causes the airway to collapse when the tube is removed or dislodged. Because many infants and children with upper airway problems have little airway reserve, if replacement of the dislodged tube is impossible, a smaller tube should be inserted. If the stoma cannot be cannulated with another tracheostomy tube, the stoma may be covered with gauze and manual breaths administered through a bag valve mask device until emergency help arrives (Boroughs & Dougherty, 2015).

CHEST TUBE PROCEDURES

A chest tube is placed to remove fluid or air from the pleural or pericardial space. Chest tube drainage systems collect air and fluid while inhibiting backflow into the pleural or pericardial space. Indications for chest tube placement include pneumothorax, hemothorax, chylothorax, empyema, pleural or pericardial effusion, and prevention of accumulation of fluid in the pleural and pericardial space after cardiothoracic surgery. Nursing responsibilities include assisting with chest tube placement, managing chest tubes, and assisting with chest tube removal.

Before chest tube insertion, assess hematologic and coagulation studies for any risk of bleeding during the procedure. Notify the physician of abnormal findings. Prepare the drainage system with sterile water as described in the package insert (some systems may not require this step). Administer pain and sedation medications as ordered. Monitor airway, breathing, circulation, and pulse oximetry throughout the procedure.

After the tube has been inserted and connected to the chest drainage system, secure the tubing to the patient's gown or diaper so that it does not become disconnected. If suction is required, use connection tubing to join the drainage system to a wall suction adapter and adjust suction on the drainage system as ordered (usually −10 to −20 cm H_2O). There should be gentle, continuous bubbling in the suction control chamber. Place occlusive dressing over the chest tube insertion site per hospital policy. Note the date, time, and your initials on the dressing. Ensure that the drainage system is positioned below the patient's chest and secured to the floor or bed. Keep the drainage tubing free of dependent loops. Obtain a chest radiograph to confirm placement of the chest tube. Ensure that daily chest radiographs are scheduled to monitor placement of the chest tube as well as resolution of the pneumothorax or effusion. An emergency kit consisting of clamps, petroleum gauze, sterile gauze, and a transparent occlusive dressing should be kept at the patient's bedside in case of emergency.

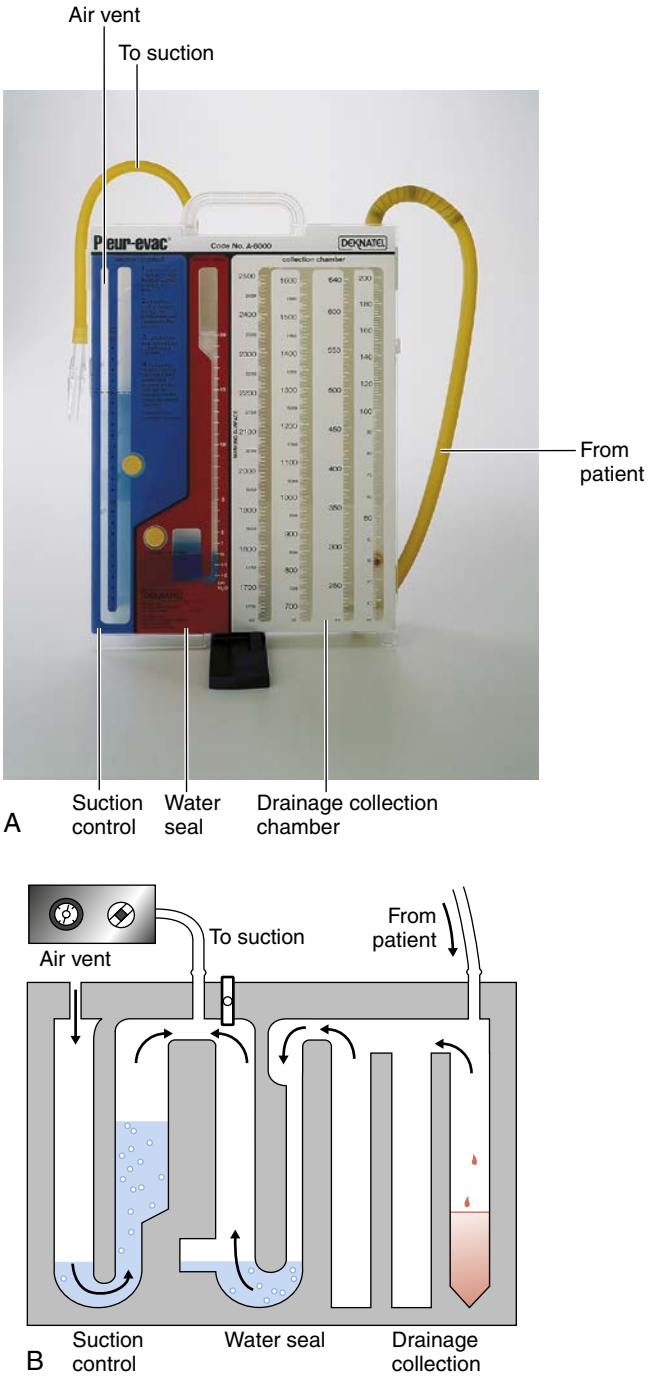

Fig. 20.27 **A,** The Pleur-Evac drainage system, a commercial three-bottle chest drainage device. **B,** Schematic of the drainage device. (From Ignatavicius, D. D., & Workman, L. M. [2013]. *Medical-surgical nursing: Patient-centered collaborative care* [7th ed.]. Philadelphia, PA: Saunders/Elsevier.)

Disposable chest drainage systems typically consist of three chambers next to one another in one drainage unit (Fig. 20.27). The fluid collection chamber collects drainage from the patient's pleural or pericardial space. The water seal chamber is directly connected to the fluid collection chamber and acts as a one-way valve, protecting patients from air returning to the pleural or pericardial space. The suction chamber may be a dry suction or calibrated water chamber. It is connected to external vacuum suction set to the amount of suction

ordered and controls the amount of suction that patients experience. Chest tube drainage and settings should be monitored at least once every shift.

Assess for blood clots and fibrin strands in tubes with sanguinous or serosanguineous drainage and ensure that there are no obstructions to drainage in the tube. Maintain chest tube clearance per hospital policy. Milking or stripping of chest tubes is not recommended for chest tube clearance because of the high negative intrathoracic pressure that is created. Striping of chest tubes should be performed only with a provider order. However, some special circumstances warrant chest tube clearance with these methods, such as maintaining chest tube patency while a patient is bleeding. Notify the physician immediately if chest tube obstruction is suspected. Generally, chest tubes should not be clamped. However, it may be necessary to clamp a chest tube when exchanging the collection chamber or to determine the site of an air leak (see Nursing Care Guidelines box).

NURSING CARE GUIDELINES

Ongoing Patient and Chest Drainage System Assessment

Drainage type (sanguinous, serosanguineous, serous, chylous, empyemic), color, amount, consistency. If there is a marked decrease in the amount of drainage, assess for drainage around the chest tube insertion site.

Dressing is clean, dry, and intact.

Chest tube sutures are intact.

Prescribed amount of suction is applied.

Water level is at 2 cm. If the water column is too high, the flow of air from the chest may be impeded.

Bubbling in the water seal chamber is normal if the chest tube was placed to evacuate a pneumothorax. The bubbling will stop when the pneumothorax has resolved.

Fluctuations may be seen in the water column because of changes in intrathoracic pressure. Substantial fluctuations may reflect changes in a patient's respiratory status.

Signs and symptoms of infection or skin breakdown.

Palpate for the presence of subcutaneous air.

Interventions

Notify the physician of any changes in the quantity or quality of drainage.

If 3 ml/kg/h or greater of sanguinous drainage occurs for 2 to 3 consecutive hours after cardiothoracic surgery, it may indicate active hemorrhaging and warrants immediate attention by the physician.

Change dressing and perform site care per hospital policy. Typically, a minimal, occlusive dressing is applied.

When the collection chamber is almost full, exchange existing drainage system with a new one per manufacturer's instructions using sterile technique.

To lower the water column, depress the manual vent on the back of the unit until the water level reaches 2 cm. *Do not depress the filtered manual vent when the suction is not functioning or connected.*

If evacuation of a pneumothorax was not the indication for placement of the chest tube, bubbling in the water seal chamber may be the result of a break in the chest drainage system. Identify the break in the system by briefly clamping the system between the drainage unit and the patient. When the clamp is placed between the unit and the break in the system, the bubbling will stop. Tighten any loose connections. If the air leak is suspected to be at the patient's chest wall, notify the physician.

Encourage patient ambulation. Secure chest tube drainage system to prevent chest tube dislodgment from patient or disconnection from drainage system.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A new nurse in orientation is preparing to discharge a 2-year-old girl who will need to continue oral antibiotics at home. Which statements below, if made by the new nurse, indicate a need for further nursing education on the best methods for teaching parents to administer an oral medication at home? **Select all that apply.**
   - **A.** The best means for measuring small amounts of medication is a plastic cup.
   - **B.** Using a dropper is acceptable, remembering that thick fluids are easier to measure than viscous fluids.
   - **C.** For more exact measuring, emptying dropper contents into a medicine cup can be helpful.
   - **D.** The most accurate means of measuring small amounts of medication is using a plastic disposable calibrated oral syringe.
   - **E.** A measuring teaspoon is often the unit of measurement for pediatric medication and is especially helpful when working with families.
   - **F.** Household spoons can provide accurate measurement when other devices are not available.

2. The nurse will be giving an intramuscular injection. The infant is 6 months of age and is to receive his scheduled vaccinations. Which principles would the nurse consider when giving the scheduled injections? **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**

   Usually __1__ of fluid is the maximum volume that would be administered intramuscularly in a single site to infants. The __2__ muscle should never be used to administer immunizations.

Option 1	Option 2
5 ml	deltoid
2 ml	dorsogluteal
1 ml	ventrogluteal
8 ml	vastus lateralis

3. A mother of a newborn is extremely upset because blood was obtained by a heelstick. She found bruising at the site and believes that the procedure was performed incorrectly. What statements below are appropriate for the nurse to discuss with the mother? **Select all that apply.**
   - **A.** "Feeding your newborn during the heel lance can reduce pain."
   - **B.** "A heelstick can be performed safely using the outer aspect of the heel."
   - **C.** " We use a device that delivers a precise puncture depth and is less painful."
   - **D.** "We avoid osteochondritis (underlying calcaneus bone, infection, and abscess of the heel), the puncture by going no deeper than 5 mm."
   - **E.** "The heelstick is performed on a newborn because it is less invasive and less painful than a venipuncture."
   - **F.** "Breastfeeding during the heelstick can reduce pain if you would like to try this before the next blood draw."

4. The nurse is preparing to insert a peripheral intravenous line on a 9-year-old girl who has sickle cell disease and experiencing a vaso-occlusive crisis. The child has been stuck numerous times because of the disease and tells the nurse she is not afraid of needles. Which actions would the nurse take? **Use an X for the nursing action statements below that are Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Nursing Action	Indicated	Contraindicated	Non-Essential
An 18-gauge catheter needs to be inserted.			
A blunt plastic cannula needs to be used because it prevents the need for steel needles.			
An injection port site is used to deliver medications.			
An opaque covering of the IV site needs to be used.			
Music should be played in the background when performing the insertion.			
A padded board would be placed below the hand where the catheter is inserted.			
Fingers are left unoccluded by tape or dressing to assess circulation.

CONCEPTS

- Gas Exchange
- Inflammation
- Infection
- Fluid and Electrolyte Balance
- Patient Education

RESPIRATORY INFECTIONS

Infections of the respiratory tract are described according to the anatomic area of involvement. The upper respiratory tract, or upper airway, consists of the oronasopharynx, pharynx, larynx, and upper part of the trachea. The lower respiratory tract consists of the lower trachea and two cone-shaped lungs including the bronchi, bronchioles, and innumerable small air sacs, or alveoli (see Chapter 4, Lungs). The bronchi and bronchioles are the reactive portion of the lower respiratory tract because they have smooth muscle content and the ability to constrict. Respiratory infections often spread from one structure to another because of the contiguous nature of the mucous membrane lining the entire tract. Consequently, respiratory tract infections involve several areas rather than a single structure, although the effect on one area may predominate in any given illness. The impact of COVID-19 is widespread. Children are less likely to become severely ill than older adults but there are subpopulations of children with an increased risk for more significant illness. Children with underlying pulmonary pathology, immunocompromising conditions, and those who are younger are associated with more severe outcomes (Cruz & Zeichner, 2020). Nursing care for the severely ill child with COVID-19 is similar to the child with acute respiratory distress syndrome found on p. 643 of this chapter.

ETIOLOGY AND CHARACTERISTICS

Respiratory tract infections account for the majority of acute illnesses in children. The age of the child, season, living conditions, and preexisting medical problems influence the cause and course of the infections.

Infectious Agents

The respiratory tract is subject to a wide variety of infective organisms. Most infections are caused by viruses, particularly respiratory syncytial virus (RSV), rhinovirus, nonpolio enterovirus (coxsackievirus A and B), adenovirus, parainfluenza virus, influenza virus, and human metapneumovirus. Other agents involved in primary or secondary invasion include group A beta-hemolytic streptococci (GABHS), staphylococci, *Haemophilus influenzae, Bordetella pertussis, Chlamydia trachomatis, Mycoplasma* organisms, and pneumococci.

Age

Healthy full-term infants younger than 3 months old are presumed to have a lower infection rate because of the protective function of maternal antibodies. However, infants are susceptible to respiratory tract infections, such as pertussis, during this time. The infection rate increases from 3 to 6 months old, which is the period between the disappearance of maternal antibodies and the infant's own antibody production. The viral infection rate remains high during the toddler and preschool years. By 5 years old, viral respiratory tract infections are less frequent, but the incidence of *Mycoplasma pneumoniae* and GABHS infections increases. The amount of lymphoid tissue increases throughout middle childhood, and repeated exposure to organisms confers increasing immunity as children grow older.

Some viral or bacterial agents produce a mild illness in older children but severe lower respiratory tract illness or croup in infants. For example, pertussis causes a relatively harmless tracheobronchitis in childhood but is a serious disease in infancy.

Size

Anatomic differences influence the response to respiratory tract infections. The diameter of the airways is smaller in young children and subject to considerable narrowing from edematous mucous membranes and increased production of secretions. In addition, the distance between structures within the tract is shorter in the young child. Therefore organisms may move rapidly down the shorter respiratory tract, causing more extensive involvement. The relatively short and open eustachian tube in infants and young children allows pathogens easy access to the middle ear.

Resistance

The ability to resist pathogens depends on several factors. Deficiencies of the immune system place the child at risk for infection. Other conditions that decrease resistance are malnutrition, anemia, and fatigue. Conditions

BOX 21.1 Signs and Symptoms Associated With Respiratory Tract Infections in Infants and Small Children

Fever
May be absent in neonates (<28 days)
Greatest at 6 months to 3 years old
Temperature may reach 103°F to 105°F (39.5°C to 40.5°C) even with mild infections
Often appears as first sign of infection
May leave child listless and irritabile, with altered activity pattern (i.e., restless, fatigued)
Tendency to develop high temperatures with infection in certain families
May precipitate febrile seizure (see Chapter 27)

Meningismus
Meningeal signs without infection of the meninges
Occurs with abrupt onset of fever
Accompanied by:
- Headache
- Pain and stiffness in the back and neck
- Presence of Kernig and Brudzinski signs

Subsides as body temperature decreases

Anorexia
Common with most childhood illnesses
Frequently the initial evidence of illness
Persists to a greater or lesser degree throughout febrile stage of illness; often extends into convalescence

Vomiting
Common in small children with illness
A clue to onset of infection
May precede other signs by several hours
Usually short lived but may persist during the illness
Is frequent cause of dehydration

Diarrhea
Usually mild, transient diarrhea but may become severe
Often accompanies viral respiratory infections

Abdominal Pain
Common complaint
Sometimes indistinguishable from pain of appendicitis
May represent referred pain (e.g., chest pain associated with pneumonia)
May be caused by mesenteric lymphadenitis
May be linked to muscle spasms from vomiting, especially in nervous, tense child

Nasal Blockage
Small nasal passages of infants easily blocked by mucosal swelling and exudation
Can interfere with respiration and feeding in infants
May contribute to the development of otitis media and sinusitis

Nasal Discharge
Common sign
May be thin and watery (rhinorrhea) or thick and purulent
Depends on the type and stage of infection
Associated with itching
May irritate upper lip and skin surrounding the nose

Cough
Common sign
May be evident only during acute phase
May persist several months after a disease

Respiratory Sounds
Sounds associated with respiratory disease:
- Cough
- Hoarseness
- Grunting
- Stridor
- Wheezing

Findings on auscultation:
- Wheezing
- Crackles
- Absence of air movement

Sore Throat
Frequent complaint of older children
Young children (unable to describe symptoms) may not complain even when highly inflamed
Increased drooling noted by parents
Refusal to take oral fluids or solids

that weaken defenses of the respiratory tract and predispose children to infection also include allergies (e.g., allergic rhinitis), bronchopulmonary dysplasia (BPD), asthma, history of RSV infection, cardiac anomalies that cause pulmonary congestion, and cystic fibrosis (CF). Daycare attendance and exposure to secondhand smoke increase the likelihood of infection.

Seasonal Variations

The most common respiratory pathogens appear in epidemics during the winter and spring months, but mycoplasmal infections occur more often in autumn and early winter. Infection-related asthma (e.g., asthmatic bronchitis) occurs more frequently during cold weather. Winter and spring are typically RSV season, when children are indoors in close contact and more likely to spread the disease to one another.

CLINICAL MANIFESTATIONS

Infants and young children, especially those between 6 months and 3 years old, react more severely to acute respiratory tract infections than older children. Young children display a number of generalized signs and symptoms and local manifestations that differ from those seen in older children and adults. Signs and symptoms associated with respiratory tract illnesses are outlined in (Box 21.1).

NURSING CARE OF THE CHILD WITH A RESPIRATORY TRACT INFECTION

Assessment of the respiratory system follows the guidelines described in Chapter 4 (for assessment of the ears, nose, mouth and throat, chest, and lungs). The assessment should include respiratory rate, depth and rhythm, heart rate, oxygenation, hydration status, body temperature, level of consciousness, activity level, and level of comfort. Special attention should also be given to the observations outlined in Box 21.1 and the components in Box 21.2 and to assessment of the following:

- Respiratory effort (respiratory rate, rhythm and depth; accessory muscle use; retractions; nasal flaring)

BOX 21.2 Components for Assessing Respiratory Function

Pattern of Respirations

Rate: Rapid (tachypnea), normal, or slow for the particular child

Depth: Normal depth, too shallow (hypopnea), too deep (hyperpnea); usually estimated from the amplitude of thoracic and abdominal excursion (age dependent)

Ease: Effortless, labored (dyspnea), orthopnea (difficult breathing except in upright position), associated with intercostal or substernal retractions (inspiratory "sinking in" of soft tissues in relation to the cartilaginous and bony thorax), pulsus paradoxus (blood pressure falling with inspiration and rising with expiration), nasal flaring, head bobbing (head of sleeping child with suboccipital area supported on caregiver's forearm bobbing forward in synchrony with each inspiration), grunting, wheezing, or stridor

Labored breathing: Continuous, intermittent, becoming steadily worse, sudden onset, at rest or on exertion, associated with wheezing, grunting, and/or chest pain

Rhythm: Variation in rate and depth of respirations

Other Observations

In addition to respirations, particular attention is addressed to:

Evidence of infection: Check for elevated temperature; enlarged cervical lymph nodes; inflamed mucous membranes; and purulent discharges from the nose, ears, or lungs (sputum).

Cough: Observe the characteristics of the cough (if present), when the cough is heard (e.g., night only, on arising), the nature of the cough (paroxysmal with or without wheeze, "croupy" or "brassy"), frequency of the cough, association with swallowing or other activity, character of the cough (moist or dry), productivity.

Wheeze: Note whether it is with expiration or inspiration, high pitched or musical, prolonged, slowly progressive or sudden, association with labored breathing.

Cyanosis: Note distribution (peripheral, perioral, facial, trunk, and face), degree, duration, association with activity.

Chest pain: Older children tend to have this complaint. Note location and circumstances: localized or generalized; referral to base of neck or abdomen; dull or sharp; deep or superficial; association with rapid, shallow respirations or grunting.

Sputum: Older children may provide sputum sample by coughing, whereas young children may need use of bulb suction or early-morning gastric lavage to provide a sample. Note volume, color, viscosity, and odor.

Bad breath (halitosis): May be associated with some throat and lung infections.

- Oxygenation (pulse oximetry, skin color)
- Body temperature
- Child's activity level
- Child's level of comfort

The nursing care of the child with a respiratory tract infection follows established guidelines based on the child's and family's individualized needs (see Next-Generation NCLEX® Examination-Style Unfolding Case Study).

Ease Respiratory Efforts

Many acute respiratory tract infections are mild and cause few symptoms. Although children may feel uncomfortable and have a "stuffy" nose and some mucosal swelling, acute respiratory distress occurs infrequently. Interventions delivered at home are usually sufficient to relieve minor discomfort and ease respiratory efforts. However, in some cases, the infant or child may require hospitalization for close observation and therapy.

