Definitive therapy is directed toward improvement of oxygenation. The use of endotracheal intubation, PEEP, and low tidal volume may be required to ensure maximum oxygen delivery by increasing functional residual capacity, reducing intrapulmonary shunting, and reducing pulmonary fluid. Inappropriate use of mechanical ventilation may worsen the lung injury by causing volutrauma, barotrauma, atelectrauma, and biotrauma to the injured lungs. Ventilation with low tidal volumes (6 ml/kg ideal body weight) has been associated with lower mortality rates in children with ALI (Wong, Jit, Sultana, et al., 2017). Other supportive strategies include use of the prone position, pharmacologic neuromuscular blockade to facilitate ventilation, administration of inhaled nitric oxide or prostaglandins, and high-frequency oscillatory ventilation. The evidence to support these therapies is variable and evolving. Extracorporeal membrane oxygenation (ECMO) should be considered in cases of severe ARDS when the cause of respiratory failure is believed to be reversible or if the child is likely to be suitable for consideration for lung transplantation (Pediatric Acute Lung Injury Consensus Conference Group, 2015).

Prognosis

The prognosis for patients with ARDS is improving. Nonetheless, the mortality rate remains high and ranges from 14% to 45% in children (Lopez-Fernandez, Azagra, de la Oliva, et al., 2012). The precipitating disorder influences the outcome; the worst prognosis is associated with profound hypoxemia, uncontrolled sepsis, bone marrow transplantation, cancer, and multisystem involvement with hepatic failure.

Children who recover may have persistent cough, exertional dyspnea, and pulmonary function test abnormalities.

Nursing Care Management

The child with ARDS is cared for in the ICU during the acute stages of illness. Nursing care involves close monitoring of oxygenation and respiratory status, cardiac output, perfusion, fluid and electrolyte balance, and renal function (urinary output). Blood gas analysis, acid-base status, and pulse oximetry are important evaluation tools. Most children with ARDS require invasive monitoring with arterial and central venous catheters. Diuretics may be administered to reduce pulmonary fluid, and vasodilators may be administered to decrease pulmonary vascular pressure. Nutritional support is often required because of the prolonged acute phase of the illness. Nursing management also includes monitoring the effects of the numerous parenteral fluids and drugs used to stabilize the child and monitoring for changes in the child's hemodynamic status. To prevent superimposed ventilator-associated pneumonia (VAP), nursing care includes elevation of the head of the bed to between 30 and 35 degrees (crib at 20 degrees) unless contraindicated. Additional strategies to prevent VAP include use of a closed suctioning system, removal of oropharyngeal secretions, and draining breathing circuit condensate periodically. The risk of pressure ulcers is greater with the head of the bed in an elevated position, and this must be balanced with the risk of VAP. Nursing should perform frequent oral care at least every 4 hours with ongoing observation of skin for pressure areas. The multidisciplinary care team performs a daily assessment of readiness to wean or liberate from mechanical ventilation. The child must also be assessed for risk of deep vein thrombosis, and appropriate prophylactic strategies must be initiated (e.g., passive range-of-motion exercises as able, sequential compression devices, anticoagulant therapy, early ambulation). Respiratory distress is a frightening situation for both the child and the parents, and attention to their psychologic needs is a major element in the care of these children. The child is often sedated during the acute phase of the illness, and weaning from sedation requires close monitoring and interventions to promote comfort.

SMOKE INHALATION INJURY

A number of noxious substances that may be inhaled are toxic to humans. They are primarily products of incomplete combustion and cause more deaths from fires than flame injuries. The severity of the injury depends on the nature of the substances generated by the material burned, whether the victim is confined in a closed space, and the duration of contact with the smoke.

Three distinct syndromes of pulmonary complications may occur in children suffering from inhalation injury: (1) early carbon monoxide (CO) poisoning, airway obstruction, and pulmonary edema; (2) ARDS occurring at 24 to 48 hours or later in some cases; and (3) late complications of pneumonia and pulmonary emboli (Antoon, 2020). Smoke inhalation causes three types of injury: heat, chemical, and systemic.