Moisturized air is a common therapeutic measure for symptomatic relief of respiratory discomfort. The moisture soothes inflamed membranes and is beneficial when there is hoarseness or laryngeal involvement. Mist tents have been used in the hospital for humidifying the air and relieving discomfort but are seldom used in developed countries. The use of steam vaporizers in the home is often discouraged because of the hazards related to their use and limited evidence to support their efficacy (Lonie, Baker, & Teixeira, 2016; Verma, Lodha, & Kabra, 2013).

A time-honored (but not evidence-based) method of producing steam is the shower. Running a shower of hot water into an empty bathtub or open shower stall with the bathroom door closed produces a quick source of steam. Keeping a child in this environment for approximately 10 to 15 minutes humidifies inspired air and may help ease respiratory efforts. A small child may sit on the lap of a parent or other adult. The use of kettles or bowls of boiling water is strongly discouraged due to the risk of accidental scalding.

Promote Comfort

Children who have an acute febrile illness should be encouraged to drink fluids and rest, but accumulated nasal secretions may interfere with these activities. Older children are usually able to manage nasal secretions with little difficulty. Instruct parents in the correct administration of prescribed nose drops or throat gargles and the correct technique for removing nasal secretions. For very young infants who normally breathe through their noses, an infant nasal aspirator or a bulb syringe is helpful in removing nasal secretions before feeding and sleeping. This practice, in addition to instillation of saline nose drops, may clear nasal passages and promote feeding and rest. Saline nose drops can be prepared at home by dissolving ½ to 1 tsp of salt in 1 cup of warm water. Two to three drops of saline can be put into the nostril, and a bulb syringe can be used to suction it out.

Topical vapor rubs could be considered for children older than 2 years of age to ease nasal congestion. A study by Santhi and colleagues (2017) found that people with the common cold had significantly improved sleep quality when using a vapor rub containing camphor, menthol, and eucalyptus oils compared with placebo. These vapor rubs should never be given orally or placed beneath the nose.

! NURSING ALERT

To avoid rebound nasal congestion, vasoconstrictive nose drops or sprays should not be administered for more than 3 days.

The hospitalized child may be apprehensive; the treatments and tests are frightening and stress producing. It is important to involve the entire family in the care as appropriate and to encourage questions and facilitate effective communication. Reducing anxiety and apprehension reduces psychologic distress in the child, and when the child is more relaxed, the respiratory efforts are reduced. Easing respiratory efforts makes the child less apprehensive, and encouraging the presence of the caregiver provides the child with a source of comfort and support.

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

The Child With Acute Respiratory Tract Illness

Day 1, 8:00 am

1. A 7-month-old infant girl is being evaluated in the emergency department for fever and cough. Mom reports over the past 2 days that she has not been as active as usual and is eating less. She started coughing during the night and upon awakening had a temperature of 103°F (39.4°C). The mother states her infant is "*breathing fast and she doesn't seem to be getting enough air.*" The nurse performs a complete history and assessment and finds the following. **Select the assessment findings that require follow-up by the nurse. Select all that apply.**
   - A. Nasal flaring
   - B. Decrease appetite
   - C. Skin color—pallor
   - D. Irritable and restless
   - E. Pulse = 164 beats/min
   - F. Retractions visualized
   - G. Respiration = 42 breaths/min
   - H. SaO_2 on pulse oximeter 88%
   - I. Blood pressure = 100/60 mm Hg
   - J. Rhonchi and fine crackles in left lung
   - K. Axillary temperature = 102.4° F (39.1° C)

2. The nurse understands that common conditions that affect the bronchi in children. The nurse plans care knowing which findings are **most likely** to be noted? **Chose the most likely options for the information missing from the table below by selecting from the lists of option provided.**

Diagnosis	Characteristics	Treatment
Asthma	Wheezing, cough, labored respirations	Inhaled corticosteroids, bronchodilators
Bronchitis	2	Cough suppressants
1	Labored respirations, poor feeding, cough tachypnea, retractions, flaring nares, fever	3

Options for 1	Options for 2	Options for 3
pneumonia	Persistent dry, hacking cough worse at night, more productive in 2-3 days	Inhaled corticosteroids, antibiotics
bronchiolitis	Retractions, labored respirations	Allergen and "triggers control"
emphysema	Poor feeding, inability to sleep, gastrointestinal symptoms	Supplemental oxygen, fluid intake, suctioning as needed
wheezing	Seizures, altered consciousness, inability to focus	Long-term anti-inflammatory medications

Day 1, 3:00 pm

3. The infant has been diagnosed with bronchiolitis and laboratory results confirm it is caused by respiratory syncytial virus (RSV). The infant is resting comfortably on oxygen therapy and receiving intravenous antibiotics and fluids. The nursing assessment reveals the following:
   - Axillary temperature = 99.0° F (37.2° C)
   - Pulse = 92 beats/min
   - Respiration = 24 breaths/min
   - SpO_2 on pulse oximeter 97% room air
   - Blood pressure = 102/54 mm Hg
   - No retractions visualized
   - No nasal flaring
   - Rhonchi and fine crackles in left lung
   - Skin color—no pallor noted
   - Sleeping

Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided. The nurse realizes that bronchiolitis is the most common infectious disease of the _____1_____ airways. RSV affects the _____2_____ cells of the respiratory tract. The respiratory illness usually begins with an upper respiratory infection after an incubation of about ____3____ days.

Options for 1	Options for 2	Options for 3
upper	Skin	1-2
middle	Epithelial	2-3
lower	Blood	5-8
extreme	Muscle	10-14
Left	Nasal	14-18
right	Bone	21-24

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—cont'd

4. What are the most appropriate immediate nursing interventions for this infant with acute respiratory tract illness? **Indicate which nursing action number listed in the far-left column is appropriate for the potential complication listed in the middle column. Place the number in the far-right column. Note that NOT all nursing actions will be used.**

Nursing Action	Potential Complication	Nursing Action for Complication
1. Position infant for maximum ventilation and airway patency	Inability to identify alterations in temperature, respiratory status, or circulation and need for additional interventions is missed	
2. Monitor vital signs, including temperature and respiratory, cardiac, and oxygen status	Nasal mucosal membrane drying	
3. Provide humidified oxygen as indicated	Fever	
4. Suction airway (nares, mouth, nasopharynx) as indicated	Bronchial constriction and decreased ventilation	
5. Provide gentle chest percussion and chest physiotherapy (CPT) as indicated	Secretions causing lack of airway patency	
6. Administer antipyretics as indicated	Infection	
7. Administer bronchodilators as indicated	Spread of infection	
8. Administer antibiotics if indicated	Dehydration or fluid overload	
9. Obtain specimens (e.g., secretions, blood) as indicated		
10. Maintain appropriate precautions such as Standard Precautions, droplet isolation, and frequent hand washing		
11. Monitor hydration status through strict intake and output and daily weights		
12. Implement comfort measures such as allowing parent presence, parent holding infant, and comfort item such as favorite blanket or stuffed animal		

Day 2, 9:00 am

5. The infant remains hospitalized and the nurse caring for performs the change of shift assessment. Which of the assessment findings support discharge of the infant to home? **Select all that apply.**
   - A. SaO_2 of 97% on room air.
   - B. Axillary temperature = 102.4° F (39.1° C)
   - C. Respiratory rate 24 breaths/ min
   - D. Oral intake 100mL/24 hours
   - E. Minimal nasal secretions in past 24 hours
   - F. Lungs clear to auscultation

Day 3, 10:00 am

6. The infant has been afebrile for 24 hours and has an SpO_2 of 98% on room air. She is now taking oral fluids and there is no longer any nasal discharge. The nurse prepares for discharge teaching and evaluates how prepared the parents are for taking the infant home. **Use an X for the health teaching evaluation below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching Evaluation	Indicated	Contraindicated	Non-Essential
Parents able to verbalize definition and characteristics of acute respiratory tract infection.			
Parents able to verbalize treatment, including medication and interventions that promote ventilation and airway clearance.			
Parents can identify discharge medications, including antipyretics, bronchodilators, and antibiotics as prescribed.			
Parents want to purchase a pulse oximeter before taking the infant home so they can constantly monitor the oxygen level.			
Parents feel that keeping the infant supine will assist with any nasal secretions the infant may have.			
Parents want to purchase another bed for the infant to keep her close to them at night.			

Continued

Prevent Spread of Infection

Perform careful hand washing when caring for children with respiratory tract infections. Children and families should use a tissue or their elbow to cover their mouth or nose when they cough or sneeze, dispose of the used tissues properly, and wash their hands. Used tissues should be immediately thrown into the wastebasket and not allowed to accumulate in a pile. Children with respiratory tract infections should not share drinking cups, eating utensils, washcloths, or towels. To decrease respiratory virus contamination, wash hands frequently and do not touch eyes or noses with the hands.

Parents should try to remove affected children from contact with other children when possible. An effort should be made to teach well children to stay away from ill children, to wash their hands frequently, and to avoid eating and drinking from the same utensils or cups.

Reduce Body Temperature

If the child has a significantly elevated body temperature, controlling the fever is important for comfort. Nurses should verify that family members have a thermometer and know how to correctly take a child's temperature and read a thermometer accurately.

If the practitioner prescribes an antipyretic such as ibuprofen (for children 6 months of age and older) or acetaminophen, parents may need instruction on administering the drug. Most parents can read the label and calculate the desired dosage, but some may require detailed instruction. It is important to emphasize accuracy in both the amount of drug given and the time intervals for drug administration to avoid cumulative effects.

Children with respiratory illnesses will perform activities as appropriate to their energy level. One of the cardinal signs that the child is feeling better is an increase in activity; however, this may be temporary if a high fever returns after a few hours of increased activity. Liquids are encouraged to reduce the temperature and minimize the chances of dehydration (see Chapter 20, Controlling Elevated Temperatures).

! NURSING ALERT

Parents are cautioned about over-the-counter combination "cold" remedies because these often include acetaminophen. Careful calculation of both the acetaminophen given separately and the acetaminophen in combination medications is necessary to avoid an overdose.

Promote Hydration

Dehydration is a potential complication when children have respiratory tract infections and are febrile or anorexic, especially when vomiting or diarrhea is present. Infants are especially prone to fluid and electrolyte deficits when they have a respiratory illness because a rapid respiratory rate that accompanies such illnesses precludes adequate oral fluid intake. In addition, the presence of fever increases the total body fluid turnover in infants. If the infant has nasal secretions, this further prevents adequate respiratory effort by blocking the narrow nasal passages when the infant reclines to bottle-feed or breastfeed and ceases the compensatory mouth breathing effort, thus causing the child to limit intake of fluids. Parents are instructed to encourage adequate fluid intake by offering small amounts of favorite fluids (clear liquids if vomiting) at frequent intervals. Oral rehydration solutions, such as Infalyte or Pedialyte, are beneficial for infants and young children, and water or low-carbohydrate (≤5 g per 8 oz) flavored drinks are appropriate for older children. Fluids with caffeine (tea, coffee) are avoided because these may act as diuretics and promote fluid loss. Carbonated drinks, fruit drinks, and energy drinks are not recommended for oral rehydration (Davies, 2015). Infants who are breastfeeding should continue to be breastfed, because human milk confers some degree of protection from infection (see Chapter 7). Fluids should not be forced. Gentle persuasion with preferred beverages is usually more successful. Intravenous (IV) fluids may be required for a short period to reestablish hydration if the child is dehydrated and not drinking. A nasogastric (NG) tube may be placed to provide enteral hydration using Infalyte or Pedialyte.

To assess their child's level of hydration (see Chapter 22), advise parents to observe the frequency of voiding and to notify the nurse or practitioner if there is insufficient voiding. In the hospital, diapers are weighed to assess output, which should be approximately 1 ml/kg/h in a child who weighs less than 30 kg. It should be at least 30 ml/h in patients weighing more than 30 kg. The practitioner should be notified if the urine output is below normal range for the child's weight.

Observe for Deterioration

Signs of clinical deterioration include increasing respiratory distress, increasing respiratory rate, increasing heart rate, worsening hypoxia, poor perfusion, reduced level of consciousness, and lethargy. The primary service is notified of any deterioration. Some institutions operationalize a rapid response team whereby a designated group of health care providers can be called on to deliver critical care expertise upon deterioration of a patient's condition outside the intensive care unit (ICU).

Provide Nutrition

Loss of appetite is characteristic of children with acute infections. In most cases, children can be permitted to determine their own need for food. Urging foods on anorexic children may precipitate nausea and vomiting and cause an aversion to feeding that may extend into the convalescent period and beyond. Many children show no decrease in appetite, and others respond well to foods such as soup, gelatin, popsicles, and puddings (see Chapter 20, Feeding the Sick Child). In the acute period of the illness, maintaining hydration with encouragement of fluids is of greater importance.

Provide Family Support and Home Care

Young children with respiratory tract infections may be irritable and difficult to comfort. Therefore the family needs support, encouragement, and practical suggestions concerning comfort measures and administration of medication.

In addition to antipyretics and nose drops, the child may require antibiotic therapy. Parents of children receiving oral antibiotics need to understand the importance of administering the drug regularly and continuing it for the prescribed length of time regardless of whether the child appears ill. Parents are cautioned against giving their children any medications that are not approved by the practitioner or prescribed for another child (see Chapter 20 for administration of medications and family teaching). Adverse effects have occurred in children who have received preparations intended for adults (e.g., some long-acting nose drops and dextromethorphan cough squares [mistaken for candy]).

UPPER RESPIRATORY TRACT INFECTIONS

ACUTE VIRAL NASOPHARYNGITIS

Acute nasopharyngitis (equivalent of the "common cold") is caused by a number of viruses such as rhinoviruses, RSV, adenoviruses, influenza virus, and parainfluenza virus. Symptoms are more severe in infants and children than in adults. Fever is common in young children, whereas older children may have low-grade fevers that appear early in the course of the illness. In children 3 months to 3 years old, fevers occur suddenly and are associated with irritability, restlessness, open-mouth breathing, decreased appetite and fluid intake, and decreased activity; these children also may develop vomiting and diarrhea. The initial symptoms in older children are dryness and irritation of nasal passages and the pharynx, followed by chilling sensations, muscular

aches, skin-irritating nasal discharge, and occasionally coughing or sneezing. Clinical manifestations are listed in Box 21.3.

The disease is self-limiting, and symptoms typically last 10 to 14 days with a peak on day 2 to 3 of illness. Occasionally, fever recurs and a child (particularly an infant) might experience otitis media (OM), usually early or after the initial phase of nasopharyngitis is past. Pneumonia is less frequent but may occur in some infants.

Therapeutic Management

Children with nasopharyngitis are managed at home. There is no specific treatment, and effective vaccines are not available. Antipyretics may be prescribed for fever and discomfort (see Chapter 20 for management of fever). Fluids and rest are recommended.

Over-the-counter cough suppressants are not routinely recommended and should be prescribed with caution (cough is a protective way of clearing secretions) (Lowry & Leeder, 2015). A cough is normal when the airway is irritated and suppressing it may result in adverse outcomes. Products containing dextromethorphan may be prescribed for a dry, hacking cough, especially at night. Some preparations contain 22% alcohol and can cause adverse effects, such as confusion, hyperexcitability, dizziness, nausea, and sedation. Parents should monitor the child carefully for potential adverse effects.

Recent concerns regarding serious side effects of cough and cold preparations in young children, particularly infants, and lack of convincing evidence that such medications are effective in reducing symptoms have prompted recommendations by health experts to carefully evaluate the benefits and risks of recommending such preparations for children (Lowry & Leeder, 2015). In 2015 the American Academy of Pediatrics stated that over-the-counter cough and cold medications do not work for children under 6 years of age and in some cases may pose a health risk (Clarke, 2017).

Antihistamines are largely ineffective in treatment of nasopharyngitis. These drugs have a weak atropine-like effect that dries secretions, but they can cause drowsiness or, paradoxically, have a stimulatory effect on children. There is no support for the usefulness of expectorants, and antibiotics are usually not indicated because most infections are viral.

BOX 21.3 Clinical Manifestations of Acute Nasopharyngitis and Pharyngitis

Nasopharyngitis

Younger Children

Fever
Irritability, restlessness
Decreased appetite and fluid intake
Sneezing
Nasal mucus (abundant) causing mouth breathing
Vomiting or diarrhea may be present
Decreased activity

Older Children

Dryness and irritation of nose and throat initially
Nasal discharge causing mouth breathing
Chilling sensations
Muscular aches
Cough or sneezing (occasionally)

Physical Assessment Signs

Edema and vasodilation of mucosa

Pharyngitis

Younger Children

Fever
General malaise
Anorexia
Moderate sore throat
Headache

Older Children

Fever (may reach 104°F [40°C])
Headache
Anorexia
Dysphagia
Abdominal pain
Vomiting

Physical Assessment Signs

Younger Children

Mild to moderate hyperemia

Older Children

Mild to bright red, edematous pharynx
Hyperemia of tonsils and pharynx; may extend to soft palate and uvula
Often abundant follicular exudate that spreads and coalesces to form pseudomembrane on tonsils
Cervical glands enlarged and tender

Prevention

Nasopharyngitis is so widespread in the general population that it is impossible to prevent. The best methods for preventing transmission of these viruses are frequent hand washing and avoiding touching one's eyes, nose, and mouth. Children are more susceptible because they have not yet developed resistance to many viruses. Very young infants are subject to relatively serious complications; therefore they should be protected from exposure.

Nursing Care Management

The common cold is often the parents' first introduction to an illness in their infant. Most discomfort of nasopharyngitis is related to the nasal obstruction, especially in small infants. Elevating the head of the bed or crib mattress assists with drainage of secretions. Suctioning and vaporization may also provide relief. Saline nose drops and gentle suction with a bulb syringe before feeding and sleep time may be useful.

Maintaining adequate fluid intake is essential during any infectious process. Although a child's appetite for solid foods is usually diminished for several days, it is important to offer appropriate fluids to prevent dehydration. Fluids can be cool (e.g., gelatin, popsicles) or warm (e.g., soups, broths), depending on individual preference.

Because nasopharyngitis is spread from secretions, the best means for prevention is avoiding contact with affected persons. This goal is difficult to accomplish when large numbers of people are confined in a small area for a long time, such as daycare centers and classrooms. Family members with a cold should carefully dispose of tissues; not share towels, glasses, or eating utensils; and avoid direct contact with others if possible. They should cover the mouth and nose with tissues or an elbow when coughing or sneezing and wash hands thoroughly after nose blowing or sneezing. The most frequent carriers of infection are the human hands, which deposit viruses on doorknobs, faucets, and other objects. Children should wash their hands thoroughly or use hand sanitizer and avoid touching their eyes, noses, and mouths.

Family Support

Support and reassurance are important elements of care for families of young children with recurrent upper respiratory infections (URIs). Because URIs are so frequent in children younger than 3 years old, families may need reassurance that frequent colds are a normal part of childhood. Usually by 5 years old, most children will have developed immunity to many viruses. When children spend time in daycare centers, their infection rate is higher than if they are cared for in the home because of increased exposure. Conversely, children who were cared for at home before starting school have an increased infection rate when exposed to more children at school.

Parents should know the signs of respiratory complications and should notify a health professional if such signs appear (e.g., signs of dehydration, the child does not improve within 2 to 3 days) (Box 21.4).

ACUTE STREPTOCOCCAL PHARYNGITIS

Group A beta-hemolytic streptococci (GABHS) infection of the upper airway (strep throat) is not in itself a serious disease, but affected children are at risk for serious sequelae: acute rheumatic fever, which is an inflammatory disease of the heart, joints, and central nervous system (CNS; see Chapter 23), and acute glomerulonephritis, which is an acute kidney infection (see Chapter 26). Permanent damage can result from these sequelae, especially from acute rheumatic fever. GABHS may also cause skin manifestations, including impetigo and pyoderma.

BOX 21.4 Early Evidence of Respiratory Complications

Parents are instructed to notify the health professional if any of the following are noted:

- Evidence of earache
- Respirations faster than 50 to 60 breaths/min
- Fever over 101°F (38.3°C)
- Listlessness
- Crying
- Increasing irritability with or without fever
- Persistent cough for 2 days or more
- Wheezing
- Refusal to eat
- Restlessness and sleep pattern disturbance

Modified from National Association of Pediatric Nurse Practitioners. (2017). *Cold and flu sniffles?* New York, NY: CW Publishing Group; American Academy of Pediatrics. (2018). Children and colds. Retrieved from https://www.healthychildren.org/English/health-issues/conditions/ear-nose-throat/Pages/Children-and-Colds.aspx

Scarlet fever may also occur as a result of a strain of group A streptococcus. The clinical manifestations of scarlet fever include pharyngitis and a characteristic erythematous sandpaper-like rash; otherwise, scarlet fever shares the same clinical manifestations as those mentioned for GABHS, and treatment and sequelae are the same. Severe scarlet fever is rarely seen in the United States.

Clinical Manifestations

GABHS infection is generally a relatively brief illness that varies in severity from subclinical (no symptoms) to severe toxicity. The onset is often abrupt and characterized by pharyngitis, headache, fever, and abdominal pain. The tonsils and pharynx may be inflamed and covered with exudate (Fig. 21.1), which usually appears by the second day of illness. However, streptococcal infections should be suspected in children older than 2 years of age who have pharyngitis even if no exudate is present (Fig. 21.2).

Anterior cervical lymphadenopathy (30% to 50% of cases) usually occurs early, and the nodes are often tender. Pain can be relatively mild to severe enough to make swallowing difficult. Clinical manifestations usually subside in 3 to 5 days unless complicated by sinusitis or parapharyngeal, peritonsillar, or retropharyngeal abscess. Nonsuppurative complications may appear after the onset of GABHS: acute nephritis in about 10 days and rheumatic fever in an average of 18 days.

Children who are GABHS carriers may have a positive throat culture but often experience a coincidental viral illness. Although antibiotic administration is not indicated for most GABHS carriers, some conditions may require antibiotic therapy (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Transmission to others from a carrier is reportedly minimal.

Diagnostic Evaluation

Although 80% to 90% of all cases of acute pharyngitis are viral, rapid streptococcal antigen testing (obtained by vigorous swabbing of both tonsils and the posterior pharynx) and/or throat culture may be performed to rule out GABHS (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Rapid identification of GABHS with diagnostic test kits is possible in the office or clinic setting. However, because these kits have questionable sensitivity and depend on a high-quality swab being obtained, a confirmatory throat culture is recommended in patients who have a negative test result with a rapid diagnostic test kit but in whom classic signs of the infection are present (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Fig. 21.1 Tonsillitis and pharyngitis. (Courtesy Dr. Edward L. Applebaum, Head, Department of Otolaryngology, University of Illinois Medical Center, Chicago, IL.)

Fig. 21.2 Pharyngitis associated with group A beta-hemolytic streptococci (GABHS) infection. (From Cohen, J., & Powderly, W. G. [2004]. *Infectious diseases* [2nd ed.]. St Louis, MO: Mosby.)

Because some children normally harbor streptococci in their throats, a positive culture or antigen test is not always conclusive evidence of active disease. Most streptococcal infections are short-term illnesses, and antibody (antistreptolysin O) responses appear later than symptoms and are useful only for retrospective diagnosis.

Therapeutic Management

If streptococcal sore throat infection is present, oral penicillin or other antibiotics such as amoxicillin are prescribed for 10 days to control the acute local manifestations and maintain an adequate level to eliminate any organisms that might remain to initiate rheumatic fever symptoms. Penicillin does not prevent the development of acute glomerulonephritis in susceptible children. However, it may prevent the spread of a nephrogenic strain of GABHS to others in the family. Penicillin usually produces a prompt response within 24 hours. Some patients require retreatment if the organism is not eradicated. Amoxicillin given once a day (50 mg/kg; maximum 1000 mg) for 10 days is as effective as penicillin or amoxicillin given multiple times per day (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Intramuscular (IM) penicillin G benzathine is also an appropriate therapy. This drug ensures adequate blood concentrations and avoids the problem of compliance, yet it is painful. An oral macrolide or azalide (e.g., erythromycin, azithromycin, clarithromycin) is indicated for children who are allergic to penicillin. Other antibiotics used to treat GABHS are oral cephalosporins, clindamycin, and amoxicillin with clavulanic acid (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Nursing Care Management

The nurse often obtains a throat swab for culture and instructs the parents about administering the antibiotic and analgesic as prescribed. Cold or warm compresses to the neck may provide relief. In children old enough to cooperate, warm saline gargles offer relief of throat discomfort.

Ibuprofen (for ages 6 months and older) and acetaminophen may be effective in decreasing throat pain; liquid preparations or chewable forms may be preferable because of the pain associated with swallowing. Pain may interfere with oral intake, and the child should not be forced to eat, but fluid intake is essential. Encourage intake of cool liquids, ice chips, or flavored ice pops that may be tolerated better than solid foods.

Special emphasis is placed on correctly administering oral medication and completing the total course of antibiotic therapy (see Chapter 20, Administration of Medication, and Compliance). If an antibiotic injection is required, it must be administered deep into a large muscle mass (e.g., vastus lateralis or ventrogluteal muscle). To reduce pain, application of a topical anesthetic cream, such as LMX4 (4% lidocaine) or eutectic mixture of local anesthetics (EMLA; lidocaine and prilocaine) over the injection site 30 minutes before the injection may be helpful (see Chapter 20, Intramuscular Administration). Parents need to be aware of the residual tenderness that may develop. Local applications of heat may be helpful in relieving the discomfort. If the child continues to be febrile and/or has not improved within 24 to 48 hours, or appears toxic, further evaluation by the health care provider is important.

Children are considered infectious to others at the onset of symptoms and up to 24 hours after initiation of oral antibiotic therapy. It is generally recommended that the children not return to school or daycare until they have been taking antibiotics for a full 24-hour period. Nurses should remind the children with a streptococcal throat infection and parents to discard the child's toothbrush and replace it with a new one after taking antibiotics for 24 hours. Orthodontic appliances should be washed thoroughly because they may harbor the organisms. Parents are cautioned to prevent other household members, especially if immunocompromised, from having close contact with the sick child and avoid sharing towels and drinking or eating items.

DRUG ALERT

Never administer penicillin G procaine or penicillin G benzathine suspensions intravenously (they may cause embolism or toxic reaction with ensuing death in minutes). Instead, administer these medications deep into the muscle tissue to decrease localized reactions and pain.

TONSILLITIS

The tonsils are masses of lymphoid tissue located in the pharyngeal cavity. The tonsils filter and protect the respiratory and alimentary tracts from invasion by pathogenic organisms and also play a role in antibody formation. Although the size of tonsils varies, children generally have larger tonsils than adolescents or adults. This difference is thought to be a protective mechanism because young children are especially susceptible to URIs.

Pathophysiology

Several pairs of tonsils are part of a mass of lymphoid tissue encircling the nasopharynx and oropharynx, known as the Waldeyer tonsillar ring (Fig. 21.3). The palatine, or faucial, tonsils are located on either side of the oropharynx, behind and below the pillars of the fauces (opening from the mouth). A surface of the palatine tonsils is usually visible during oral examination. The palatine tonsils are those removed during tonsillectomy. The pharyngeal tonsils, also known as the adenoids, are located above the palatine tonsils on the posterior wall of the nasopharynx. Their proximity to the nares and eustachian tubes causes difficulties in instances of inflammation. The lingual tonsils are located at the base of the tongue. The tubal tonsils, found near the posterior nasopharyngeal opening of the eustachian tubes, are not part of the Waldeyer tonsillar ring.

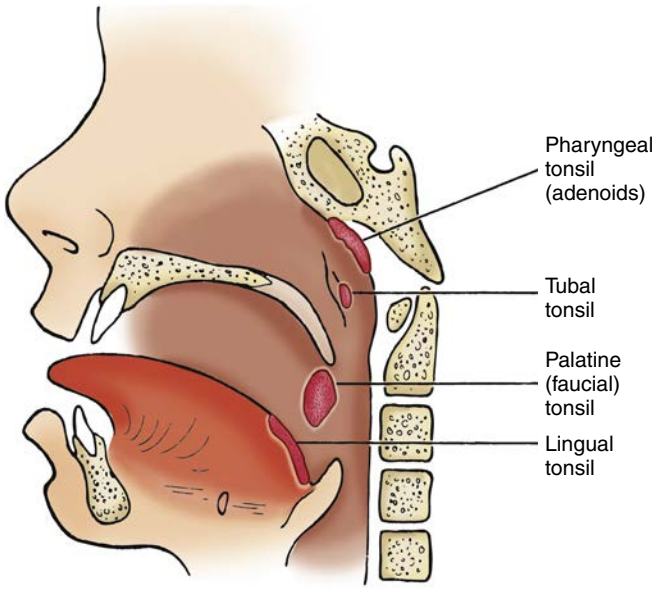

Fig. 21.3 Location of various tonsillar masses.

Etiology

Tonsillitis often occurs with pharyngitis. Because of the abundant lymphoid tissue and the frequency of URIs, tonsillitis is a common cause of illness in young children. The causative agent may be viral or bacterial.

Clinical Manifestations

The manifestations of tonsillitis are caused by inflammation. As the palatine tonsils enlarge from edema, they may meet in the midline (touching or kissing tonsils), obstructing the passage of air or food. The child has difficulty swallowing and breathing. When enlargement of the adenoids occurs, the space behind the posterior nares becomes blocked, making it difficult or impossible for air to pass from the nose to the throat. As a result, the child breathes through the mouth. Chronic enlargement of the tonsils and adenoids may result in obstruction of breathing during sleep.

If mouth breathing is continuous, the mucous membranes of the oropharynx become dry and irritated. There may be an offensive mouth odor and impaired senses of taste and smell. The voice may have a nasal and muffled quality, and a persistent cough is also common. Because of the proximity of the adenoids to the eustachian tubes, this passageway is frequently blocked by swollen adenoids, interfering with normal drainage and frequently resulting in OM or difficulty hearing.

Therapeutic Management

Because tonsillitis is self-limiting, treatment of viral pharyngitis is symptomatic. Throat cultures positive for GABHS infection require antibiotic treatment. It is important to differentiate between viral and streptococcal infection in febrile, exudative tonsillitis. Because most infections are viral, early rapid tests can eliminate unnecessary antibiotic administration.

Tonsillectomy (surgical removal of the palatine tonsils) may be indicated for massive enlargement that results in difficulty breathing or eating. Absolute indications are peritonsillar abcess, PFAPA (periodic fever, aphthous stomatitis, pharyngitis, adenitis), airway obstruction, chronic tonsillitis unresponsive to antimicrobials, multiple antibiotic allergies, and tonsils requiring tissue pathology

(Ingram & Friedman, 2015). Tonsillectomy is considered when there have been seven or more episodes of tonsillitis in the previous year, or at least five episodes of tonsillitis in each of the previous 2 years, or at least three episodes of tonsillitis in each of the previous 3 years and/or sleep-disordered breathing (Baugh, Archer, Mitchell, et al., 2011; Ingram & Friedman, 2015; Mitchell, Archer, Ishman, et al., 2019).

Adenoidectomy (the surgical removal of the adenoids) is recommended for children who have enlarged adenoids that obstruct nasal breathing or a history of four or more episodes of recurrent purulent rhinorrhea in the previous 12 months in a child younger than 12 years old (one episode should be documented by intranasal examination or imaging) (American Academy of Otolaryngology–Head and Neck Surgery, 2011). Other indications include persisting symptoms of adenoiditis after two courses of antibiotics, sleep disturbance with nasal obstruction lasting more than 3 months, hyponasal speech, otitis media with effusion (OME) for more than 3 months, dental malocclusion or orofacial growth disturbance as validated by an orthodontist or dentist, OME in a child at least 4 years old, or cardiopulmonary complications associated with adenoid hypertrophy (American Academy of Otolaryngology–Head and Neck Surgery, 2011).

For some children, the effectiveness of tonsillectomy or adenoidectomy is modest and may not justify the risk of surgery. In practice, many providers rely on individualized decision making and do not subscribe to an absolute set of eligibility criteria for these surgical procedures.

A Cochrane review (Burton, Glasziou, Chong, et al., 2014) concluded that there was a modest benefit to adenotonsillectomy in children with recurrent sore throats; others have reached similar conclusions (Morad, Sathe, Francis, et al., 2017). The American Academy of Otolaryngology–Head and Neck Surgery's recent evidence-based guideline update recommended further research be done to investigate the treatment of recurrent throat infections by tonsillectomy versus antibiotics or watchful waiting in children older than 12 months of age and younger than 12 years of age (Mitchell et al., 2019).

Contraindications to either tonsillectomy or adenoidectomy are (1) cleft palate, because the tonsils help minimize escape of air during speech; (2) acute infections at the time of surgery, because locally inflamed tissues increase the risk of bleeding; and (3) uncontrolled systemic diseases or blood dyscrasias.

Generally, removal of the tonsils should not occur until after 3 or 4 years of age because of the problem of excessive blood loss in young children and the possibility of regrowth or hypertrophy of lymphoid tissue. The tubal and lingual tonsils often enlarge to compensate for the lost lymphoid tissue, resulting in continued pharyngeal and eustachian tube obstruction.

Nursing Care Management

Nursing care of the child with tonsillitis involves providing comfort and minimizing activities or interventions that precipitate bleeding. A soft to liquid diet is generally preferred. Warm saltwater gargles, warm fluids, throat lozenges, and regularly prescribed nonopiods (such as acetaminophen and ibuprofen) are used to promote comfort. Often a combination nonopioid and opioid are needed to reduce pain for the child to drink. The American Academy of Otolaryngology–Head and Neck Surgery's updated guidelines state that clinicians must not administer or prescribe codeine, or any medication containing codeine, after tonsillectomy in children younger than 12 years of age because of the US Food and Drug Administration's 2013 black box warning about codeine-related fatalities (Mitchell et al., 2019).

If surgery is needed, the child requires the same psychologic preparation and physical care as for any procedure (see Chapters 19 and 20). The following discussion focuses on nursing care for tonsillectomy and adenoidectomy (T&A), although both procedures may not be performed.

The nurse takes a complete history, with special notation of any bleeding tendencies because the operative site is highly vascular. Baseline vital signs are important for postoperative monitoring and observation. All patients, especially those with sleep-disordered breathing, require close monitoring of airway and breathing postoperatively. Signs of loose teeth or any URIs are noted and reported, and bleeding and clotting times may be obtained with the usual laboratory work prior to surgery.

After the surgery, until they are fully awake, children are positioned to facilitate drainage of secretions. Suctioning is usually avoided, but when performed, it is done carefully to avoid trauma to the oropharynx. When alert, the child may prefer sitting up. The child is discouraged from coughing frequently, clearing the throat, blowing the nose, and any activities that may aggravate the operative site.

Some secretions, particularly dried blood from surgery, are common. Inspect all secretions and vomitus for evidence of fresh bleeding (some blood-tinged mucus is expected). Dark brown (old) blood is usually present in the emesis, in the nose, and between the teeth. If parents are not prepared regarding the presence of these possible secretions, they may be frightened at a time when they need to be calm and reassuring.

The throat is usually very sore after surgery. An ice collar may provide relief, but many children find it bothersome and refuse to use it. Most children experience moderate pain after a T&A and need pain medication at regular intervals for at least the first 24 to 48 hours. Analgesics may be given rectally or intravenously to avoid the oral route, but liquid analgesics may be given as tolerated. Local anesthetics, such as tetracaine lollipops or ice pops, and antiemetics, such as ondansetron (Zofran) or a Scopolamine transdermal patch (ages 12 years and older), may be administered postoperatively (see Chapter 5, Pain Management).

An integrative review of pain management for pediatric tonsillectomy revealed that preoperative education (child and parent) regarding anxiety and pain were important in the management of the child's postoperative pain (Howard, Finn Davis, Phillips, et al., 2014). In addition, family education on both pharmacologic and nonpharmacologic pain management in the home setting was viewed as being crucial to successful outcomes. An optimal pharmacologic postoperative pain medication regimen was not described, but reviews suggest that acetaminophen, ibuprofen, and hydrocodone may be safe and effective for postoperative pain (Howard et al., 2014; Mitchell et al., 2019).

Food and fluids are restricted until the child is alert and able to swallow with no signs of hemorrhage. Cool water, crushed ice, flavored ice pops, or diluted fruit juice may be given, but fluids with a red or brown color may be avoided to distinguish fresh or old blood in emesis from the ingested liquid. Citrus juice may cause discomfort and is usually not well tolerated. Milk, ice cream, and pudding are usually not offered until clear fluids are retained because milk products coat the mouth and throat, causing the child to clear the throat, which may initiate bleeding.

Children often begin soft foods, particularly gelatin, cooked fruits, sherbet, soup, and mashed potatoes, on the first or second postoperative day or as the child tolerates feeding. The pain from surgery often inhibits oral intake, reinforcing the need for adequate pain control.

Postoperative hemorrhage is unusual but may occur between 5 and 10 days after surgery with the sloughing of the primary eschar as the tonsil bed heals (Mitchell et al., 2019). The nurse observes the throat directly for evidence of bleeding, using a good source of light and, if necessary, carefully inserting a tongue depressor. Other signs of hemorrhage are tachycardia, pallor, frequent clearing of the throat or swallowing by a younger child, and vomiting of bright red blood. Restlessness, an indication of hemorrhage, may be difficult to differentiate from general discomfort after surgery. Decreasing blood pressure is a much later sign of shock.

Surgery may be required to cauterize or ligate a bleeding vessel. Airway obstruction may also occur as a result of edema or accumulated secretions and is indicated by signs of respiratory distress, such as stridor, drooling, restlessness, agitation, increasing respiratory rate, and progressive cyanosis. Suction equipment and oxygen should be available after tonsillectomy.

! NURSING ALERT

The most obvious early sign of bleeding is the child's continuous swallowing of the trickling blood. While the child is sleeping, note the frequency of swallowing. If continuous bleeding is suspected, notify the surgeon immediately.

Family Support and Home Care

Discharge instructions include (1) avoiding irritating and highly seasoned foods, (2) avoiding the use of gargles or vigorous toothbrushing, (3) discouraging the child from coughing or clearing the throat or putting objects in the mouth, (4) using pain medications as prescribed, and (5) limiting activity to decrease the potential for bleeding. Hemorrhage may occur after surgery, therefore any sign of bleeding warrants immediate medical attention. Objectionable mouth odor and slight ear pain with a low-grade fever are common a few days postoperatively. However, persistent severe earache, fever, or cough requires medical evaluation. Most children are ready to resume normal activity within 1 to 2 weeks after the operation.

Most children are admitted to a same-day surgery or ambulatory surgery unit and discharged home after a recovery period. T&A often represents the first hospitalization experience for the child and family. Because the surgery is usually an elective procedure, there is ample opportunity to prepare both the child and parents for this event. Both need reassurance about what to expect at the time of admission, before and after surgery, and at discharge.

INFLUENZA

Influenza (the "flu") is caused by the orthomyxoviruses and classified into three antigenically distinct groups: types A and B, which cause epidemic disease (included in the vaccine), and type C, which causes milder disease and is not included in the vaccine. The viruses undergo significant changes from time to time. Major changes that occur at intervals of usually 5 to 10 years are called antigenic shift; minor variations within the same subtypes, antigenic drift, occur almost annually. Consequently, antigenic drift can alter the virus sufficiently to result in susceptibility of individuals to a type for which they were previously immunized or infected.

Influenza is spread from one individual to another by direct contact (large-droplet infection) usually occurring during talking, sneezing, coughing, or via articles recently contaminated by nasopharyngeal secretions. Attack rates are highest in young children who have had no previous contact with a strain, pregnant women, and patients with chronic medical conditions (e.g., diabetes, asthma). Influenza is frequently most severe in infants and older adults. During epidemics, infection among school-age children is believed to be a major source of transmission in a community.

The disease is more common during the winter months and has a 1- to 4-day incubation period (average of 2 days), and affected persons are most infectious for 24 hours before and 5 to 7 days after the onset of symptoms (Centers for Disease Control and Prevention, 2016, 2018a). The virus has a peculiar affinity for epithelial cells of the respiratory tract mucosa, where it destroys ciliated epithelium with metaplastic hyperplasia of the tracheal and bronchial epithelium with associated edema. The alveoli may also become distended with a hyaline-like material. The viruses can be isolated from nasopharyngeal secretions early after the onset of infection, and serologic tests identify the type by complement fixation or the subgroups by hemagglutination inhibition.

H1N1 (swine flu) is a subtype of influenza type A. In 2009 a pandemic of H1N1 caused significant morbidity and mortality, particularly in Mexico and the United States, lasting until the end of August 2010. A pandemic is defined by the World Health Organization as the spread of a new disease to which the population has little or no immunity and that spreads rapidly from human to human. The H1N1 vaccine has been included in the seasonal influenza vaccination since the 2011–2012 season. Any influenza virus that is novel in nature is reportable to the Centers for Disease Control and Prevention (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Clinical Manifestations

The manifestations of influenza may be subclinical, mild, moderate, or severe. In most cases, there is a dry cough and a tendency toward hoarseness. A sudden onset of fever and chills may be accompanied by flushed face, photophobia, myalgia, sore throat, headache, hyperesthesia, fatigue and sometimes prostration, vomiting, and diarrhea. Subglottal croup is common, especially in infants. The symptoms of influenza last for 4 or 5 days. Complications include severe viral pneumonia (often hemorrhagic), febrile seizures, encephalitis, encephalopathy, dehydration, and secondary bacterial infections, such as myocarditis, OM, sinusitis, or pneumonia. Diagnosis is confirmed by analyzing nasopharyngeal secretions for viral culture or rapid detection testing. Influenza A and B can be rapidly detected by direct fluorescent antibody and indirect immunofluorescent antibody staining.

Therapeutic Management

Uncomplicated influenza in children usually requires only symptomatic treatment, including acetaminophen or ibuprofen for fever and sufficient fluids to maintain hydration. Several influenza antiviral drugs were approved by the US Food and Drug Administration for use in the United States, but only oral oseltamivir (Tamiflu), inhaled zanamivir (Relenza), and IV peramivir (Rapivab) are recommended because of widespread resistance to amantadine (Symmetrel) and rimantadine (Flumadine) (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Oseltamivir (a neuroaminidase inhibitor) is the antiviral drug of choice that may be administered orally for 5 days to decrease flu symptoms. The medication can be used for infants and children of any age and is effective for types A and B influenza (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). As with other antiviral drugs, for best results the medication should be started within 2 days of the onset of symptoms. Children should not receive aspirin because of its possible link with Reye syndrome.