Heat injury causes thermal damage to the upper airway, but because air has low specific heat, the injury goes no farther than the upper airway. Reflex closure of the glottis prevents injury to the lower airway. Heat may reach the middle airway occasionally, but it rarely penetrates to the lungs.

Chemical injury involves gases that may be generated during the combustion of materials, such as clothing, furniture, and floor coverings. Acids, alkalis, and their precursors in smoke can produce chemical burns. These substances can be carried deep into the respiratory tract, including the lower respiratory tract, in the form of insoluble gases. Soluble gases tend to dissolve in the upper respiratory tract. Heated plastics are the source of extremely toxic vapors, including chlorine and hydrochloric acid from polyvinylchloride and hydrocarbons, aldehydes, ketones, and acids from polyethylene. Irritant gases such as nitrous oxide or carbon dioxide combine with water in the lungs to form corrosive acids. Chemical burns to the airways are similar to burns on the skin, except they are painless because the tracheobronchial tree is relatively insensitive to pain.

Inhalation of small amounts of noxious irritants produces alveolar and bronchiolar damage that can lead to obstructive bronchiolitis. Severe exposure causes further injury, including alveolar-capillary damage with hemorrhage, necrotizing bronchiolitis, inhibited secretion of surfactant, and formation of hyaline membranes, which are all manifestations of ARDS.

Systemic injury occurs from gases that are nontoxic to the airways (e.g., CO, hydrogen cyanide). However, these gases cause injury and death by interfering with or inhibiting cellular respiration. CO is responsible for more than half of all fatal inhalation poisonings in the United States. CO is a colorless, odorless, tasteless gas with an affinity for hemoglobin 230 times greater than that of oxygen. When CO enters the bloodstream, it binds readily with hemoglobin to form carboxyhemoglobin (COHb). Because CO is released less readily than oxygen, tissue hypoxia reaches dangerous levels before oxygen is available to meet tissue needs.

! NURSING ALERT

With carbon monoxide (CO) poisoning, the oxygen saturation (SaO_2) obtained by pulse oximetry will be normal because the device measures only oxygenated and deoxygenated hemoglobin; it does not measure dysfunctional hemoglobin, such as carboxyhemoglobin (COHb).

Accidental CO poisoning is most often a result of exposure to fumes of heaters or smoke from structural fires, although poorly ventilated recreational vehicles with improperly operated or maintained gas lamps or stoves and cooking in underventilated areas with charcoal grills are also frequent causes. CO is produced by incomplete combustion of carbon or carbonaceous material, such as wood or charcoal. CO poisoning can also occur in a running vehicle parked in a closed garage for a long period or in a vehicle with inadequate vented exhaust that leaks into the vehicle's passenger (or closed truck bed) compartment.

The signs and symptoms of CO poisoning are secondary to tissue hypoxia and vary with the level of COHb. Mild manifestations include headache, visual disturbances, irritability, and nausea, whereas more severe intoxication causes confusion, hallucinations, ataxia, and coma. CO may increase cerebral blood flow, increase cerebral capillary permeability, and increase cerebrospinal fluid pressure, all of which contribute to CNS signs. The bright, cherry red lips and skin often described are less common than pallor and cyanosis. Patients who have significant exposure to CO can develop a delayed neurologic deficit, which can occur 3 to 240 days after initial exposure. The deficits can last up to 1 year.

Therapeutic Management

Treatment of children with smoke inhalation injury is largely symptomatic. The most widely accepted treatment is placing the child on humidified 100% oxygen as quickly as possible to rapidly reverse tissue hypoxia and to displace CO and cyanide from protein-binding sites. The child is monitored for signs of respiratory distress and impending failure. A laryngoscopy or bronchoscopy evaluation may be done to assess for airway damage. Baseline ABGs and COHb levels are obtained. PaO_2 may be within normal limits unless there is marked

respiratory depression. If CO poisoning is confirmed, 100% oxygen is continued until COHb levels fall to the nontoxic range of about 10%. If CO poisoning is severe, the patient may benefit from hyperbaric oxygen therapy. Hyperbaric oxygen therapy may be useful in the treatment of neurologic complications related to CO poisoning. In a hyperbaric oxygen therapy chamber, the air pressure is increased to three times higher than normal air pressure and so lungs can gather more oxygen than would be possible breathing pure oxygen at normal air pressure. Hyperbaric oxygen therapy significantly decreases the half-life of COHb compared with 100% oxygen treatment alone. Pulmonary care may be facilitated by bronchodilators, inhaled corticosteroids, humidification, and CPT to enhance the removal of necrotic material, minimize bronchoconstriction, and avoid atelectasis. Bronchoscopy may be needed to clear heavy secretions.