Zanamivir can be used for treatment of influenza in patients 7 years of age and older or as a prophylaxis for patients 5 years of age and older (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Zanamivir is an inhaled medication effective for types A and B influenza. The drug is taken twice daily for 5 days and is administered by a specially designed oral inhaler (Diskhaler). Bronchospasm and a decline in lung function can occur when zanamivir is used in patients with underlying airway disease, such as asthma or chronic obstructive pulmonary disease (COPD).

Prevention

The influenza vaccine is now recommended annually for children over 6 months old. Influenza vaccine (inactivated influenza vaccine) may be given to healthy children 6 months of age and older and is administered yearly because different strains of influenza are used each year in the manufacture of the vaccine. The vaccine is safe and effective provided the antigens in the vaccine correlate with the circulating influenza viruses (see Chapter 6, Immunizations). During the 2016–2017 influenza season, the live attenuated influenza vaccine, administered intranasally, was discontinued due to concerns about its effectiveness (Belongia, Karron, Reingold, et al., 2018). See Chapter 6 for guidelines for administering influenza vaccine to patients with a hypersensitivity to eggs.

Nursing Care Management

Nursing care is the same as for any child with a URI, including helping the family implement measures to relieve symptoms. Prolonged fever or the appearance of fever during early convalescence is a sign of secondary bacterial infection and should be reported to the practitioner for antibiotic therapy. Nursing care of the child with influenza also includes educating the parents on the prevention of spread of the disease to other individuals, especially those who are at higher risk for complications, and on the use of antiviral medications. Many institutions have developed protocols to allow nurses to screen patients for eligibility to receive the influenza vaccine.

OTITIS MEDIA

Otitis media (OM) is the presence of fluid in the middle ear along with acute signs of illness and symptoms of middle ear inflammation (Venekamp, Damoiseaux, & Schilder, 2017). The standard terminology used to define OM is outlined in Box 21.5. OM is one of the most prevalent illnesses of early childhood. Its incidence is highest in the winter months. Many cases of bacterial OM are preceded by a viral respiratory infection. Most episodes of acute otitis media (AOM) occur in the first 24 months of life, but the incidence decreases with age except for a small increase at 5 or 6 years old when children enter school. OM occurs infrequently in children older than 7 years of age. Attending daycare is a significant risk factor for OM. Children who have siblings or parents with a history of chronic OM also have a higher incidence of OM.

Children living in households with many members (especially smokers) are more likely to have OM than those living with fewer persons. Passive smoking increases the risk of persistent middle ear effusion by enhancing attachment of the pathogens that cause otitis to the respiratory epithelium in the middle ear space, by prolonging the inflammatory response, and by impeding drainage through the eustachian tube (Kerschner & Preciado, 2020). Family socioeconomic status and extent of exposure to other children are important identifiable risk factors for the occurrence of OM (Kerschner & Preciado, 2020).

BOX 21.5 Standard Terminology for Otitis Media

Otitis media (OM): An inflammation of the middle ear without reference to etiology or pathogenesis

Acute otitis media (AOM): An inflammation of the middle ear space with a rapid onset of the signs and symptoms of acute infection—namely, fever and otalgia (ear pain)

Otitis media with effusion (OME): Fluid in the middle ear space without symptoms of acute infection

Etiology

The most common bacteria causing AOM are *Streptococcus pneumoniae, H. influenzae,* and *Moraxella catarrhalis*. The two viruses most likely to precipitate OM are RSV and influenza, although the adenoviruses, human metapneumoviruses, and picornaviruses (rhinovirus and enterovirus) also cause a significant number of URIs and OM. The etiology of noninfectious OM is unknown but may occur because of blocked eustachian tubes. Predisposing factors include URIs, allergic rhinitis, Down syndrome, cleft palate, daycare attendance, exposure to secondhand smoke, and bottle propping during feeding. Infants fed breast milk have a lower incidence of OM than formula-fed infants (Abrahams & Labbok, 2011; Korvel-Hanquist, Djurhuus, & Homoe, 2017). Breastfeeding may protect infants against respiratory viruses and allergy because breast milk contains secretory immunoglobulin A, which limits the exposure of the eustachian tube and middle ear mucosa to microbial pathogens and foreign proteins. Reflux of milk up the eustachian tubes is less likely in breastfed infants because of the semivertical positioning during breastfeeding compared with bottle-feeding.

Pathophysiology

OM is primarily a result of a dysfunctioning eustachian tube. Mechanical or functional obstruction of the eustachian tube causes accumulation of secretions in the middle ear. Infection or allergy can cause intrinsic obstruction. Extrinsic obstruction is usually a result of enlarged adenoids or nasopharyngeal tumors. Eustachian tube obstruction results in negative middle ear pressure with fluid pulled from the mucosal lining. The sustained negative pressure impairs the ciliary transport within the eustachian tube, inhibiting the fluid drainage that accumulates and tends to become colonized by infectious organisms. When the passage is not totally obstructed, contamination of the middle ear can take place by reflux, aspiration, or insufflation during crying, sneezing, nose blowing, and swallowing when the nose is obstructed.

Diagnostic Evaluation

Careful assessment of tympanic membrane mobility with a pneumatic otoscope is essential to differentiate AOM from OME (Kerschner & Preciado, 2020). A diagnosis of AOM is made with moderate to severe bulging of the tympanic membrane, acute onset of ear drainage not due to acute otitis externa, mild bulging of the tympanic membrane with onset of pain in less than 48 hours, and intense erythema of the tympanic membrane (Kerschner & Preciado, 2020). An immobile tympanic membrane or an orange, discolored membrane indicates OME, with other nonspecific symptoms such as rhinitis, cough, or diarrhea often present. Clinical symptoms of otitis are also helpful in making the diagnosis (Box 21.6). In OME, other symptoms may be manifested through poor balance, behavioral problems, school performance issues, or limited progress with ongoing speech therapy (Rosenfeld, Shin, Schwartz, et al., 2016). Several tests provide an assessment of mobility of the tympanic membrane (see Chapter 4).

BOX 21.6 Clinical Manifestations of Otitis Media

Acute Otitis Media

Follows an upper respiratory tract infection
Otalgia (earache)
Fever—may or may not be present
Purulent discharge (otorrhea)—may or may not be present

Infants and Very Young Children

Crying, fussiness, restlessness, irritability, especially on lying down
Tendency to rub, hold, or pull affected ear
Rolling head from side to side
Difficulty comforting child
Loss of appetite, refusal to feed

Older Children

Crying or verbalizing feelings of discomfort
Irritability
Lethargy
Loss of appetite

Chronic Otitis Media

Hearing loss
Difficulty communicating
Feeling of fullness, tinnitus, or vertigo may be present

Therapeutic Management

Treatment for AOM is one of the most common reasons for antibiotic use in the ambulatory setting. However, concerns about drug-resistant strains have led infectious disease authorities to recommend careful and judicious use of antibiotics for the treatment of this illness. Treatment guidelines for AOM emphasize the need for accurate diagnosis, pain management, and watchful waiting in children with "nonsevere" AOM (Schilder, Marom, Bhutta, et al., 2017). However, the watchful waiting approach is not recommended for children younger than 2 years old who have persistent acute symptoms of fever and severe ear pain (Kerschner & Preciado, 2020). In addition, immediate antibiotic treatment is reserved for high-risk children, including infants younger than 6 months old, because of their immature immune systems and the potential for infection with bacteria.

When antibiotics are necessary, oral amoxicillin in high doses (80 to 90 mg/kg/day divided twice daily) is recommended for 5 to 7 days with children 2 years of age and older and for 10 days with younger children; children with underlying medical conditions, craniofacial anomalies, or tympanic membrane perforation; and children with chronic otitis media.

Second-line antibiotics used to treat OM include amoxicillin/clavulanate, azithromycin, and cephalosporins (such as cefdinir, cefuroxime, and cefpodoxime). IM ceftriaxone is used if the causative organism is a highly resistant pneumococcus or if there is noncompliance with the therapy. An important consideration with the use of single-dose IM injections is the pain involved in this therapy. One strategy to minimize pain at the injection site is to reconstitute the cephalosporin with 1% lidocaine (without epinephrine). A topical analgesic cream such as LMX4 or EMLA can also be applied to the site beforehand to reduce pain.

Supportive care or symptomatic treatment of AOM includes treating the fever and pain. For fever or discomfort associated with OM, analgesic-antipyretic drugs such as acetaminophen or ibuprofen (ibuprofen only if over 6 months of age unless prescribed) may be given. Topical pain relief is recommended by external application of heat or cold, or the practitioner may prescribe topical pain relief drops such as benzocaine drops. Antibiotic ear drops have no value in treating AOM. Children with AOM may be seen after antibiotic therapy is complete to evaluate the effectiveness of the treatment and to identify potential complications, such as effusion or hearing impairment.

Myringotomy, a surgical incision of the eardrum, may be necessary to alleviate the severe pain of AOM. A myringotomy is also performed to drain infected middle ear fluid in the presence of complications (mastoiditis, labyrinthitis, or facial paralysis) or to allow purulent middle ear fluid to drain into the ear canal for culture. A minimally invasive laser-assisted myringotomy procedure may be performed in outpatient settings. These procedures should be performed only by ear, nose, and throat (ENT) specialists.

Tympanostomy tube placement and adenoidectomy are surgical procedures that may be done to treat recurrent chronic OM (three episodes in 6 months or four episodes in 1 year, with one episode during the preceding 6 months) (Kerschner & Preciado, 2020). Tympanostomy tubes are pressure-equalizer (PE) tubes or grommets that facilitate continued drainage of fluid and allow ventilation of the middle ear. They are inserted to treat severe eustachian tube dysfunction, OME, or complications of OM (mastoiditis, facial nerve paralysis, brain abscess, labyrinthitis).

The additive benefit of adenoidectomy to tympanostomy tubes in recurrent AOM and OME is controversial and age dependent (Schilder et al., 2017). The American Academy of Otolaryngology–Head and Neck Surgery guidelines' recommendation is against adenoidectomy for OME in children younger than 4 years old, including those with prior tympanostomy, unless a distinct indication, such as nasal obstruction or chronic adenoiditis, exists (Rosenfeld et al., 2016)

In some children, residual middle ear effusions remain after episodes of AOM. Some children have fluid that persists in the middle ear for weeks or months. Antibiotics are not required for initial treatment of OME (Kerschner & Preciado, 2020; Rosenfeld et al., 2016). Placement of tympanostomy tubes is recommended after a total of 3 to 6 months of bilateral effusion with a bilateral hearing deficit (Kerschner & Preciado, 2020; Rosenfeld et al., 2016). This therapy allows for mechanical drainage of the fluid, which promotes healing of the membrane and prevents scar formation and loss of elasticity. The primary objective is to allow the eustachian tissue a period of recovery while the surgically placed tube performs its functions. The surgery is relatively benign; however, sometimes the tubes become plugged and may require reinsertion. Myringotomy with or without insertion of PE tubes should not be performed for initial management of OME but may be recommended for children who have recurrent episodes of OME with a long cumulative duration. A meta-analysis concluded that tympanostomy tubes had a significant improvement in hearing and a decrease in the incidence of AOM compared with watchful waiting (Steele, Adam, Di, et al., 2017).

Prolonged middle ear disorders may develop several complications such as cholesteatoma (epithelial lining forms scales in middle ear space), tympanosclerosis (eardrum scarring), or adhesive OM (thickening of mucous membranes), but the most frequently associated complication is mild to moderate impairment of hearing. The causes of hearing loss include negative middle ear pressure, effusion in the middle ear, involvement of the eighth cranial nerve, and/or structural damage to the tympanic membrane. Therefore a hearing test should also be performed, especially if OME persists for 3 months or more or if there is evidence of language or learning delays. Follow-up examinations of children with chronic OME should be maintained on a 3- to 6-month basis with repeat hearing test until the OME is resolved (Rosenfeld et al., 2016; Schilder et al., 2017). Children with hearing

loss should be referred to a pediatric otolaryngologist and possibly to a pediatric allergist for identification and treatment of the cause. They should receive a speech and language evaluation as necessary.

Prevention

Routine immunization with the pneumococcal vaccine has reduced the incidence of AOM in some infants and children, especially those with frequent episodes of AOM (Kerschner & Preciado, 2020). A conjugate vaccine, Prevnar 13, replaced Prevnar 7 and is approved for use in patients 6 weeks to 17 years old (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). The vaccine is administered as a four-dose series beginning at 2 months of age. Influenza vaccination to children older than 6 months of age is also important (see Chapter 6, Immunizations).

Nursing Care Management

Nursing objectives for children with AOM include relieving pain, facilitating drainage when possible, preventing complications or recurrence, educating the family on care of the child, and providing emotional support to the child and family.

Analgesics (ibuprofen and acetaminophen) are helpful in reducing severe ear pain and controlling fever. Ibuprofen has a longer duration of action (about 6 hours) and is especially beneficial for nighttime comfort but should not be used in children younger than 6 months of age unless directed by a medical provider. Lying on the affected side may reduce pain in some children, as it may facilitate drainage from a ruptured eardrum or myringotomy.

If the ear is draining, the external canal may be cleaned with sterile cotton swabs coupled with topical antibiotic treatment, as directed by the provider. If ear wicks or lightly rolled sterile gauze packs are placed in the ear after surgical treatment, they should be loose enough to allow accumulated drainage to flow out of the ear; otherwise, infection may be transferred to the mastoid process. Parents should be instructed to keep the wicks dry during shampoos and baths. Occasionally, drainage is so profuse that the pinna and surrounding skin become excoriated from the exudate. Frequent cleansing and application of various moisture barriers (e.g., Proshield Plus), zinc oxide–based products, or petrolatum jelly (e.g., Vaseline) can prevent or treat skin irritation.

Tympanostomy tubes may allow water to enter the middle ear, but recommendations for earplugs are inconsistent. Most patients, including very young children, often need no special water precautions. Recent research has indicated that there is no need for water precautions unless the child develops recurrent drainage after swimming (Moualed, Masterson, Kumar, et al., 2016). Health care providers tend to offer recommendations for water precautions.

The tympanostomy tube is eventually pushed out of the eardrum, usually 8 to 18 months after tube placement. Parents should be aware of the appearance of a tympanostomy tube (usually a tiny plastic spool-shaped tube) so that they can recognize it if it falls out. They are reassured that this is normal and requires no immediate intervention, although they should notify the practitioner.

Prevention of recurrence requires adequate parent education on antibiotic therapy. Because the symptoms of pain and fever usually subside within 24 to 48 hours, nurses must emphasize that although the child may appear well, the infection is not completely eradicated until all prescribed medication is taken. It is important to stress the potential complications of OM, especially hearing loss, which can be prevented with adequate treatment and follow-up care.

Parents also need anticipatory guidance regarding methods to reduce the risks of OM, especially in children younger than 2 years old. Reducing the chances of OM is possible with measures such as sitting or holding an infant upright for feedings, maintaining routine childhood immunizations, and exclusively breastfeeding until at least 6 months old. Propping bottles is discouraged to avoid pooling of milk while the child is in the supine position and to encourage human contact during feeding. Eliminating tobacco smoke and known allergens is also recommended. Early detection of middle ear effusion is essential to prevent complications. Infants and preschool children should be screened for effusion, and all schoolchildren, especially those with learning disabilities, should be tested for hearing deficits related to a middle ear effusion.

ACUTE OTITIS EXTERNA

Acute otitis externa is commonly caused by *Pseudomonas aeruginosa* or *Staphylococcus aureus* but may include other pathogens such as *Aspergillus* and *Candida* species. Ordinarily the external ear canal is protected by a waxy, water-repellent coating composed of highly viscid secretions of the sebaceous glands and the watery, pigmented secretions of apocrine glands, in combination with exfoliated surface cells. Inflammation occurs when this environment is altered by swimming or increased environmental humidity; by infection, dermatoses, or insufficient cerumen; or by trauma from a foreign body (FB) or a finger. The ear canal becomes irritated, and maceration takes place. It is most common in 5- to 14-year-olds and peaks in summer (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). It is commonly referred to as swimmer's ear.

The predominant symptom of external ear infection is ear pain accentuated by manipulation of the pinna, especially pressure on the tragus. Conductive hearing loss may be present as a result of the edema, secretions, and accumulation of debris within the canal. Edema, erythema, a cheesy green-blue-gray discharge, tenderness, and fever may appear as the infection progresses. The external canal may be so tender and swollen that visualization is difficult. In advanced cases the pain is intense, constant, and aggravated by jaw motion or ear manipulation.

Therapeutic objectives include relief of pain, edema, and itching, as well as restoration of normal flora, cerumen, and canal epithelium. Analgesics are prescribed for pain. Debris is removed with gentle suction and wisps of cotton on metal cotton carriers. Otic preparations such as polymyxin B sulfate/neomycin sulfate, ciprofloxacin, and gentamycin sulfate, with or without corticosteroids, are instilled in the canal for 7 to 10 days. If the child has tympanostomy tubes, polymyxin B sulfate, neomycin sulfate, or gentamycin should not be used because of the risk of ototoxicity. A gauze wick may be inserted if edema is present to facilitate the medication reaching the site of inflammation. The wick is removed after swelling and pain have subsided, but the drops are continued for at least 3 days after relief of pain. The best management for external ear inflammation is prevention.

Nursing Care Management

Nurses can teach parents or patients simple steps to prevent recurrent infections. Children should limit their stay in the water to less than 1 hour, if possible, and ears should dry completely (1 to 2 hours) before entering the water again. Placing a 50:50 combination of acetic acid (white vinegar) and rubbing alcohol in both ear canals on arising, at bedtime, and at the end of each swim is effective in restoring pH and preventing recurrence. This mixture must not be used if tympanostomy tubes are present. The solution should remain in the ear canal for 5 minutes. The child should be cautioned not to submerge his or her head in water for 7 to 10 days, but well-fitting earplugs can be used if this is not possible. Caution children not to pick at the ears with a pencil, cotton swab, bobby pin, or other object, which can injure or infect the ear canal.

INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis is an acute, self-limiting infectious disease that is common among young people under 25 years old. Symptoms include fever, exudative pharyngitis with petechiae, lymphadenopathy, hepatosplenomegaly, and an increase in atypical lymphocytes. The course is usually mild but occasionally can be severe or, rarely, accompanied by serious complications.

Etiology and Pathophysiology

The Epstein-Barr virus (EBV) is the principal cause of infectious mononucleosis. It appears in both sporadic and epidemic forms, but the sporadic cases are more common. The virus is believed to be transmitted by direct contact (close personal contact is needed to transmit the virus), blood transfusion, or transplantation. It is mildly contagious, and the period of communicability is unknown. The incubation period after exposure is approximately 30 to 50 days (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Diagnostic Tests

The diagnosis is established based on clinical manifestations, increase in atypical leukocytes in a peripheral blood smear, and a positive heterophil agglutination test.

Heterophil antibody tests (Monospot or Paul-Bunnell) determine the extent to which the patient's serum will agglutinate sheep red blood cells. The response is primarily to immunoglobulin M (IgM), which is present in the first 2 weeks of the illness and may last for 6 months (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Because children younger than 4 years of age have a lower rate of heterophil antibody responses, the diagnosis may be overlooked in this group.

The spot test (Monospot) is a slide test of venous blood that has high specificity for the diagnosis of infectious mononucleosis. It is rapid, sensitive, inexpensive, and easy to perform, and it has the advantage that it can detect significant agglutinins at lower levels, thus allowing earlier diagnosis. Blood is usually obtained for the test by finger puncture or venous sampling and is placed on special paper. If the blood agglutinates, forming fragments or clumps, the test result is positive for the infection.

Clinical Manifestations

The onset of symptoms may be acute or insidious and may appear anywhere from 10 days to 6 weeks after exposure. The presenting symptoms vary greatly in type, severity, and duration (Box 21.7). The characteristics of the disease are malaise, sore throat, fatigue, and fever with generalized lymphadenopathy and splenomegaly that may persist for several months. The child's chief complaint is difficulty in maintaining the usual level of activity. The clinical manifestations of infectious mononucleosis are usually less severe (often subclinical or unapparent), and the recovery phase is shorter in younger children than in older children and young adults. Many young children do not develop all of the expected clinical and laboratory findings. The extensive mononuclear infiltration produces symptoms related to any body tissue, and the clinical picture can resemble that of many conditions.

Therapeutic Management

No specific treatment exists for infectious mononucleosis. A mild analgesic is usually sufficient to relieve the headache and fever. Rest is encouraged for fatigue and malaise but is not imposed for any specific period. Gargles, warm drinks, analgesic or anesthetic troches, or analgesics, including opioids, can relieve a sore throat. Persons suspected to have infectious mononucleosis should not receive ampicillin or amoxicillin, which may cause a significant nonallergic, maculopapular rash in the presence of active EBV infection. A short course of corticosteroids may have a beneficial effect on some acute symptoms; however, because of the potential adverse effects, their use should be considered only for patients with marked tonsillar inflammation with impending airway obstruction, massive splenomegaly, myocarditis, and hemolytic anemia (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Strenuous activity and contact sports should be avoided for 21 days after onset of symptoms of infectious mononucleosis (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). After 21 days, limited noncontact aerobic activity can be allowed if there are no symptoms and there is no overt splenomegaly. Clearance to participate in contact sports is appropriate after 4 to 6 weeks following the onset of symptoms if the athlete is asymptomatic and has no overt splenomegaly (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Prognosis

The course of infectious mononucleosis is self-limiting and usually uncomplicated. Acute symptoms often disappear within 7 to 10 days, and persistent fatigue subsides within 2 to 4 weeks. The child is encouraged to maintain limited exercise to prevent deconditioning.

Complications are uncommon but can be serious and require appropriate management. Neurologic complications occur in some outbreaks and vary in severity and outcome. These include seizures, ataxia, aseptic meningitis, encephalitis, optic neuritis, cranial nerve palsies, and perceptual distortions of shapes, spatial relationships, and sizes. Other complications include pneumonitis, orchitis, myocarditis, transverse myelitis, hemolytic anemia, agranulocytosis, thrombocytopenia, hemophagocytic lymphohistiocytosis, and ruptured spleen. Some evidence indicates a depressed cellular immune reactivity during the course of the disease and for some time afterward. Thus it is best to avoid live vaccines until several months after recovery.

BOX 21.7 Clinical Manifestations of Infectious Mononucleosis

Early Signs
Headache
Epistaxis
Malaise
Fatigue
Chills
Low-grade fever
Loss of appetite
Puffy eyes

Acute Disease
Cardinal Features
Fever
Sore throat
Cervical adenopathy

Common Features
Splenomegaly (may persist for several months)
Palatine petechiae
Macular eruption (especially on trunk)
Exudative pharyngitis or tonsillitis
Hepatic involvement to some degree, often associated with jaundice

Nursing Care Management

Direct nursing responsibilities toward providing comfort measures to relieve the symptoms and helping affected children and adolescents and their families determine appropriate activities for the stage of the disease and their interests. Throat pain may be severe, therefore careful nursing assessment of the airway is imperative to detect serious airway edema and airway compromise. Pain medications in elixir form, such as acetaminophen, ibuprofen, or hydrocodone, may be required during the acute phase so that the young person can maintain an adequate fluid intake. In addition, the nurse should encourage the affected individual to curtail activities that are strenuous until splenomegaly is resolved. Make every effort to prevent a secondary infection by counseling the child and adolescent to limit exposure to persons outside the family, especially during the acute phase of illness.

! NURSING ALERT

Advise the family to seek medical evaluation of the child or adolescent if:

- Breathing becomes difficult
- Severe abdominal pain develops
- Sore throat pain is so severe that the child is unable to eat or drink
- Respiratory stridor is observed

CROUP SYNDROMES

Croup is a general term applied to a symptom complex characterized by hoarseness, a resonant cough described as "barking" or "brassy" (croupy), varying degrees of inspiratory stridor, and varying degrees of respiratory distress resulting from swelling or obstruction in the region of the larynx and subglottic airway. It occurs primarily in children 6 months to 3 years of age and is rare after 6 years of age. Acute infections of the larynx are of greater importance in infants and small children because of the increased incidence in children in this age-group and the smaller airway diameter that places them at risk for significant narrowing with inflammation. With widespread immunization programs aimed at preventing *H. influenzae* type B (Hib), most cases of croup in the United States are attributed to viruses—namely, influenza types A and B, adenovirus, RSV, and measles (Rodrigues & Roosevelt, 2020). Bacteria such as *M. pneumoniae* can also cause croup.

Croup syndromes affect to varying degrees the larynx, trachea, and bronchi. However, laryngeal involvement often dominates the clinical picture because of the severe effects on the voice and breathing. Croup syndromes are usually described according to the primary anatomic area affected (i.e., epiglottitis [or supraglottitis], laryngitis, laryngotracheobronchitis [LTB], and tracheitis). In general, LTB occurs in very young children, whereas epiglottitis is more common in older children. A comparison of croup syndromes is provided in Table 21.1.

ACUTE EPIGLOTTITIS

Acute epiglottitis, or acute supraglottitis, is a medical emergency that requires immediate medical attention. It is a serious obstructive inflammatory process that occurs predominantly in children 2 to 5 years old but can occur from infancy to adulthood. The obstruction is supraglottic as opposed to the subglottic obstruction of laryngitis. The causative agent is usually *H. influenzae*. However, since the administration of the Hib conjugate vaccine, the incidence of epiglottitis has declined. The disease now is often caused by viral agents. LTB and epiglottitis do not occur together. Epiglottitis (noninfectious) may also be caused by ingestion of caustic agents, smoke inhalation, or foreign bodies (Abdallah, 2012).

Clinical Manifestations

The onset of epiglottitis is abrupt and can rapidly progress to severe respiratory distress. The child usually goes to bed asymptomatic to

TABLE 21.1 Comparison of Croup Syndromes

	Acute Epiglottitis	Acute LTB	Acute Spasmodic Laryngitis	Acute Tracheitis
Age-group affected	2-5 years old but varies	Infant or child younger than 5 years old	1-3 years old	1 month old–6 years old
Etiologic agent	Bacterial	Viral	Viral with allergic component	Viral or bacterial with allergic component
Onset	Rapidly progressive	Slowly progressive	Sudden; at night	Moderately progressive
Major symptoms	Dysphagia Stridor aggravated when supine Drooling High fever Toxic appearance Rapid pulse and respirations	URI Stridor Brassy cough Hoarseness Dyspnea Restlessness Irritability Low-grade fever Nontoxic appearance	URI Croupy cough Stridor Hoarseness Dyspnea Restlessness Symptoms awakening child but disappearing during day Tendency to recur	URI Croupy cough Purulent secretions High fever No response to LTB therapy
Treatment	Airway protection, possible intubation, tracheotomy Humidified oxygen Corticosteroids Fluids Antibiotics Reassurance	Humidified mist if needed Corticosteroids Fluids Reassurance Nebulized epinephrine (possible short-term improvement) Heliox: moderate to severe croup	Cool mist Reassurance	Antibiotics Fluids

LTB, Laryngotracheobronchitis; *URI,* upper respiratory infection.

awaken later, complaining of sore throat and pain on swallowing. The child has a fever and appears sicker than clinical findings suggest. The child insists on sitting upright and leaning forward (tripod position) with the chin thrust out, mouth open, and tongue protruding. Drooling of saliva is common because of the difficulty or pain on swallowing and excessive secretions.

NURSING ALERT

Three clinical observations that are predictive of epiglottitis are absence of spontaneous cough, presence of drooling, and agitation.

The child is irritable and extremely restless and has an anxious, apprehensive, and frightened expression. The voice is thick and muffled, with a froglike croaking sound on inspiration, but the child is not hoarse. Suprasternal and substernal retractions may be visible. Slow, quiet breathing provides better air exchange. The sallow color of mild hypoxia may progress to frank cyanosis if treatment is delayed. The throat is red and inflamed, and a distinctive large, cherry red, edematous epiglottis is visible on careful throat inspection.

NURSING ALERT

Throat inspection should be performed only when immediate endotracheal intubation or an emergency tracheotomy can be performed if needed.

Therapeutic Management

Epiglottitis may develop suddenly, with respiratory obstruction appearing rapidly. Progressive obstruction leads to hypoxia, hypercapnia, and acidosis followed by decreased muscular tone and reduced level of consciousness; when obstruction becomes more or less complete, sudden death may ensue.

A lateral neck radiograph of the soft tissues is indicated for diagnosis. Experienced personnel with advanced airway management skills should accompany the child to the radiology department. For a young child who is likely to become more agitated by the procedure, it is preferable that the child remain on the parent's lap if content during transportation and in the examination area during portable radiology.

The child who is suspected of having epiglottitis should be examined in a setting where emergency airway equipment is readily available. Examination of the throat with a tongue depressor is contraindicated until experienced personnel and equipment are available to proceed with immediate intubation or tracheostomy if the examination precipitates further or complete obstruction.

Endotracheal intubation is usually considered for the child with epiglottitis with severe respiratory distress. Nasotracheal intubation is sometimes preferred. It is recommended that the intubation or any invasive procedure, such as starting an IV infusion, be performed in an area where emergency airway maintenance can be easily and quickly accomplished. For patients who are not intubated, humidified oxygen is administered as necessary either via mask in older children or via blow-by in younger children to avoid further agitation (see Translating Evidence Into Practice box, later in the chapter). Whether or not there is an artificial airway, the child requires intensive observation by experienced personnel. The epiglottal swelling usually decreases after 24 hours of antibiotic therapy, and the epiglottis is near normal by the third day. Intubated children are generally extubated at this time.

Children with suspected bacterial epiglottitis are given antibiotics intravenously usually after obtaining culture (blood and an epiglottic in intubated patient) and followed by oral antibiotic administration to complete a 7- to 10-day course. Ceftriaxone/cefotaxime and vancomycin are generally the first antibiotics started. The use of corticosteroids for reducing edema may be beneficial during the early treatment phase.

Nursing Care Management

Epiglottitis is a serious and frightening disease for the child, family, and health professionals. It is important to act quickly but calmly and to provide support without increasing anxiety. The child can remain in the position that provides the most comfort and security and the parents are reassured that everything possible is being done to obtain relief for their child.

NURSING ALERT

Nurses who suspect epiglottitis should not attempt to visualize the epiglottis directly with a tongue depressor or take a throat culture but should have the child seen by the provider immediately. Resuscitation equipment and suction should be immediately available and ready at the child's bedside.

Droplet isolation precautions are indicated for 24 hours with the initiation of effective antibiotic therapy to control spread of respiratory organisms. Prophylactic antibiotic treatment of household and other contacts may be indicated. Continuous monitoring of respiratory status, including pulse oximetry (and blood gases if the patient is intubated), is an important part of nursing observations, and the IV infusion is maintained as described in Chapter 20 (see Critical Thinking Case Study).

CRITICAL THINKING CASE STUDY

Epiglottitis

Kim, a 4-year-old, is admitted to the emergency department with a sore throat, pain on swallowing, drooling, and a fever of 102.2°F (39°C). She looks ill, is agitated, and prefers to sit up and lean over. According to her mother, she has not had anything to eat or drink since early morning.

Initial Assessment. What immediate concerns do you have about Kim's condition?

Clinical Reasoning. What interventions are appropriate for her immediate care?

Teaching Points

- Infants or children with epiglottis can have severe respiratory distress occur quickly.
- Absence of spontaneous cough, presence of drooling, and agitation are important clinical observations.
- If epiglottitis is suspected, do not attempt to examine the throat without appropriate expertise and equipment available in case intubation or tracheostomy is needed.

Critical Thinking Answers

Initial Assessment. Kim presents with classic symptoms of epiglottitis. Immediate intervention is needed with a focus on respiratory stability.

Clinical Reasoning. An appropriate nursing action is to act quickly and calmly to provide support while rapid assessment and interventions are being implemented. Continuous monitoring of respirations, including pulse oximetry, is the immediate course of action while the diagnosis is established. Examination must occur when emergency airway equipment is readily available.

ACUTE LARYNGOTRACHEOBRONCHITIS

Acute laryngotracheobronchitis (LTB) is the most common type of croup syndrome that primarily affects children 6 months to 3 years old. Organisms responsible for LTB are the parainfluenza virus type 1, followed by parainfluenza virus types 2 and 3, adenoviruses, RSV, and *M. pneumoniae.* Less common causative organisms include influenza A and B, rhinoviruses, enteroviruses, herpes simplex virus. *S. aureus, Streptococcus pyogenes,* and *S. pneumoniae.* The illness is usually preceded by a URI, which gradually descends to adjacent structures. It is characterized by a gradual onset of low-grade fever, and the parents often report that the child went to bed and later awoke with a barky, brassy cough.

Inflammation of the mucosal lining of the larynx and trachea causes a narrowing of the airway. When the airway is significantly narrowed, the child struggles to inhale air past the obstruction and into the lungs, producing the characteristic inspiratory stridor and suprasternal retractions. Other classic manifestations include cough and hoarseness. Respiratory distress in infants and toddlers may be manifested by nasal flaring, intercostal retractions, tachypnea, and continuous stridor. The typical child with LTB is a toddler who develops the classic barking or seal-like cough and acute stridor after several days of rhinitis. When the child is unable to inhale a sufficient volume of air, symptoms of hypoxia become evident. Obstruction that is severe enough to prevent adequate ventilation and exhalation of carbon dioxide can cause respiratory acidosis and eventually respiratory failure.

Therapeutic Management

The major objective in medical management of infectious LTB is maintaining an airway and providing for adequate respiratory exchange. Children with mild croup (no stridor at rest) can be managed at home. Parents should be instructed on the signs of respiratory distress so that they can obtain professional help if needed. Children with progressively worsening respiratory distress (e.g., labored respirations, stridor, other respiratory symptoms) should receive immediate medical attention.

Cool mist may provide relief for children with mild croup, although there is no substantial evidence of its efficacy (Petrocheilou, Tanou, Kalampouka, et al., 2014). In the hospital, mist may be provided with a face mask or as blow-by, but controversy surrounds the use of mist therapy to treat croup. The cool-temperature therapy modalities assist by constricting edematous blood vessels. In the home environment, suggestions to provide cool air include taking the child outside to breathe in cool night air, using a cold-water vaporizer or humidifier, standing in front of the open freezer, or taking the child to a cool basement or garage. Although these are often recommended, there is no evidence to unconditionally support their use. A ride in the car with the window down may help relieve symptoms, and the child often improves on the way to the emergency department (ED) due to exposure to cool air.

Nebulized racemic epinephrine is administered as quickly as possible for moderate to severe cases. The beta-adrenergic effects cause mucosal vasoconstriction and subsequently decrease subglottic edema. The onset of action is rapid, the peak effect is observed within 2 hours, and additional doses may be administered every 20 to 30 minutes as needed. Close observation of patients receiving nebulized racemic epinephrine is critical to detect the reappearance of symptoms, monitor the response to therapy, and note any deterioration in respiratory status. The patient who has received nebulized epinephrine for croup should be observed for 3 to 4 hours for any visible signs of respiratory distress.

Oral steroids (dexamethasone), due to their antiinflammatory effects, have proven effective in the treatment of croup (often as a single dose) and are considered standard treatment for this condition. IV or IM dexamethasone may be given to children who are unable to tolerate oral dosing. The onset of action is clinically detectable as early as 6 hours after administration, with continued improvement over a period of 12 to 24 hours.

Supplemental oxygen with mist may be needed if hypoxemic. On occasion, intubation and ventilation may be required when airway obstruction becomes more severe.

Nursing Care Management

The most important nursing function in the care of children with LTB is continuous, vigilant observation and accurate assessment of respiratory status. Cardiac, respiratory, and pulse oximetry monitoring supplement visual observation. Changes in therapy are frequently based on the nurses' observations and assessments of a child's status, response to therapy, and tolerance of procedures. The trend away from early intubation of children with LTB emphasizes the importance of nursing observations and the ability to recognize impending respiratory failure so that intubation can be implemented without delay. Therefore intubation equipment and bag valve mask equipment should be readily accessible.

! NURSING ALERT

Early signs of impending airway obstruction include increased pulse and respiratory rate; substernal, suprasternal, and intercostal retractions; flaring nares; and increased restlessness.

Infants or small children find that being placed on a face mask, coughing, having laryngeal spasms, and needing IV therapy are additional sources of distress. Infants and small children prefer sitting upright, and most want to be held. Blow-by mist can be administered by a parent while the child is being held. Children need the security of the parent's presence. Because crying increases respiratory distress and hypoxia, the nurse needs to assess a child's individual tolerance for these therapies.

The rapid progression of croup, the alarming sound of the cough and stridor, and the child's apprehensive behavior and ill appearance combine to create a frightening experience for the parents. Parents should be provided with frequent reassurance (provided in a calm, quiet manner), explanation of treatment, and education regarding what they can do to make their child more comfortable. Fortunately, as the crisis subsides and the child responds to therapy, breathing becomes easier and the recovery is generally prompt. Home care after discharge includes monitoring for worsening symptoms, continued humidity, adequate hydration, and nourishment.

ACUTE SPASMODIC LARYNGITIS

Acute spasmodic laryngitis (spasmodic croup, "midnight or twilight croup") is distinct from laryngitis and LTB and characterized by recurrent paroxysmal attacks of laryngeal obstruction that occur chiefly at night. Signs of inflammation are absent or mild with a usual history of previous attacks lasting for 2 to 5 days, followed by an uneventful recovery. The child goes to bed well or with some mild respiratory symptoms but awakens suddenly with the characteristic barking, metallic cough; hoarseness; noisy inspirations; and restlessness. The child appears anxious and frightened. However, there is no fever, the episode subsides in a few hours, and the child appears well the next day, with the exception of slight hoarseness. Some children appear to

be predisposed to the condition; allergies or hypersensitivities may be implicated in some cases.

Cool mist is recommended for the child's room. Warm mist provided by steam from hot running water in a closed bathroom may be helpful. Parents are usually advised to have the child sleep in humidified air until the cough has subsided to prevent subsequent episodes. The disease is usually self-limiting.

BACTERIAL TRACHEITIS

Bacterial tracheitis, an infection of the mucosa and soft tissues of the upper trachea, is a distinct entity with features of both croup and epiglottitis. The disease occurs typically at a mean age between 5 and 7 years and may cause severe airway obstruction (Rodrigues & Roosevelt, 2020). It is believed to be a complication of LTB or other viral URIs, and although *S. aureus* is the most frequent organism responsible, *M. catarrhalis, S. pneumoniae, S. pyogenes,* alpha-hemolytic streptococci, and *H. influenzae* have also been implicated. Causes of bacterial tracheitis are often polymicrobial. Viruses such as influenza A and B, RSV, parainfluenza, measles, and enteroviruses have been associated with bacterial tracheitis.

Anteroposterior or lateral neck x-rays show narrowing (steeple sign), and infiltrates may be seen. An endoscopy of the airway performed in the operating room (OR) or intensive care unit (ICU) is usually indicated to remove secretions and obtain cultures.

Many of the manifestations of bacterial tracheitis are similar to those of LTB but are unresponsive to LTB therapy. The child has a history of previous URI with croupy cough, stridor unaffected by position, toxicity, absence of drooling, high fever, and elevated white blood cell count. Thick, purulent tracheal secretions are common, and respiratory difficulties are secondary to these copious secretions.

Therapeutic Management and Nursing Care Management

Bacterial tracheitis requires vigorous management with maintenance of adequate airway and fluid status and treatment with antibiotics and antipyretics. Many children require endotracheal intubation and mechanical ventilation; patients are closely monitored for impending respiratory failure if not intubated. Early recognition is essential to prevent life-threatening airway obstruction.

INFECTIONS OF THE LOWER AIRWAYS

The reactive portion of the lower respiratory tract includes the bronchi and bronchioles in children. Cartilaginous support of the large airways is not fully developed until adolescence. Consequently, the smooth muscle in these structures represents a major factor in the constriction of the airway, particularly in the bronchioles, the portion that extends from the bronchi to the alveoli. Table 21.2 compares some of the major features of bronchial and bronchiolar infections.

BRONCHITIS

Bronchitis (sometimes referred to as tracheobronchitis) is inflammation of the large airways (trachea and bronchi), which is frequently associated with URIs. Viral agents are the primary cause of the disease, including influenza A and B, parainfluenza, coronavirus (types 1 to 3), rhinovirus, respiratory syncytial virus, and human metapneumovirus. The condition is characterized by a dry, hacking, and nonproductive cough that is worse at night, lasting more than 5 days but that can persist for 1 to 3 weeks.

Bronchitis is a mild, self-limiting disease that requires only symptomatic treatment, including analgesics, antipyretics, and humidity. Cough suppressants may be useful to allow rest, especially at night, but can interfere with clearance of secretions. Most patients recover uneventfully in 5 to 10 days. It can be associated with other underlying conditions (such as CF and bronchiectasis) and can become chronic in nature (cough >3 months). Adolescents with chronic bronchitis (>3 months) should be screened for tobacco or marijuana use.

TABLE 21.2 Comparison of Conditions Affecting the Bronchi

	Asthma[a]	Bronchitis	Bronchiolitis
Description	Exaggerated response of bronchi to a trigger such as URI, animal dander, cold air, exercise Bronchospasm, exudation, and edema of bronchi	Usually occurs in association with URI Seldom an isolated entity	Most common infectious disease of lower airways Maximum obstructive impact at bronchiolar level
Age-group affected	Infancy to adolescence or adulthood	First 4 years of life	Usually children 2-12 months old; rare after 2 years old Peak incidence approximately 6 months old
Etiologic agents	Most often viruses such as RSV in infants but may be any of a variety of URI pathogens	Usually viral Other agents (e.g., bacteria, fungi, allergic disorders, airborne irritants) can trigger symptoms	Viruses, predominantly RSV; also adenoviruses, parainfluenza viruses, human metapneumovirus, and *Mycoplasma pneumoniae*
Predominant characteristics	Wheezing, cough, labored respirations	Persistent dry, hacking cough (worse at night) becoming productive in 2-3 days	Labored respirations, poor feeding, cough, tachypnea, retractions and flaring nares, increased nasal mucus, wheezing, may have fever
Treatment	Inhaled corticosteroids, bronchodilators, leukotriene modifiers, allergen control, control of triggers	Cough suppressants if needed	Supplemental oxygen if saturations ≤90%; bronchodilators (optional) Suction nasopharynx Ensure adequate fluid intake Maintain adequate oxygenation

[a]See Asthma later in the chapter.
RSV, Respiratory syncytial virus; *URI,* upper respiratory infection.