Respiratory distress may occur early in the course of smoke inhalation as a result of hypoxia, or patients who are breathing well on admission may suddenly develop respiratory distress. Therefore endotracheal intubation equipment should be readily available. Transient edema of the airways can occur at any level in the tracheobronchial tree. Assessment and localization of the obstruction should be accomplished before severe swelling of the head, neck, or oropharynx occurs. Intubation is often necessary when (1) severe burns in the area of the nose, mouth, and face increase the likelihood of developing oropharyngeal edema and obstruction; (2) vocal cord edema causes obstruction; (3) the patient has difficulty handling secretions; and (4) progressive respiratory distress requires artificial ventilation. Controversy surrounds tracheostomy, but many prefer this procedure when the obstruction is proximal to the larynx and reserve nasotracheal intubation for lower tract involvement.

Nursing Care Management

Nursing care of the child with inhalation injury is the same as that for any child with respiratory distress. The initial goal is to maintain a patent airway and effective ventilation status; endotracheal intubation may be required early, depending on the patient's respiratory status and the progression of airway and pulmonary edema. In the acute phase, the nurse should monitor vital signs, oxygenation, work of breathing, and other respiratory assessments frequently. The administration of nebulized bronchodilators, humidified oxygen, and inhaled corticosteroids is often part of the nursing care. Chest percussion and postural drainage are often required. Fluid requirements for children experiencing inhalation injury are greater than for those with surface burns alone, and IV fluids are generally prescribed. However, one concern is the development of pulmonary edema; therefore accurate monitoring of fluid intake and output is essential.

In addition to observation and management of the physical aspects of inhalation injury, the nurse also deals with the psychologic needs of a frightened child and distraught parents. Parents need support, reassurance, and information regarding the child's condition, treatment, and progress. The nurse can provide anticipatory guidance and educate families on prevention of inhalation injuries and the importance of CO detectors in the home.

ENVIRONMENTAL TOBACCO SMOKE EXPOSURE

Numerous investigations indicate that parental or family smoking is an important cause of morbidity in children. Children exposed to passive or environmental tobacco smoke have an increased number of respiratory illnesses, increased respiratory symptoms (i.e., cough, sputum, and wheezing), and reduced performance on pulmonary function tests (PFTs). AOM and OME are also increased in children who have smoking family members. Indoor exposure to tobacco smoke has been linked to asthma in children (Makadia, Roper, Andrews, et al., 2017). Among children with asthma, there is an association between parental or family member cigarette smoking and asthma exacerbations, trips to the ED, medication use, and impaired recovery after hospitalization for acute asthma. Maternal cigarette smoking is associated with increased respiratory symptoms and illnesses in children; decreased fetal growth; increased deliveries of low birth weight, preterm, and stillborn infants; and a greater incidence of sudden infant death syndrome (SIDS). Antenatal maternal smoking has emerged as a significant risk factor for SIDS (Friedmann, Dahdouh, Kugler, et al., 2017). The risk for diagnosis of early-onset asthma in the first years of life is associated with in utero exposure to maternal and paternal smoking (Harju, Keski-Nisula, Georgiadis, et al., 2016). Exposure to tobacco smoke during childhood may also contribute to the development of chronic lung disease in the adult.

Electronic cigarettes (e-cigarettes) have increased in popularity among adolescents and adults. Regular use of electronic cigarettes has increased tenfold among high school students, from 1.5% in 2011 to 16% in 2015 (Chun, Moazed, Calfee, et al., 2017), and 5% of middle school students reported regular use of electronic cigarettes in 2015 (Chun et al., 2017). This increase may be due to adolescents' belief that electronic cigarettes are less harmful and less addictive than cigarettes (Amrock, Lee, & Weitzman, 2016). Although these products are advertised as being safe because they are smokeless, the battery-powered cigarettes still contain nicotine and other chemicals. Recent studies have shown toxic effects on the pulmonary system, including altered airways, increased oxidative stress, interference in lung development, and impaired immune defense against bacterial and viral pathogens (Chun et al., 2017). Electronic cigarettes can also increase the risk for cancer (Canistro, Vivarelli, Cirillo, et al., 2017).