RESPIRATORY SYNCYTIAL VIRUS AND BRONCHIOLITIS

Bronchiolitis is an acute viral infection with maximum effect at the bronchiolar level. The infection typically begins with upper respiratory symptoms and occurs primarily in winter and early spring. Most cases of bronchiolitis are caused by RSV, adenoviruses, parainfluenza viruses, and human metapneumovirus, but RSV is the most common cause, resulting in more than 57,000 hospitalizations and 2.1 million outpatient visits each year (Smith, Seales, & Budzik, 2017). Occasionally, *M. pneumoniae* has been associated with bronchiolitis in children.

RSV is transmitted predominantly through direct or close contact with contaminated respiratory secretions. Viable RSV can live on environmental surfaces (e.g., countertops, paper tissues, cloth) for several hours and on hands for 30 minutes or more (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

RSV occurs less frequently in breastfed infants and more frequently in children who live in crowded conditions. RSV infection is the most frequent cause of hospitalization in children younger than 2 years old. Severe RSV infections in the first year of life represent a significant risk factor for the development of asthma that can persist into adulthood (American Academy of Pediatrics, Committee on Infectious Diseases, 2018; Smith et al., 2017). However, the association between RSV infection early in life and subsequent asthma remains poorly understood (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Pathophysiology

RSV infection affects the epithelial cells of the respiratory tract. The ciliated cells swell, protrude into the lumen, and lose their cilia. The walls of the bronchi and bronchioles are infiltrated with inflammatory cells, and peribronchiolar interstitial pneumonitis is usually present. Because luminal epithelial cells are shed into the bronchioles when they die, the lumina are frequently obstructed, particularly on expiration. The varying degrees of obstruction produced in small air passages lead to hyperinflation, obstructive emphysema resulting from partial obstruction, and patchy areas of atelectasis. Dilation of bronchial passages on inspiration allows sufficient space for intake of air, but narrowing of the passages on expiration prevents air from leaving the lungs. Thus air is trapped distal to the obstruction and causes progressive overinflation (emphysema).

Clinical Manifestations

The younger the infant, the greater the likelihood that severe lower respiratory tract disease will develop, requiring hospitalization. The peak incidence for RSV is less than 3 months of age, but it can occur at all ages. Higher rates occur in children who attend a daycare home or daycare center. The severity of RSV tends to diminish with age and repeated infections.

Symptoms such as rhinorrhea and low-grade fever often appear first after an incubation ranging from 2 to 8 days. In time, a cough may develop. If the disease progresses, it becomes a lower respiratory tract infection and manifests typical symptoms (Box 21.8). Infants may have several days of URI symptoms or no symptoms except slight lethargy, poor feeding, or irritability. When the lower airway is involved, classic manifestations include signs of altered air exchange, such as wheezing, retractions, crackles, dyspnea, tachypnea, and diminished breath sounds. Apnea may be the first recognized indicator of RSV infection in very young infants (younger than 1 month old). Children who are infected with RSV have viral shedding for 3 to 8 days, but some infants and patients with weakened immune systems can be contagious for as long as 4 weeks (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

BOX 21.8 Signs and Symptoms of Respiratory Syncytial Virus Infection

Initial
Rhinorrhea
Pharyngitis
Coughing, sneezing
Wheezing
Possible ear or eye drainage
Intermittent fever

With Progression of Illness
Increased coughing and wheezing
Fever
Tachypnea and retractions
Refusal to nurse or bottle-feed
Copious secretions

Severe Illness
Tachypnea, greater than 70 breaths/min
Listlessness
Apneic spells
Altered air exchange (e.g., retractions, crackles)
Diminished breath sounds

Diagnostic Evaluation

Routine testing for specific viruses is no longer recommended because bronchiolitis may be caused by many viruses (Smith et al., 2017). Routine x-rays are also not indicated (Smith et al., 2017). If identification is necessary, rapid immunofluorescent antibody–direct fluorescent antibody staining or enzyme-linked immunosorbent assay techniques for RSV antigen detection are performed on nasopharyngeal secretions. The more traditional viral culture is becoming obsolete because it takes several days to get a result (see Chapter 20, Respiratory Secretion Specimens).

Other simultaneous viral or bacterial infections may occur with RSV. The infant should be carefully evaluated for the presence of urinary tract infection, meningitis, and bacteremia; antibiotics are prescribed only for a coexisting bacterial infection.

Therapeutic Management

Most children with bronchiolitis can be managed at home. Uncomplicated cases of bronchiolitis are treated symptomatically with adequate fluid intake, airway maintenance, and medications. Hospitalization is recommended for children with respiratory distress or those with poor feeding, lethargy, dehydration, moderate to severe respiratory distress, apnea, or hypoxemia. Other reasons for hospitalization include complicating conditions, such as underlying lung or heart disease (e.g., prematurity) or caregiver inability to provide adequate care during illness.

The American Academy of Pediatrics recommends that continuous pulse oximetry and supplemental oxygen are not necessary if oxygen saturations are 90% or higher (Smith et al., 2017). Heated high-flow nasal cannula (HHFNC) has been increasingly used for hospitalized infants and young children with bronchiolitis who are at risk of respiratory failure. (Fig. 21.4). HHFNC allows extra humidity blended with oxygen administration and continuous positive airway pressure (CPAP) to be administered. The medical provider indicates the flow rate and percentage of the oxygen therapy. The HHFNC improves functional residual capacity, reducing the work of breathing. If respiratory acidosis is present,

Fig. 21.4 High-flow nasal cannula (HFNC).

CPAP, bilevel positive airway pressure (BiPAP), or intubation may be required.

Routine chest percussion and drainage is not recommended (Smith et al., 2017). Infants with abundant nasal secretions benefit from regular suctioning, especially before feeding. Nasal aspiration of the external nares using an aspirator may be sufficient to remove most secretions. Nasopharyngeal suctioning is traumatic to the airways but can be considered if there are signs of respiratory distress or deoxygenation. Researchers found that the use of deep suctioning on the first day of admission and not suctioning the nose at least every 4 hours results in a longer length of stay for infants (Mussman, Parker, Statile, et al., 2013).

Fluids by mouth may be contraindicated because of tachypnea, weakness, and fatigue. Therefore IV fluids are preferred until the acute stage of the disease has passed. Nasogastric fluids may be required if the infant is unable to tolerate oral fluids and a peripheral IV is difficult to establish.

Clinical assessments, noninvasive oxygen monitoring, and, in severe cases, blood gas values may guide therapy. Medical therapy for bronchiolitis is primarily supportive and aimed at decreasing airway hyperresonance and inflammation and promoting adequate fluid intake. Bronchodilators are not recommended and are rarely beneficial. The use of 3% nebulized (hypertonic) saline is associated with an increase in mucociliary clearance in children with RSV when used for more than 24 hours, but it is recommended for use only in patients hospitalized for more than 3 days (Smith et al., 2017).

The use of systemic corticosteroids is controversial, but they may be used in some centers. Studies have reported prolonged viral shedding with corticosteroid use. Antibiotics are not part of the treatment of RSV unless there is a coexisting bacterial infection such as OM or pneumonia. Additional treatment recommendations are to encourage breastfeeding, avoid passive tobacco smoke exposure, and promote preventive measures, including hand washing and the administration of palivizumab (Synagis) to high-risk infants.

Ribavirin, an inhaled antiviral agent (synthetic nucleoside analog), is the only specific therapy approved for hospitalized children. However, use of this drug in infants with RSV is controversial because of concerns about the high cost, aerosol route of administration, potential toxic effects among exposed health care personnel, and conflicting results of efficacy trials (American Academy of Pediatrics, Committee on Infectious Diseases, 2018; Mejias & Ramilo, 2015).

Prevention of Respiratory Syncytial Virus Infection

The only product available in the United States for prevention of RSV is palivizumab (Synagis), a humanized monoclonal antibody, which is given at the onset of the RSV season and then monthly in an IM injection or IV infusion for a maximum of five doses to prevent hospitalization associated with RSV.

Candidates for this drug include the following (Smith et al., 2017):

- Infants born before 29 weeks of gestation
- Infants in the first year of life with hemodynamically significant heart disease
- Infants in the first year of life for preterm infants (<32 weeks of gestation) with chronic lung disease or children in the second year of life with chronic lung disease who require continued medical intervention

Some children acquire the illness despite palivizumab prophylaxis. Additional age and condition recommendations are outlined in the American Academy of Pediatrics Bronchiolitis Guidelines Committee policy statement (American Academy of Pediatrics, Committee on Infectious Diseases, 2014).

QUALITY PATIENT OUTCOMES: Bronchiolitis

- Oxygen (O_2) saturation 90% or higher
- Respiratory rate less than 60 breaths/min
- Adequate oral fluid intake

Nursing Care Management

Children admitted to the hospital with suspected RSV infection are usually assigned separate rooms or grouped with other RSV-infected children. Contact and Standard Precautions are used with hospitalized patients, and some institutions use Droplet Precautions as well. Proper hand washing is essential to reduce the spread of the illness. Other isolation procedures of potential benefit are those aimed at diminishing the number of hospital personnel, visitors, and uninfected children in contact with the child. Another measure is to organize patient assignments so that nurses assigned to children with RSV are not caring for other patients who are considered high risk for RSV. Staff must be careful to avoid touching the nasal mucosa or conjunctiva.

Due to the copious nasal secretions associated with RSV infection, infants often have difficulty with breathing and feeding. Breastfeeding mothers are encouraged to continue feeding the infant or, if feedings are contraindicated due to severity of the illness, mothers should pump their milk and store it appropriately for later use (see Chapter 7). Parents are taught how to instill normal saline drops into the nares and suction the mucus with bulb syringe before feedings and before bedtime so that the child may more easily eat, rest, and sleep.

To address the issue of decreased fluid intake, parents may offer small amounts of fluids, 5 to 10 ml at a time, using a medication syringe every 10 minutes or so to maintain adequate hydration. Infants' hydration status may also be affected by coughing and/or vomiting as the secretions settle in the throat and stomach.

Nursing care is also aimed at monitoring oxygenation with pulse oximetry as clinically indicated, monitoring IV fluids or NG fluids, monitoring for fever, administering prescribed medications, and providing information for the parent and family regarding the infant's status. In most cases, infants recover quickly from the disease and resume normal daily activities, including fluid intake.

PNEUMONIA

Pneumonia, inflammation of the pulmonary parenchyma, is common in childhood but occurs more frequently in infancy and early childhood. Clinically, pneumonia may occur either as a primary disease or as a complication of another illness.

The most useful classification of pneumonia is based on the etiologic agent (e.g., viral, bacterial, mycoplasmal, or aspiration of foreign substances) (see Aspiration Pneumonia, later in the chapter). The causative agent is usually introduced into the lungs through inhalation or from the bloodstream. Other terms that describe pneumonias are *hemorrhagic, fibrinous,* and *necrotizing.*

Pneumonitis is a localized acute inflammation of the lung without the toxemia associated with lobar pneumonia. The clinical manifestations of pneumonia vary depending on the etiologic agent, the child's age, the child's systemic reaction to the infection, the extent of the lesions, any underlying conditions, and the degree of bronchial and bronchiolar obstruction. The clinical history, the child's age, the general health history, the physical examination, radiography, and the laboratory examination can help identify the etiologic agent. Many organisms can cause pneumonia, and vary according to the child's age:

- **Neonates:** Group B streptococci, gram-negative enteric bacteria, cytomegalovirus, *Ureaplasma urealyticum, Listeria monocytogenes, C. trachomatis*
- **Infants:** RSV, parainfluenza virus, influenza virus, adenovirus, metapneumovirus, *S. pneumoniae, H. influenzae, M. pneumoniae, Mycobacterium tuberculosis,* group A streptococci, *M. catarrhalis*
- **Preschool children:** RSV, parainfluenza virus, influenza virus, adenovirus, metapneumovirus, *S. pneumoniae, H. influenzae, M. pneumoniae, M. tuberculosis,* group A streptococci, *M. catarrhalis*
- **School-age children:** *M. pneumoniae, Chlamydia pneumoniae, M. tuberculosis,* group A streptococci, *S. aureus, M. catarrhalis,* and respiratory viruses

Viral Pneumonia

Viral pneumonias occur more frequently than bacterial pneumonias, are seen in children of all ages, and are often associated with viral URIs. The pathologic changes involve interstitial pneumonitis with mucosal inflammation of the walls of bronchi and bronchioles with possible parenchymal involvement. The onset may be acute or insidious, and symptoms vary from mild fever, slight cough, and malaise to high fever, severe cough, and fatigue. Early in the illness, the cough is likely to be unproductive or productive for small amounts of whitish sputum. Radiography reveals diffuse or patchy infiltration with a peribronchial distribution (Box 21.9).

The prognosis is generally good, although viral infections of the respiratory tract render the affected child more susceptible to secondary bacterial invasion, especially when there is denuded bronchial mucosa. Treatment is symptomatic and includes measures to promote oxygenation and comfort, such as oxygen administration, chest percussion and postural drainage, antipyretics for fever management, monitoring fluid intake, and family support. Antibiotics are reserved for children in whom a bacterial infection is demonstrated.

BOX 21.9 General Signs of Pneumonia

Fever: Usually high

Respiratory

- Cough: unproductive to productive with whitish sputum
- Tachypnea
- Breath sounds: crackles or rhonchi
- Dullness with percussion
- Chest pain
- Retractions
- Nasal flaring
- Pallor to cyanosis (depends on severity)

Chest radiography: Diffuse or patchy infiltration with peribronchial distribution

Behavior: Irritability, restlessness, lethargic

Gastrointestinal: Anorexia, vomiting, diarrhea, abdominal pain

Primary Atypical Pneumonia

Atypical pneumonia refers to pneumonia that is caused by pathogens other than the traditionally most common and readily cultured bacteria (e.g., *S. pneumoniae*). In the category of atypical pneumonias, *M. pneumoniae* is the most common cause of community-acquired pneumonia in children 5 years or older (Jain, Williams, Arnold, et al., 2015). Community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) has become prevalent in certain areas. Community-acquired pneumonia occurs principally in the fall and winter months and is more prevalent in crowded living conditions.

The onset may be sudden or insidious and is usually accompanied by general systemic symptoms, including fever, chills (in older children), headache, malaise, anorexia, and muscle pain (myalgia). These symptoms are followed by rhinitis, sore throat, and a dry, hacking cough. The cough, initially nonproductive, produces seromucoid sputum that later becomes mucopurulent or blood streaked. The degree of fever varies widely, from several days to 2 weeks. Dyspnea occurs infrequently

Radiographic examination may reveal evidence of pneumonia before physical signs are apparent. Most affected persons recover from acute illness in 7 to 10 days with symptomatic treatment followed by 1 week of convalescence. The incubation period is 2 to 3 weeks, but the cough may last several weeks. Hospitalization is rarely necessary. Erythromycin, azithromycin, and clarithromycin are the primary agents used for treating atypical pneumonia.

Bacterial Pneumonia

S. pneumoniae is the most common bacterial pathogen responsible for community-acquired pneumonia in both children and adults. Other bacteria that cause pneumonia in children are group A streptococcus, *S. aureus, M. catarrhalis, M. pneumoniae,* and *C. pneumoniae.*

Pneumonia in the immediate neonatal period is different from other types of pneumonia described. If infection occurs within 3 to 5 days of birth, the pathogen is usually obtained from the mother transplacentally, or through aspiration of infected amniotic fluid intrauterine or during or after birth (e.g., Group B hemolytic, chlamydial, or herpes simplex viral pneumonia). Early symptoms of neonatal pneumonia can be abrupt and nonspecific but may include respiratory distress.

Beyond the neonatal period, bacterial pneumonias display distinct clinical patterns that facilitate their differentiation from other forms of pneumonia. The onset of illness generally follows a viral infection that disturbs the natural defense mechanisms of the upper respiratory tract. In the 3-month to 5-year age-group, *S. pneumoniae, M. catarrhalis,* and

group A streptococci are common causes. *H. influenzae* type B causes fewer infections because of the Hib vaccine. *S. aureus* pneumonia is rare but is particularly progressive and must be treated aggressively. The child with bacterial pneumonia usually appears ill. Symptoms include fever, malaise, rapid and shallow respirations, cough, and chest pain. The associated cough may persist for several weeks or months. The pain of pneumonia may be referred to the abdomen in young children. Chills and meningeal symptoms (meningism) without meningitis are common.

Most older children with pneumonia can be treated at home if the condition is recognized and treatment is initiated early. Antibiotic therapy, rest, liberal oral intake of fluid, and administration of an antipyretic for fever are the principal therapeutic measures. Chest percussion and postural drainage may be indicated, but there is a lack of evidence to show that they have benefit to children with pneumonia.

Infants and young children develop more severe symptoms than older children. Cyanosis and apnea are common, and the parent may report that the infant's activity and eating pattern was decreased for a few days. Additional clinical manifestations in infants include abrupt fever, vomiting, diarrhea, and abdominal distention. Because pneumonia in newborns carries a high morbidity and mortality rate, bacterial infection should be suspected in all neonates with respiratory symptoms.

A follow-up examination is recommended for small infants and toddlers. Hospitalization is indicated when pleural effusion or empyema accompanies the disease, when moderate or severe respiratory distress or deoxygenation occurs, in situations in which compliance with therapy is estimated to be poor, in infants younger than 6 months old, and when there are chronic illnesses such as congenital heart disease or BPD (Barson, 2015). IV fluids may be necessary to ensure adequate hydration, and oxygen is required if the child is in respiratory distress; some children may require initial therapy with parenteral antibiotics because of the severity of illness.

Complications

At present, the classic features and clinical course of pneumonia are rarely seen because of early and vigorous antibiotic and supportive therapy. However, some children, especially infants, with staphylococcal pneumonia develop empyema, pyopneumothorax, or tension pneumothorax. AOM and pleural effusion are common in children with pneumococcal pneumonia (Box 21.10) (see Translating Evidence Into Practice box). As previously mentioned, vaccination with pneumococcal vaccines is an important part of preventing pneumococcal pneumonia.

TRANSLATING EVIDENCE INTO PRACTICE

Nursing Interventions for Prevention of Ventilator-Associated Pneumonia in Children

Ask the Question

PICOT Question

What nursing interventions prevent VAP in children?

Search for the Evidence

Search Strategies

Search selection included English-language publications on nursing interventions for prevention of VAP in children and adolescents.

Databases Used

PubMed, AHRQ.

Critically Analyze the Evidence

- Implementation of VAP bundle resulted in a decreased VAP rate from 5.6 infections per 1000 ventilator days at baseline to 0.3 per 1000 ventilator days (Bigham, Amato, Bondurrant, et al., 2009). Another study reported similar results with implementation of a VAP bundle that had a decreased VAP rate from 21.6 per 1000 ventilator days at baseline to 11.6 per 1000 ventilator days (P = 0.01) (Parisi, Gerovasili, Dimopoulos, et al., 2016).
- Common VAP prevention interventions include the following (Bigham et al., 2009; Chinnadurai, Fenlason, Bridges, et al., 2016; Coffin, Klompas, Classes, et al., 2008; Garland, 2010; Kollef, 2004; Morrow, Argent, Jeena, et al., 2009; Norris, Barnes, & Roberts, 2009):
  - Change ventilator circuits and in-line suction catheters only when soiled.
  - Every 2 to 4 hours, drain condensate from ventilator circuit (use heated wire circuits to reduce rainout).
  - Rinse oral suction devices after use and store in a nonsealed plastic bag at the bedside.
  - Hand hygiene should be used before and after contact with ventilator circuit.
  - Wear PPE before providing care to patients when soiling from respiratory secretions is anticipated.
  - Maintenance of ET tube cuff pressure adequate to prevent aspiration of secretions.
  - Minimizing transportation outside the ICU for other procedures.
  - Use of noninvasive ventilation when possible.
  - Every 2 to 4 hours, follow unit mouth care policy.
  - Unless contraindicated, elevate head of bed to 30 to 45 degrees.
  - Before repositioning patient, always drain ventilator circuit.
  - For patients older than 12 years of age, when possible, use ET tube with dorsal lumen above ET cuff to help suction secretions above the cuff.
  - Evaluate daily for possible extubation.
  - Avoid reintubation.
- Infants in supine position (infant lying on back with ET tube held upright in the vertical position) had increased colony counts or new organisms in tracheal aspirate compared to infants in lateral position (infant lying on side with ET tube at same level as the trachea) (Aly, Badawy, El-Kholy, et al., 2008).
- Staff education on VAP and improvements to practice changes can have a substantial impact on reducing VAP (Garland, 2010; Hill, 2016; Richardson, Hines, Dixon, et al., 2010; Turton, 2008).
- A 7-day versus 3-day ventilator circuit change was not associated with increased VAP rates (Samransamruajkit, Jirapaiboonsuk, Siritantiwat, et al., 2010).
- Use of low-sodium solution for airway care was associated with a decrease in VAP as well as chronic lung disease (Christensen, Henry, Baer, et al., 2010).
- In bronchoalveolar lavage fluid, PAI-1 levels can aid in early diagnosis of VAP (Srinivasan, Song, Wiener-Kronish, et al., 2011).
- Reduced mortality rates were observed in patients with VAP when a silver-coated ET tube was used versus an uncoated ET tube (Afessa, Shorr, Anzueto, et al., 2010).

Apply the Evidence: Nursing Implications

There is **moderate evidence** with a **strong recommendation** (Guyatt, Oxman, Vist, et al., 2008) for use of interventions to prevent VAP in children. Some prevention methods included in VAP bundles are hand hygiene, oral hygiene, use of PPE, elevation of head of bed 30 to 45 degrees, and more. Staff education and engagement in VAP prevention initiatives is important.

BOX 21.10 Pneumothorax

Pneumothorax occurs when air accumulates in the pleural space; this air increases intrapleural pressure, making it more difficult to expand the affected lung. This leads to the clinical manifestations of dyspnea, chest pain and often back pain, labored respirations, tachycardia, and decreased oxygen saturation (SaO_2). In neonates and infants on mechanical ventilation, the first clinical signs of a pneumothorax are oxygen desaturation and hypotension. The three major types of pneumothorax are tension, spontaneous, and traumatic. The definitive diagnosis of pneumothorax is a chest radiograph. The emergent treatment involves needle aspiration of the air within the pleural space; subsequently a chest tube to closed drainage is usually inserted to prevent the reaccumulation of air.

Pleural effusion occurs when there is an excessive accumulation of fluid in the pleural space. The diagnosis is made by chest radiography, and the treatment involves evacuation of the fluid by needle aspiration followed by insertion of a chest tube to closed drainage.

When fluid is either suspected or identified by radiograph in the pleural cavity, a needle aspiration or thoracentesis may be performed. Nonpurulent effusions do not require surgical drainage.

Continuous closed chest drainage may be instituted with complicated pleural effusion. If a large amount of purulent drainage is obtained, an appropriate antibiotic may be instilled into the chest cavity, and chest drainage is discontinued for approximately 1 hour after the instillation. Closed drainage using a chest tube is continued until drainage fluid is minimal and free of pathogens, which rarely requires more than 5 to 7 days. Sometimes repeated pleural taps are sufficient to remove fluid; however, if the purulent drainage accumulates rapidly and is highly viscous, continuous drainage is preferred. Rarely, thoracotomy with open debridement of the infected lung tissue is required.

Additional therapies for empyema may involve instillation of intrapleural fibrinolytics such as urokinase or streptokinase or video-assisted thoracoscopy (Livingston, Colozza, Vogt, et al., 2016; van Loo, van Loo, Selvadurai, et al., 2014). These therapies may preclude the need for open debridement and thoracotomy.

Nursing Care Management

Nursing care of the child with pneumonia is primarily supportive and symptomatic but necessitates thorough respiratory assessment and administration of supplemental oxygen (as required), fluids, and antibiotics. The child's respiratory rate and status, oxygenation, general disposition, and level of activity are frequently assessed. To prevent dehydration, fluids may be needed intravenously during the acute phase. An NG tube may be placed to provide hydration and antibiotics if oral intake is poor.

Nursing care of the child with a chest tube requires close attention to respiratory status, as noted previously. The chest tube and drainage device used are monitored for proper function (e.g., drainage is not impeded, vacuum setting is correct, tubing is free of kinks, dressing covering chest tube insertion site is intact, water seal is maintained [if used], drainage tube is below the chest tube entry site and chest tube remains in place). Movement in bed and ambulation with a chest tube are encouraged according to the child's respiratory status, but children may require frequent doses of analgesia due to possible chest tube discomfort. If needed, supplemental oxygen may be administered by nasal cannula, face mask, blow-by, or face tent. Children are usually more comfortable in a semierect position (Fig. 21.5) but should be allowed to determine the position of comfort. Lying on the affected side if the pneumonia is unilateral ("good lung up") splints the chest on that side and reduces the pleural rubbing that often causes discomfort. Fever is controlled by cooling the environment and administrating antipyretic drugs as prescribed.

Vital signs and oxygenation are monitored to assess the progress of the disease and to detect early signs of complications. Children with ineffectual cough or difficulty handling secretions, especially infants, may require suctioning to maintain a patent airway. A simple bulb suction syringe is usually sufficient for clearing the nares and nasopharynx of infants, but mechanical suction should be readily available if needed. A nasal aspirator device can be attached to wall suction to remove secretions from nares without causing trauma to the nasal mucosa. Older children can usually handle secretions without assistance. Postural drainage, chest percussion, and nebulized bronchodilator therapy may be prescribed, depending on the child's condition. However, there is lack of empirical support on the benefit of chest percussion in children with community-acquired pneumonia.

Fig. 21.5 Child placed in semierect position is often more comfortable, and this position enhances diaphragmatic expansion.

The nurse educates the family regarding observation for worsening symptoms, antibiotic and antipyretic administration, and encouragement of oral fluid intake. If the ill child rejects solid foods, fluid intake should be encouraged until the child feels well enough to eat solids. The hospitalized child may be apprehensive because the treatments and tests tend to be frightening and stress producing. It is important to involve the family in the care and to encourage questions and facilitate effective communication. Reducing the child's anxiety, apprehension, and psychologic distress leads to relaxation and decreased respiratory efforts. Easing respiratory efforts further reduces the child's apprehension. Encouraging the presence of the caregiver provides the child with a source of comfort and support.

OTHER INFECTIONS OF THE RESPIRATORY TRACT

PERTUSSIS (WHOOPING COUGH)

Pertussis, or whooping cough, is an acute respiratory tract infection caused by *Bordetella pertussis* that occurs primarily in children younger than 4 years old who were not immunized. It is highly contagious and is particularly threatening in young infants, who have a higher morbidity and mortality rate. Infants younger than 6 months of age may not come to the practitioner with the typical whooping cough yet may present with apnea, but usually the infant tends to look deceptively well with coryza, sneezing, and mild cough (Cherry, 2016). Older children are known to manifest the disease with a persistent cough and the absence of the characteristic whoop (see Table 6.3 for signs, symptoms, and management of pertussis). It presents as a URI, and cough symptoms develop. The cough can be mild but is generally more severe in unimmunized children. It persists for 6 to 10 weeks and can result in encephalopathy, seizures, pneumonia, rib fractures (adolescents), bleeding into the conjunctiva, or even death (infants). The incubation period is 7 to 10 days but can be as long as 21 days (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). The incidence is highest in the spring and summer months, and a single attack confers lifetime immunity.

Pertussis is diagnosed using the *B. pertussis* polymerase chain reaction (PCR) test or culture on specimens obtained with a nasopharyngeal swab. The PCR test has optimal sensitivity during the first 3 weeks of cough, is unlikely to be useful if antimicrobial therapy has been given for more than 5 days, and has lower sensitivity in previously immunized people, but still is more sensitive than culture (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Antibiotics (e.g., erythromycin, azithromycin, clarithromycin) in the early stage may result in a milder form of the infection and limit the spread to others. Household members, high-risk individuals (immunodeficiency, pregnancy, high-risk contacts, infants, or those who care for infants), and close contacts may be treated to prevent them from developing the infection and should be immunized when indicated (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Most children with pertussis can be managed at home with supportive care, including encouraging adequate hydration and administering antibiotic and antipyretics. When coughing spasms occur in small children, they can be frightening for the parent and family in an unvaccinated child. A child is admitted to the hospital if respiratory symptoms are severe or if apnea occurs. Hospitalized patients are placed on Droplet Precautions. Patients are considered infectious until at least 5 days of antibiotics have been completed or for 3 weeks if no antibiotics have been administered.

The resurgence of pertussis in the United States, particularly among children 10 years of age and older, has prompted concerns about the long-term effects of the pertussis vaccine. Consequently, a booster vaccine for pertussis was been approved for older children and adults. Boostrix contains acellular pertussis, diphtheria toxoid, and tetanus toxoid and is indicated as a booster for children 11 years of age and older (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). (See also Chapter 6, Immunizations.)

TUBERCULOSIS

Tuberculosis (TB) along with human immunodeficiency virus (HIV) is the leading cause of death from a single infectious disease (World Health Organization, 2018). In 2017, a total of 9093 new cases of TB were reported in the United States (Stewart, Tsang, Pratt, et al., 2018). TB occurs in all ages but is most common in urban, low-income areas and among nonwhite racial and ethnic groups (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Children who were born in other countries have accounted for more of the newly diagnosed cases of TB in children living in the United States (American Academy of Pediatrics, Committee on Infectious Diseases, 2018; Stewart et al., 2018). The following groups have the highest rates of latent TB infection: immigrants, international adoptees, refugees from or travelers to high-prevalence regions (Asia, Africa, Latin America, and countries of the former Soviet Union), homeless individuals, people who use alcohol excessively or illicit drugs, and residents of certain correctional facilities and other congregate settings (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). In recent years, more than 65% of all TB cases in the United States have been in people born outside the country (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Etiology

TB is caused by *Mycobacterium tuberculosis,* an acid-fast bacillus. Children are susceptible to the human *(M. tuberculosis)* and the bovine *(Mycobacterium bovis)* organisms. In parts of the world where TB in cattle is not controlled or milk is not pasteurized, the bovine type is a common source of infection from dairy products but also can be contacted from airborne transmission.

Other factors that influence the degree to which the organism produces an altered state in the host include heredity (resistance to the infection may be genetically transmitted), gender (higher rates

in adolescent girls), age (lower resistance in infants, higher incidence during adolescence), stress (emotional or physical), nutritional state, immunodeficiency (HIV, immunosuppressive medications), IV drug abuse, medical conditions (diabetes mellitus, chronic renal failure, malnutrition), and intercurrent infection (measles and pertussis) (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). The risk is increased for individuals who are born in another country, have a parent who was born in another country, lived outside the United States for 2 months or more, or use tobacco (World Health Organization, 2018).

Adolescents and adults being treated with tumor necrosis factor–alpha (TNF-α) antagonists for conditions such as inflammatory bowel disease or arthritis have been identified as having contracted TB; therefore it is recommended that screening for TB occur in such persons before the use of TNF-α antagonists (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Children with HIV infection have an increased incidence of TB disease, and all children with TB should be tested for HIV. TB is the leading cause of the mortality of persons infected with HIV.

Pathophysiology

The source of TB infection in children is usually an infected member of the household or a frequent visitor to the home. The airway is the usual portal of entry for the organism as the child inhales microdroplets (usually 1 to 5 mm in size) into the respiratory tract after someone has coughed or sneezed. When the *M. tuberculosis* droplet is inhaled, it passes down the bronchial tree, implants in either a bronchiole or an alveolus, and starts to multiply. In the lungs, a proliferation of epithelial cells surrounds and encapsulates the multiplying bacilli in an attempt to wall off the invading organisms, thus forming the typical tubercle. Extension of the primary lesion at the original site causes progressive tissue destruction as it spreads within the lung, discharges material from foci to other areas of the lungs (e.g., bronchi, pleura), and/or produces pneumonia. Erosion of blood vessels by the primary lesion can cause widespread dissemination of the tubercle bacillus to near and distant sites (miliary TB). Extrapulmonary (miliary) TB may be manifested as meningitis or granulomatosis inflammation of lymph nodes, bones, joints, skin, middle ear, and the mastoid (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). With the exception of meningitis, the treatment for extrapulmonary TB may be the same drug regimen as for pulmonary TB. Infants and children younger than 3 years old are more likely to develop miliary TB.

Clinical Manifestations

The clinical manifestations of the disease are extremely variable (Box 21.11). The disease may be asymptomatic or produce a broad range of symptoms, including general responses such as fever, cough, night sweats, chills, delayed growth, and weight loss or more specific symptoms related to the site of infection (e.g., lungs, bone, brain, kidneys) within 1 to 6 months after infection (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Lung disease may or may not include cough (which progresses slowly over weeks to months), aching pain and tightness in the chest, and (rarely) hemoptysis. Progression of the infection includes the generalized responses with manifestations such as persistent fever, diminished breath sounds and crackles on auscultation, pallor, anemia, weakness, and weight loss (Box 21.11).

Diagnostic Evaluation

Diagnosis is based on information derived from physical examination, history, tuberculin skin test reaction, organism cultures, and radiographic examinations. In addition, it must be determined whether the lesion is in the active, quiescent, or healed stage.

BOX 21.11 Clinical Manifestations of Tuberculosis

May be asymptomatic or produce a broad range of symptoms:
- Fever
- Malaise
- Anorexia
- Weight loss
- Cough (may or may not be present; progresses slowly over weeks to months)
- Aching pain and tightness in the chest
- Hemoptysis (rare)

With progression:
- Increasing respiratory rate
- Decreased expansion of lung on the affected side
- Diminished breath sounds and crackles
- Dullness to percussion
- Persistent fever
- Generalized symptoms
- Pallor, anemia, weakness, and weight loss

Targeted TB testing is used in children and adolescents at high risk for contracting the disease, and those patients at risk for progression to TB disease are also screened. A risk factor assessment questionnaire for TB facilitates screening of these children and should be performed at the first encounter of a child with a health care provider and then annually if possible (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Tuberculin skin test (TST) recommendations for children are listed in Box 21.12.

The tuberculin skin test (TST) is the most common test used to determine whether a child has been infected with the tubercle bacillus. Skin tests must be carried out correctly to obtain accurate results. The standard dose of purified protein derivative (PPD) is 5 tuberculin units in 0.1 ml of solution, which is administered using a 27-gauge needle and a 1-ml syringe intradermally into the volar aspect of the forearm. The tuberculin is injected intradermally with the bevel of the needle pointing upward. A wheal 6 to 10 mm in diameter should form between the layers of the skin when the solution is injected properly. If the wheal is not formed, the procedure is repeated. The reaction to the skin test is determined in 48 to 72 hours by a health care professional. Reactions occurring after 72 hours should be measured and considered the result. The size of the transverse diameter of induration, not the erythema, is measured. The diameter transverse to the long axis of the forearm is the only one standardized for measurement purposes (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

A positive TST reaction indicates that the individual has been infected and has developed sensitivity to the protein of the tubercle bacillus (Fig. 21.6). However, it does not confirm the presence of active disease. The test is usually positive 2 to 10 weeks after initial infection with the organism. Once individuals react positively, they will always react positively. Any negative reaction does not exclude active disease because false negatives can occur due to immunosuppression or certain medications. Guidelines for interpreting the TST are listed in Box 21.13. A clinical examination with a prompt chest radiographic evaluation is recommended if the child has a positive TST reaction.

The term latent tuberculosis infection (LTBI) is used to indicate infection in a person who has a positive TST, no physical findings of disease, and normal chest radiograph findings. A diagnosis of LTBI or TB disease in a young child represents a public health sentinel event often indicating recent transmission of the *M. tuberculosis* organism

BOX 21.12 Tuberculin Skin Test Recommendations for Infants, Children, and Adolescents

Children for Whom Immediate Tuberculin Skin Test Is Indicated

Contacts of persons with confirmed or suspected contagious tuberculosis (TB; contact investigation)

Children with radiographic or clinical findings suggesting TB disease

Children immigrating from endemic countries (e.g., Asia, Middle East, Africa, Latin America, countries of the former Soviet Union), including international adoptees

Children with travel histories to endemic countries or significant contact with indigenous persons from such countries[a]

Children Who Should Have Annual Tuberculin Skin Test[b]

Children infected with human immunodeficiency virus (HIV)

Children at Increased Risk for Progression of Infection to Disease

Children with other medical risk factors, including diabetes mellitus, chronic renal failure, malnutrition, and congenital or acquired immunodeficiencies, deserve special consideration. Without recent exposure, these people are not at increased risk of acquiring TB infection. Underlying immune deficiencies associated with these conditions theoretically would enhance the possibility for progression to severe disease. Initial histories of potential exposure to TB should be included for all of these patients. If these histories or local epidemiologic factors suggest a possibility of exposure, immediate and periodic tuberculin skin test (TST) should be considered. An initial TST should be performed before initiation of immunosuppressive therapy, including prolonged steroid administration, for any child with an underlying condition that necessitates immunosuppressive therapy.

[a]If child is well, TST should be delayed for up to 10 weeks after return.
[b]Initial tuberculin skin testing is done at the time of diagnosis or circumstance, beginning as early as 3 months old.
From American Academy of Pediatrics, Committee on Infectious Diseases, Kimberlin, D. W., Brady, M. T., Jackson, M. A., & Long, S.S. (Eds.). (2018). *Red book: 2018 report of the Committee on Infectious Diseases* (31st ed.). Itaca, IL: American Academy of Pediatrics.

Fig. 21.6 Induration and erythema resulting from a positive tuberculosis (TB) skin test. (From Mullins, J. E. Jr., Ogle, O., & Cottrell, D. A. [2000]. Painless mass in the parotid region. *Journal of Oral and Maxillofacial Surgery, 58*[3], 316–319.)

BOX 21.13 Definition of Positive Tuberculin Skin Test Results in Infants, Children, and Adolescents[a]

Induration ≥5 mm

Children in close contact with known or suspected contagious cases of tuberculosis (TB) disease

Children suspected to have TB disease:

- Findings on chest radiography consistent with active or previously active TB
- Clinical evidence of TB disease[b]

Children receiving immunosuppressive therapy, including immunosuppressive doses of corticosteroids, or who have immunosuppressive conditions, including human immunodeficiency virus (HIV) infection

Induration ≥10 mm

Children at increased risk of disseminated disease:

- Children younger than 4 years old
- Children with other medical risk conditions, including Hodgkin disease, lymphoma, diabetes mellitus, chronic renal failure, or malnutrition

Children at increased risk of exposure to TB:

- Children born in high-prevalence (TB) regions of the world
- Children frequently exposed to adults who are HIV infected, homeless, users of illicit drugs, residents of nursing homes, incarcerated or institutionalized
- Children who travel to high-prevalence (TB) regions of the world

Induration ≥15 mm

Children 4 years old or older without any risk factors

[a]These definitions apply regardless of previous bacillus Calmette-Guérin (BCG) immunization; erythema at the tuberculin skin test (TST) site does not indicate a positive test result. TSTs should be read at 48 to 72 hours after placement.
[b]Evidence by physical examination or laboratory assessment that would include TB in the working differential diagnosis (e.g., meningitis).
From American Academy of Pediatrics, Committee on Infectious Diseases, Kimberlin, D. W., Brady, M. T., Jackson, M. A., & Long, S.S. (Eds.). (2018). *Red book: 2018 report of the Committee on Infectious Diseases* (31st ed.). Itaca, IL: American Academy of Pediatrics.

(American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Most children are asymptomatic when a positive skin test result is found, and most of them do not go on to develop the disease. Children younger than 5 years old who have LTBI often progress rapidly to disease, and complications (such as TB meningitis and miliary TB) are more common in this age-group.

The term TB disease or clinically active TB is used when a child has clinical symptoms or radiographic manifestations caused by the *M. tuberculosis* organism. Prompt evaluation, treatment, and identification and treatment of contacts are key components to managing TB.

Sputum specimens are difficult or impossible to obtain from infants and young children because they tend to swallow any mucus coughed from the lower respiratory tract. The *Mycobacterium* organism is identified from microscopic examination of properly prepared and stained smears from early-morning gastric washings or from sputum, pleural fluid, urine, spinal fluid, draining lymph nodes, and other body fluids. Induced sputum and gastric lavage sputum specimens are often obtained for culture from children who are unable to expectorate a sputum specimen. In some cases, an induced sputum specimen may be obtained by administering aerosolized normal saline for 10 to 15 minutes, followed by CPT and suctioning of the nasopharynx for sputum collection.

The QuantiFERON-TB Gold and T-SPOT.TB are tests of interferon quantification (interferon-gamma release assay [IGRA]). They are the preferred tests to perform on asymptomatic children 2 years and older who have received the bacillus Calmette-Guérin (BCG) vaccine and have a borderline positive or negative TST (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). These tests cannot determine latent infection, but children with a positive IGRA test are considered to be infected with the *M. tuberculosis* bacterium.

Radiographic examinations may be normal or may show lymphadenopathy, pleural effusion, or cavitary TB. However, the lesions of numerous chronic intrathoracic diseases resemble tuberculous lesions, therefore chest radiography is not diagnostic by itself.

Therapeutic Management

Medical management of TB disease in children consists of adequate nutrition, pharmacotherapy, general supportive measures, prevention of unnecessary exposure to other infections that further compromise the body's defenses, prevention of reinfection, and sometimes surgical procedures. Family members and other contacts should also be assessed for symptoms by public health and treated accordingly.

Antituberculosis drugs (e.g., ethambutol, isoniazid, pyrazinamide [PZA], rifampin) are common medications used to treat LTBI or TB disease in children. They are prescribed daily or once or twice weekly with recommended directly observed therapy (DOT). DOT means that a health care worker or other responsible, mutually agreed-on individual is present when medications are administered to the patient. DOT decreases the rates of relapse, treatment failures, and drug resistance, and is recommended for treatment of children and adolescents with TB in the United States.