Secondhand smoke consists of passive smoke exposure emitted from a tobacco product. The amount of passive smoke exposure in infants and children is directly related to the number of smokers in a household. Cotinine, a byproduct of nicotine, is considered a valid biochemical marker for smoke exposure. Cotinine levels are increased in children who live in homes with smokers, and these levels increase proportionately with the number of smokers in the home.

In recent years, concern has grown regarding "thirdhand" tobacco exposure—the tobacco toxins that remain in the environment long after the smoker has stopped smoking (Jacob, Benowitz, Destaillats, et al., 2017; Samet, Chanson, & Wipfli, 2015). Thirdhand smoke has been defined as "the four Rs": tobacco chemicals (some toxic) that remain, react, re-emit, and/or are resuspended long after active smoking ends and found in such objects as cars, walls, carpet, furniture, clothing, skin, and hair (Drehmer, Walters, Nabi-Burza, et al, 2017). Reviewed evidence-based research supported advocating for environments free of thirdhand smoke contamination for families and children, therefore it is important to educate and counsel families regarding the harm thirdhand smoke poses to children (Drehmer, Walters, Nabi-Burza, et al, 2017).

Nursing Care Management

Nurses should provide information about the hazards of environmental smoke exposure in all interactions with children and their family members. Nurses and other health care professionals need to include assessments of passive smoke exposure in all children, especially those with respiratory illnesses. In families where smokers refuse to quit, house rules should be established for reducing smoke in the child's environment, such as smoking outside of the home, wearing removable clothing while smoking, and not smoking in vehicles (see Family-Centered Care box). Nurses should set an example for children and families and become advocates for "no smoking" ordinances in public

places, prohibition of advertising tobacco products in the media, and inclusion of health warnings of sidestream smoke on tobacco products.[a] Nurses have an important role in offering parents smoking cessation education resources such as counseling and classes. Adolescents should be screened for inhalation of tobacco products or marijuana with counseling on cessation offered.

FAMILY-CENTERED CARE

Decreasing Childhood Exposure to Environmental Tobacco Smoke

- Do not smoke around infants and children.
- Maintain a smoke-free home. Do not allow visitors to smoke in the home.
- Restrict smoking to outside the house where children do not play.
- Encourage exclusive breastfeeding for the first 6 months.
- Change clothing after smoking and before holding an infant in proximity. Suggest wearing a removable outer garment for smoking that is removed on return to the house or when in contact with the child.
- Do not smoke in motor vehicles with children.

LONG-TERM RESPIRATORY DYSFUNCTION

ASTHMA

Asthma is a chronic inflammatory disorder of the airways characterized by recurring symptoms, airway obstruction, and bronchial hyperresponsiveness (Pinfield, Gaskin, Bentley, et al., 2015; Trent, Zimbro, & Rutledge, 2015). Asthma is the most common chronic disease of childhood, the primary cause of school absences, and the third-leading cause of hospitalizations in children under the age of 15 years. More than 25 million people are known to have asthma, and about 7 million of them are children (National Heart, Lung, and Blood Institute, 2014). Although the onset of asthma may occur at any age, 80% to 90% of children have their first symptoms before 4 or 5 years old.

The asthma episodes are associated with airflow limitation or obstruction that is reversible either spontaneously or with treatment. Inflammation causes an increase in bronchial hyperresponsiveness to a variety of stimuli (Liu, Spahn, & Sicherer, 2020). In susceptible children, inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, especially at night or in the early morning. Recognition of the key role of inflammation has made the use of antiinflammatory agents, especially inhaled steroids, a major component in the treatment of asthma.

Asthma is classified into four categories based on the symptom indicators of disease severity. These categories are intermittent, mild persistent, moderate persistent, and severe persistent. Symptoms increase in frequency or intensity until the last category of severe persistent asthma (Box 21.14). These categories provide a stepwise approach to the pharmacologic management, environmental control, and educational interventions needed for each category. For example, if control of asthma is not maintained at one level or step, pharmacologic therapy for the next step up should be considered. If control is adequate at one step, a gradual stepwise reduction in therapy may be possible. The stepwise approach is a guide to assist clinical decision making. In addition to pharmacologic management, environmental control and educational interventions are essential at each step (Liu et al., 2020). These categories emphasize the multifaceted aspect of the disease for consideration of effects on present quality of life and functional capacity and the future risk of adverse events.

Asthma prevalence, morbidity, and mortality are increasing in the United States and may result from worsening air pollution, more premature infants with chronic lung disease, poor access to medical care, underdiagnosis, and undertreatment.

BOX 21.14 Asthma Severity Classification in Children[a]

Step 5 or 6: Severe Persistent Asthma
Continual symptoms throughout the day
Frequent nighttime symptoms (greater (>) than 1 time/week ages 0 to 4 and 7 nights/week, ages 5 and older)
Pulmonary expiratory flow (PEF): less (<) than 60%
Forced expiratory volume in 1 second (FEV1): <75% of predicted value
Interference with normal activity: Extremely limited
Use of short-acting β-agonist for symptom control: Several times a day

Step 3 or 4: Moderate Persistent Asthma
Daily symptoms
Nighttime symptoms: Three to four times a month (0 to 4 years old), >1/week but not nightly (5 to 11 years old)
PEF: 60% to 80% of predicted value (ages 5 and older)
FEV1: 75% to 80% (ages 5 and older)
PEF variability: >30%
Interference with normal activity: Some limitation
Use of short-acting β-agonist for symptom control: Daily

Step 2: Mild Persistent Asthma
Symptoms >2 times/week but <1 time/day
Nighttime symptoms: One to two times a month (0 to 4 years old), three or four times a month (5 to 11 years old)
PEF or FEV1: greater or equal (≥) 80% of predicted value
PEF variability: 20% to 30%
Interference with normal activity: Minor limitation
Use of short-acting β-agonist for symptom control: >2 days/week but not daily

Step 1: Intermittent Asthma
Symptoms ≤2 days/week
Nighttime symptoms (awakenings): None (0 to 4 years old); ≤2 nights per month (5 to 11 years old)
PEF or FEV1: ≥80% of predicted value
PEF variability: <20%
Interference with normal activity: None
Use of short-acting β-agonist for symptom control: <2 days/week

[a]The presence of one clinical feature of severity is sufficient to place a patient in that category. An individual should be assigned to the most severe grade in which any feature occurs. The characteristics in this table are general and may overlap because asthma is highly variable. An individual's classification may change over time. Risk factors for each category are not presented in this table. See original reference for additional classification data. Asthma treatment should not be based on this table.

ETIOLOGY

Studies of children with asthma indicate that allergies influence both the persistence and the severity of the disease. In fact, atopy, or the genetic predisposition for the development of an immunoglobulin E (IgE)–mediated response to common aeroallergens, is the strongest identifiable predisposing factor for developing asthma (Pinfield et al., 2015). Although allergens play an important role in asthma, 20% to 40% of children with asthma have no evidence of allergic disease. In addition to allergens, other substances and conditions can serve as triggers that may exacerbate asthma (Box 21.15). Evidence shows that viral respiratory infections, including RSV infection, may also have a significant role in the development and expression of asthma (Knudson & Varga, 2015; National Heart, Lung, and Blood Institute, 2014).