The duration of treatment depends on the medication, presence of disease versus LTBI, whether multidrug-resistant TB is present, and the patient's immune status. There are several recommended drug regimens for LTBI in children and adolescents, with the three newest treatment options being (1) 12 weeks of weekly isoniazide and rifapentine (long-acting rifamycin) in children older than 2 years of age; (2) 4 months of daily rifampin; or (3) 9 months of daily isoniazid. All of these treatment options are considered adequate (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

For the child with clinically active pulmonary and extrapulmonary TB, the goal is to achieve sterilization of the tuberculous lesion. There are several alternative regimens, but a 6-month, four-drug regimen consisting of a combination of isoniazid, PZA, and ethambutol daily or twice weekly for 2 months is recommended, followed by isoniazid and rifampicin for 4 months (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Alternatively, DOT with isoniazid, rifampin, and PZA two to three times per week for 6 months is recommended except in people with HIV-related disease and drug-resistant, disease (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Alternative treatment regimens may be used when managed by a TB specialist. Infection with *M. bovis* is treated with isoniazid and rifampin for 9 to 12 months.

When drug resistance is suspected, other antimicrobials are added to the therapeutic regimen until drug susceptibility results are available. It is not within the scope of this text to outline the treatment regimen for multiple drug–resistant and extensively drug-resistant TB (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Optimal therapy for TB in children with HIV infection has not been established, and consultation with a specialist is advised. However, the duration of the present therapy is longer for patients who have HIV infection or who have cavitary lesions or positive sputum analysis after 2 months of antimicrobial therapy (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Surgical procedures may be required to remove the source of infection in tissues that are inaccessible to pharmacotherapy or that are destroyed by the disease. Orthopedic procedures may be performed for correction of bone deformities, bronchoscopy may be done for removal of a tuberculous granulomatous polyp, or resection of a portion of a diseased lung may be performed.

Prognosis

Most children recover from primary TB infection and may be unaware of its presence. However, very young children have a higher incidence of disseminated disease. TB is a serious disease during the first 2 years of life and in children infected with HIV. Except in cases of tuberculous meningitis, death seldom occurs in treated children. Antibiotic therapy has decreased the death rate and the hematogenous spread from primary lesions.

Prevention

The only definite means to prevent TB is to avoid contact with the tubercle bacillus. Maintaining an optimal state of health with adequate nutrition and avoiding debilitating infections promote natural resistance but do not prevent infection. Pasteurization and routine testing of milk and elimination of diseased cattle have reduced the incidence of bovine TB.

Limited immunity can be produced by administration of BCG, a live vaccine containing bovine bacilli with reduced virulence (attenuated). In most instances, positive tuberculin reactions develop after inoculation with BCG. The distribution of BCG is controlled by local or state health departments, and the vaccine is not used extensively. The World Health Organization (2018) recommends the administration of the BCG vaccine in countries with a high prevalence of the disease. BCG vaccination is not generally recommended for use in the United States. However, it may be recommended for long-term protection of infants and children with negative TST results who are not infected with HIV and who (1) are at high risk for continuing exposure to persons with infectious pulmonary TB or (2) are continuously exposed to persons with TB who have bacilli resistant to both isonicotinic acid hydrazide (INH) and rifampin (American Academy of Pediatrics, Committee on Infectious Diseases, 2018).

Nursing Care Management

Hospitalization for TB is seldom necessary in the United States. Only children with the more serious forms of the disease are placed in the hospital. Children with TB typically receive their nursing care in ambulatory settings, outpatient departments, schools, and public health settings. Children younger than 10 years old with only chest adenopathy or small pulmonary lesions and nonproductive cough are rarely contagious and require only Standard Precautions. Children with no cough and negative sputum smears can be hospitalized in a room without isolation. Children and adolescents with infectious pulmonary TB (i.e., those whose sputum smears show acid-fast bacilli) should be on Isolation Precautions until effective therapy has been initiated, their sputum smears show a diminishing number of organisms, and their cough is improving. Ideally, they should be cared for in an Airborne Isolation room (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Staff should be fitted for an appropriately sized N95 or higher-level particulate-filtering respirator.

Asymptomatic children with TB can attend school or daycare facilities if they are receiving pharmacotherapy. They can return to regular activities as soon as effective therapy has been instituted, adherence to therapy has been documented, and clinical symptoms have diminished. Children receiving pharmacotherapy for TB can receive measles and other age-appropriate live virus vaccines unless they are receiving

high-dose corticosteroids, are severely ill, or have specific contraindications to immunization.

Nurses assume several roles in management of the disease, including instructing the family on the disease and its ramifications, reducing family and child anxieties, promoting optimal health, explaining the rationale for diagnostic procedures, assisting with radiographic examinations, performing and interpreting skin tests accurately, obtaining specimens for laboratory examination, and educating on the TB pharmacotherapy regimen and the rationale for DOT. Case finding in the community and follow-up of known contacts—individuals from whom the affected child may have acquired the disease and persons who may have been exposed to the child with the disease—are essential control measures. Early diagnosis affords a means for early protection or treatment and prevents further spread of the disease. The health department is notified about TB cases.

PULMONARY DYSFUNCTION CAUSED BY NONINFECTIOUS IRRITANTS

FOREIGN BODY ASPIRATION

Foreign body (FB) aspiration is a life-threatening event due to potential airway obstruction and inability to adequately oxygenate the body. Small children characteristically explore matter with their hands and mouth and are prone to place FBs into air passages (nose and mouth). They also place such objects as beads, toys, paper clips, small magnets, or food items in the nose and mouth, which can easily be aspirated into the trachea. FB aspiration or ingestion can occur at any age but is most common in children 1 to 3 years old. Severity is determined by the location, type of object aspirated, and extent of obstruction. For example, dry vegetable matter, such as a seed, nut, or piece of carrot or popcorn, that does not dissolve and may swell when moistened creates a particularly difficult problem. The high fat content of potato chips and peanuts may cause the added risk of lipoid pneumonia. "Fun foods," such as hard candy and hot dogs, are among the worst offenders. Offending foods include hot dogs, round candies, peanuts or other types of nuts, grapes, cookies or biscuits, pieces of meats, caramels, carrots, apples, peas, celery, popcorn, fruit and vegetable seeds, cherry pits, gum, and peanut butter. Other items include burst latex balloons, plastic or glass beads, marbles, pen or marker caps, button or disc batteries, magnets, and coins. Aspiration of certain medications can cause inflammation and stenosis. Aspirated objects can obstruct the air passage, producing various changes, including atelectasis, emphysema, inflammation, and abscess.

CLINICAL MANIFESTATIONS

Initially, an FB in the air passages can cause choking, gagging, wheezing, or coughing, but symptoms depend on the site of obstruction and on the interval between aspiration and presentation. However, nearly half of all children with FB ingestion may be asymptomatic.

Most inhaled FBs lodge in a mainstem or lobar bronchus, a few find their way into more distal portions of the lung field, and the remaining FBs lodge in the trachea. Laryngotracheal obstruction most commonly causes dyspnea, cough, stridor, and hoarseness because of decreased air entry. Cyanosis may occur if the obstruction becomes worse. Bronchial obstruction usually produces cough (frequently paroxysmal), wheezing, asymmetric breath sounds, decreased airway entry, and dyspnea. When an object is lodged in the larynx, the child is unable to speak or breathe. Nasal FBs often manifest by unilateral purulent drainage that does not improve with time.

If the obstruction progresses, the child's face may become livid, and if the obstruction is total, the child may become unconscious and die of asphyxiation. If obstruction is partial, hours, days, or even weeks may pass without symptoms after the initial period. Secondary symptoms are related to the anatomic area in which the FB is lodged and are usually caused by a persistent respiratory tract infection located distal to the obstruction. FB aspiration should also be suspected in the presence of acute or chronic pulmonary lesions. Often by the time secondary symptoms appear, the parents have forgotten the initial episode of coughing and gagging. The most common symptoms observed in children brought to medical attention are stridor, wheezing, sternal retraction, and cough.

DIAGNOSTIC EVALUATION

The diagnosis of FB obstruction is usually suspected based on the history and physical signs. Radiographic examination reveals opaque FBs but is of limited value in localizing vegetable matter and some plastic items. Bronchoscopy is required for a definitive diagnosis of objects in the larynx and trachea. Fluoroscopic examination is valuable in detecting FBs in the bronchi. The mainstay of diagnosis and management of FBs is endoscopy and bronchoscopy. If there is doubt about the presence of an FB, endoscopy can be diagnostic and therapeutic.

THERAPEUTIC MANAGEMENT

FB aspiration may result in life-threatening airway obstruction, especially in infants because of the small diameters of their airways. Current recommendations for the emergency treatment of the choking child include the use of abdominal thrusts for children older than 1 year of age and back blows and chest thrusts for children younger than 1 year old. An FB is rarely coughed up spontaneously; therefore it must be removed by endoscopy or bronchoscopy. This procedure usually requires sedation with an agent (such as IV propofol or midazolam) and is carried out as quickly as possible because the progressive local inflammatory process triggered by the FB hampers removal. A chemical pneumonia soon develops, and vegetable matter begins to macerate within a few days, making it even more difficult to remove. After removal of the FB, the child is usually observed for any complications such as laryngeal edema and then discharged home within a matter of hours if vital signs are stable and recovery is satisfactory.

NURSING CARE MANAGEMENT

A major role of nurses is to recognize the signs of FB aspiration and implement immediate measures to relieve the obstruction. Choking on food or other material should not be fatal. To aid a child who is choking, nurses must recognize the signs of distress. Back blows or abdominal thrusts performed by both health professionals and properly instructed lay persons can save lives.

However, not every child who gags or coughs while eating is truly choking.

! NURSING ALERT

The child in severe distress (1) cannot speak, (2) becomes cyanotic, and (3) collapses. These three signs indicate that the child is truly choking and requires immediate action. The child can die within 4 minutes. Follow-up care after the foreign body (FB) is removed includes monitoring for respiratory distress and educating the parents.

Prevention

Nurses are able to teach prevention in a variety of settings. They can educate parents singly or in groups about the hazards of aspiration in relation to the developmental level of their children and encourage them to teach their children safety. Caution parents about behaviors that their children might imitate (e.g., holding FBs such as pins, nails, and toothpicks between their lips or in the mouth). (Prevention based on the child's age is discussed in Chapters 9 and 11.) Educate parents on age-appropriate toys and how older siblings' toys could be hazardous for younger siblings.

ASPIRATION PNEUMONIA

Aspiration pneumonia occurs when food, secretions, vomitus, medications, inert materials, volatile compounds, hydrocarbons (e.g., kerosene, gasoline, solvents, lighter fluid, furniture polish, mineral oil), or liquids enter the lung and cause inflammation and a chemical pneumonitis. Aspiration of fluid or food is particularly hazardous in the child who has difficulty with swallowing or is unable to swallow because of paralysis, weakness, debility, congenital anomalies, or absent cough reflex or in the child who is force-fed, especially while crying or breathing rapidly.

Clinical signs of the aspiration of oral secretions may not be distinguishable from those of other forms of acute bacterial pneumonia. For example, if vegetable matter has been aspirated, manifestations may not appear for several weeks after the event. Classic symptoms include an increasing cough or fever with foul-smelling sputum, and other signs of lower airway involvement. Aspiration of objects typically manifest with varying degrees of cyanosis, tachycardia, tachypnea, nasal flaring, retractions, grunting, cough, wheezes, and crackles, and fever may appear within 30 minutes or be delayed for a few hours. Rarely, aspiration causes immediate death from asphyxia; more often, the irritated mucous membrane becomes a site for secondary bacterial infection. However, the severity of the lung injury depends on the pH of the aspirated material, presence of bacteria, and volatility and viscosity of the substance. Endotracheal intubation may be required if the child develops respiratory failure. Severe injury causes hemoptysis, pulmonary edema, severe cyanosis, and death within 24 hours of aspiration.

Nursing Care Management

Care of the child with aspiration pneumonia is the same as that described for the child with pneumonia from other causes. Treatment is the same as for any lower respiratory tract inflammation and consists of high humidity, supplemental oxygen, hydration, and treatment of any secondary infection. However, the major focus of nursing care is on prevention of aspiration. Proper feeding techniques should be carried out for weak, debilitated, and uncooperative children, and measures should be taken to prevent aspiration of any material that might enter the nasopharynx. Feeding tubes should be checked for correct placement before the initiation of enteral feedings, flushes, or medication administration. The child should be maintained with the head elevated during feeding and for 30 minutes after if possible. The presence of an NG feeding tube or a history of gastroesophageal reflux disease places the child at risk of aspiration. Other risk factors include decreased gastrointestinal (GI) motility, ineffective cough, poor gag reflex, impaired swallow, high gastric residual, and trauma or surgery to the neck, face, or mouth.

Children who are at risk for swallowing difficulties as a result of illness, physical debilitation, anesthesia, or sedation are kept on nothing by mouth (NPO) status until they can properly swallow fluids effectively. An evaluation by an occupational or speech therapist may be indicated to assess the child's ability to swallow effectively. The child who is at risk for vomiting and incapable of protecting the airway should be positioned in a side-lying recovery position (see Fig. 21.20). Educating parents on the prevention of aspiration pneumonia is important.

PULMONARY EDEMA

Pulmonary edema (PE) is the movement of excess fluid into the alveoli and interstitium of the lungs caused by extravasation from the pulmonary vasculature (Woods & Mazor, 2020). The two main types of PE are cardiogenic and noncardiogenic.

Cardiogenic (hydrostatic, hemodynamic) PE is caused by an increase in pulmonary capillary pressure because of an increase in pulmonary venous pressure. It can be caused by excessive IV fluid administration, renal failure, left ventricular failure, heart valve disorder (aortic regurgitation, aortic stenosis, mitral regurgitation), myocardial ischemia, myocarditis, acute tachydysrhythmia, or coronary artery disease (Powell, Graham, O'Reilly, et al., 2016). Noncardiogenic PE is caused by various conditions that result in increased pulmonary capillary permeability. Some subtypes of noncardiogenic PE include permeability PE (caused by acute respiratory distress syndrome [ARDS] or acute lung injury [ALI]), high-altitude PE (caused by rapid ascension to heights above 12,000 feet), or neurogenic PE (after CNS insult such as seizures, head injury, or cerebral hemorrhage). Some less common forms of PE are reperfusion PE (after removal of thromboemboli from the lung or a lung transplant), reexpansion PE (caused by rapid reexpansion of a collapsed lung), or PE that results from opiate overdose (e.g., methadone or heroin), salicylate toxicity (chronic), aspiration (FB inhalation), inhalation injuries, near drowning, pulmonary embolism, viral infections, or pulmonary veno-occlusive disease. Other causes include aspiration, traumatic injury, organ dysfunction caused by sepsis, multiorgan failure, alcoholism or substance abuse, pregnancy (eclampsia), chronic renal impairment, malnutrition, hypertension, or a blood transfusion (transfusion-related ALI).

Pathophysiology

Fluid flows from the pulmonary vasculature into the alveolar interstitial space and then returns to the systemic circulation in a normal lung. Movement of this fluid is controlled by the net difference between hydrostatic and osmotic pressures and the permeability of the capillary membrane (Woods & Mazor, 2020). Increased pulmonary hydrostatic pressure or increased permeability of the vascular membrane results in movement of fluid into the alveoli and interstitium of the lung. The pulmonary lymph system normally drains away any fluid from the alveoli, but when the amount of fluid present in the alveoli exceeds lymph drainage, PE occurs.

Symptoms include extreme shortness of breath, cyanosis, tachypnea, diminished breath sounds, anxiety, agitation, confusion, diaphoresis, orthopnea, respiratory crackles, expiratory wheezing (in young infants), heart murmur, third heart sound (S_3) gallop, cool peripheries, jugular venous distention, nocturnal dyspnea, cough, pink frothy sputum (if severe), tachycardia, hypertension, and hypotension (if caused by left ventricle dysfunction).

Therapeutic Management

Management of PE depends on the cause but can include oxygen therapy, positive end-expiratory pressure (PEEP) via CPAP, and intubation with ventilatory support if respiratory failure occurs. If ventricular failure is the cause, medications such as diuretics, digoxin, positive inotropes, and vasodilators (nitroglycerin) may be started, and the child may be placed on fluid and sodium restriction. Morphine may be

prescribed to relieve dyspnea. The primary goal of management is to determine why PE occurred and treat the underlying condition.

Nursing Care Management

Nursing care of the child with PE is similar to that for any other acute respiratory condition. Pulse oximetry is monitored, and vital signs are observed closely for any deterioration. The nurse should note changes in oxygen saturation (SaO_2), end-tidal carbon dioxide ($ETCO_2$), and arterial blood gas (ABG) values. An ongoing assessment of the child's cardiopulmonary status is needed by checking lung sounds and observing respiratory rate, rhythm, depth, and effort. Oxygen, medications, and other respiratory treatments are administered as prescribed. Close monitoring of intake and output, electrolytes, and comfort are important. The child should be monitored for restlessness, anxiety, and air hunger. Placing the child in a high Fowler position may help with lung expansion. Because this position places pressure on bony prominences in the sacrum and hips, pressure areas must be relieved at intervals. Most of the care of PE occurs in the ICU, which is anxiety provoking for the child and family. They should be given the opportunity to express their fears and anxieties and to ask questions. (For other nursing care activities, see the Acute Respiratory Distress Syndrome section.)

ACUTE RESPIRATORY DISTRESS SYNDROME AND ACUTE LUNG INJURY

Acute respiratory distress syndrome (ARDS) and *acute lung injury* (ALI) are potentially life-threatening inflammatory lung conditions that may occur in children and adults. They are caused by direct injury to the lungs or by systemic insults that lead indirectly to lung injury with subsequent hypoxemia and respiratory failure due to noncardiogenic PE. Sepsis, trauma, viral pneumonia, aspiration, fat emboli, drug overdose, reperfusion injury after lung transplantation, smoke inhalation, and submersion injury, among others, have been associated with ARDS and ALI. Both are characterized by respiratory distress and hypoxemia that occur within 72 hours of a serious injury or surgery in a person with previously normal lungs. ALI involves a spectrum of inflammatory disease responses to a precipitating event, with ARDS being the more severe form of ALI.

The diagnostic criteria established by the American European Consensus Conference (Bernard, Artigas, Brigham, et al., 1994) have been superseded by the Berlin definition of ARDS (ARDS Definition Task Force, Ranieri, Rubenfeld, et al., 2012). According to the Berlin definition, ARDS occurs within 1 week of a known clinical insult or new or worsening respiratory symptoms; is characterized by bilateral opacities on chest imaging not fully explained by effusions, lobar or lung collapse, or nodules; and manifests as respiratory failure not fully explained by cardiac failure or fluid overload (ARDS Definition Task Force et al., 2012). Hypoxemia is expressed in terms of the ratio of partial pressure of oxygen (PaO_2) to the fraction of inspired oxygen (FiO_2) (P/F ratio). In the setting of a PEEP or CPAP of 5 cm H_2O or greater, mild, moderate, and severe ARDS are defined by P/F ratios between 200 and 300, between 100 and 200, and 100 mm Hg or lower, respectively. In 2015 the Pediatric Acute Lung Injury Consensus Conference Group published pediatric-specific definitions, recommendations regarding treatment, and future research priorities.

Pathologically, the hallmark of ARDS is increased permeability of the alveolar-capillary membrane that results in PE. During the acute phase of ARDS, inflammatory mediators cause damage to the alveolar-capillary membrane, with an increasing pulmonary capillary permeability with resulting interstitial edema. Later stages are characterized by pneumocyte and fibrin infiltration of the alveoli, with the start of either the healing process or fibrosis. In ARDS, the lungs become stiff as a result of surfactant inactivation; gas diffusion is impaired; and eventually, bronchiolar mucosal swelling and congestive atelectasis occur. The net effect is decreased functional residual capacity, pulmonary hypertension, and increased intrapulmonary right-to-left shunting of blood. Surfactant secretion is reduced, and the atelectasis and fluid-filled alveoli provide an excellent medium for bacterial growth. Hypoxemia or increased work of breathing may require ventilatory support.

The child with ARDS may first demonstrate only symptoms caused by an injury or infection, but as the condition deteriorates, hyperventilation, tachypnea, increasing respiratory effort, cyanosis, and decreasing oxygen saturation occur. The hypoxemia may be refractory to oxygen administration.

Treatment involves supportive measures to ensure adequate oxygenation and pulmonary perfusion; treatment of infection (or the precipitating cause); and maintenance of adequate cardiac output and vascular volume, hydration, adequate nutritional support, comfort measures, prevention of complications such as GI ulceration and aspiration, and psychologic support. Specific treatment should be directed at the underlying cause (e.g., antibiotics, source control for infection). Many patients require mechanical ventilatory support. The goal of mechanical ventilation in patients with ARDS is to rest the respiratory muscles and maintain adequate gas exchange while mitigating the deleterious effects of ventilator-induced lung injury (Fan, Brodie, & Slutsky, 2018). This is usually achieved invasively (e.g., with endotracheal intubation), but occasionally noninvasive ventilation is used in milder cases. Patients requiring invasive mechanical ventilation usually require sedation, at least initially, to allow for ventilatory synchrony. Fluid administration to maintain adequate intravascular volume and end-organ perfusion must be balanced against the desire to decrease lung fluid to improve oxygenation. The provision of adequate nutrition, maintenance of patient comfort, and prevention of complications (such as GI ulceration) are essential. Psychologic support of the patient and family is also important.