Risk factors for asthma include the following:

- Atopy (includes a history of allergies or atopic dermatitis)
- Heredity (e.g., parent or sibling with asthma)
- Gender (boys are affected more frequently than girls until adolescence, when the trend reverses)
- Smoking or exposure to secondhand smoke
- Maternal smoking during pregnancy
- Ethnicity (African Americans at greatest risk)
- Low birth weight
- Being overweight

BOX 21.15 Triggers Tending to Precipitate or Aggravate Asthma Exacerbations

- Allergens
  - Outdoor: Trees, shrubs, weeds, grasses, molds, pollens, air pollution, spores
  - Indoor: Dust or dust mites, mold, cockroach antigen
- Irritants: Tobacco smoke, wood smoke, odors, sprays
- Exposure to occupational chemicals
- Exercise
- Cold air
- Changes in weather or temperature
- Environmental change: Moving to new home, starting new school
- Colds and infections
- Animals: Cats, dogs, rodents, horses
- Medications: Aspirin, nonsteroidal antiinflammatory drugs, antibiotics, beta-blockers
- Strong emotions: Fear, anger, laughing, crying
- Conditions: Gastroesophageal reflux, tracheoesophageal fistula
- Food additives: Sulfite preservatives
- Foods: Nuts, milk or other dairy products
- Endocrine factors: Menses, pregnancy, thyroid disease

PATHOPHYSIOLOGY

There is general agreement that inflammation contributes to heightened airway reactivity in asthma. It is unlikely that asthma is caused by either a single cell or a single inflammatory mediator. Rather, it appears that asthma results from complex interactions among inflammatory cells, mediators, and the cells and tissues present in the airways (Liu et al., 2020). However, recognition of the importance of inflammation has made the use of antiinflammatory agents, such as steroids, a key component of asthma therapy.

Another important component of asthma is bronchospasm and obstruction. The mechanisms responsible for the obstructive symptoms in asthma include inflammatory response to stimuli; airway edema and accumulation and secretion of mucus; spasm of the smooth muscle of the bronchi and bronchioles, which decreases the caliber of the bronchioles; and airway remodeling, which causes permanent cellular changes (Pinfield et al., 2015) (Fig. 21.7).

Airflow is determined by the size of the airway lumen, degree of bronchial wall edema, mucus production, smooth muscle contraction, and muscle hypertrophy. Bronchial constriction is a normal reaction to foreign stimuli, but in the child with asthma, it is abnormally severe, producing impaired respiratory function. The smooth muscle arranged in spiral bundles around the airway causes narrowing and shortening of the airway, which significantly increases airway resistance to airflow. Because the bronchi normally dilate and elongate during inspiration and contract and shorten on expiration, the respiratory difficulty is more pronounced during the expiratory phase of respiration.

Increased resistance in the airway causes forced expiration through the narrowed lumen. The volume of air trapped in the lungs increases as airways are functionally closed at a point between the alveoli and the lobar bronchi. This trapping of gas forces the individual to breathe at

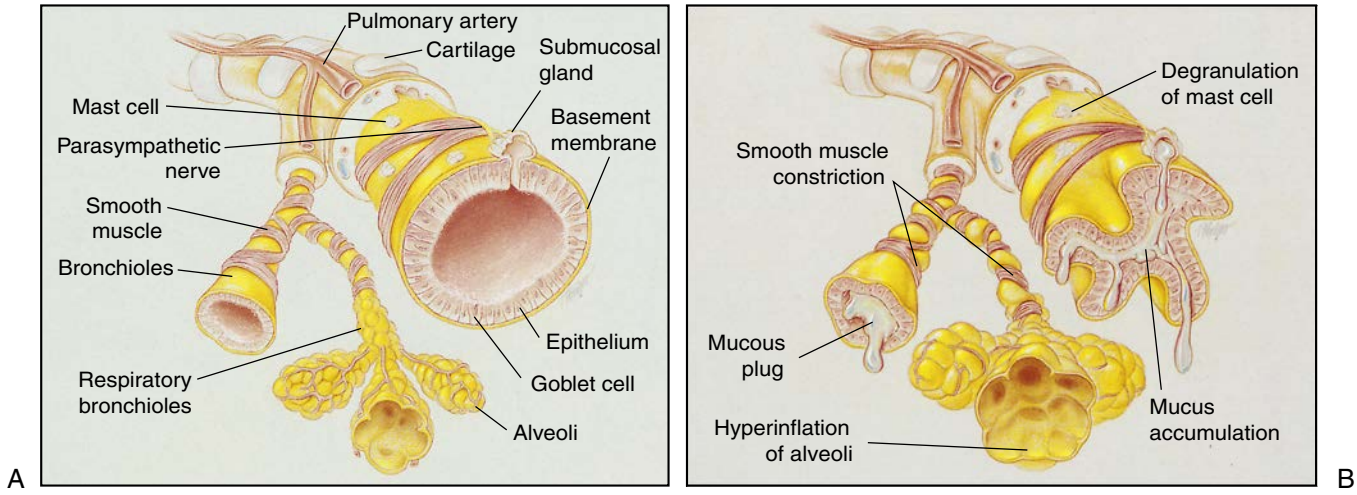

Fig. 21.7 Airway obstruction caused by asthma. **A,** A normal lung. **B,** Bronchial asthma: Thick mucus, mucosal edema, and smooth muscle spasm causing obstruction of small airways; breathing becomes labored, and expiration is difficult. (Modified from Des Jardins, T., & Burton, G. G. [1995]. *Clinical manifestations and assessment of respiratory disease* [3rd ed.]. St Louis, MO: Mosby.)

higher and higher lung volumes. Consequently, the person with asthma fights to inspire sufficient air. This expenditure of effort for breathing causes fatigue, decreased respiratory effectiveness, and increased oxygen consumption. The inspiration occurring at higher lung volumes hyperinflates the alveoli and reduces the effectiveness of the cough. As the severity of obstruction increases, there is a reduced alveolar ventilation with carbon dioxide retention; hypoxemia; respiratory acidosis; and, eventually, respiratory failure. Chronic inflammation may also cause permanent damage (airway remodeling) to airway structures and is difficult to treat successfully with current therapies.

Exacerbations are episodes of progressively worsening shortness of breath, cough, wheezing, chest tightness, or some combination of these changes. A decrease in expiratory airflow is also characteristic. Airways narrow because of bronchospasm, mucosal edema, and mucus plugging, with air being trapped behind occluded or narrowed airways. Functional residual capacity rises because the child is breathing close to total lung capacity; hyperinflation enables the child to keep the airways open and permits gas exchange to occur.

Having an allergy is the strongest epidemiologic risk factor for chronic asthma morbidity and mortality. Many substances in the environment can induce an asthmatic response, but the most significant are those that are antigenic (e.g., that evoke the immune response). The antigen (or foreign substance) is deposited on the respiratory mucosa, where lysozymes immediately digest its outer coating, releasing fragments of foreign protein that initiate the immune sequence. The antibody (immunoglobulin) most active in allergic disorders, including asthma, is IgE, located primarily in skin and mucous membranes and mediating the immediate hypersensitive reaction in the bronchial mucosa.

CLINICAL MANIFESTATIONS

The classic manifestations of asthma are dyspnea, wheezing, and coughing. An attack may develop gradually or appear abruptly and may be preceded by a URI. The age of the child is often a significant factor because the first attack frequently occurs between ages 3 and 8 years, with some children manifesting clinical signs and symptoms in infancy. In infancy, an attack usually follows a respiratory infection. Bronchoconstriction in response to an allergen can have an immediate, histamine type of pattern or a late response with airway hypersensitivity lasting for days, weeks, or months. Some children may experience a prodromal itching at the front of the neck or over the upper part of the back just before an attack, especially if the attack is related to allergies (Box 21.16).

An asthmatic episode usually begins with children feeling uncomfortable or irritable and increasingly restless. They may also complain of having a headache, feeling tired, or feeling tightness in the chest. Respiratory symptoms include a hacking, paroxysmal, irritative, and nonproductive cough caused by bronchial edema. Accumulated secretions, acting as a foreign body, stimulate the cough. As the secretions become more profuse, the cough becomes rattling and productive of frothy, clear, gelatinous sputum. Bronchial spasm and mucosal edema reduce the size of the bronchial lumen, and the bronchi may be occluded by mucous plugs.

Younger children tend to assume the tripod sitting position, whereas older children tend to sit upright with shoulders hunched over, hands on the bed or chair, and arms braced to facilitate the use of accessory muscles of respiration. The child may speak with short, panting, broken phrases. Infants and small children are restless, irritable, and unable to be comforted. If hypoxemia develops, the child may become agitated, confused, and more irritable. Examination of the chest reveals hyperresonance on percussion. Breath sounds are coarse and loud, with sonorous crackles throughout the lung fields.

BOX 21.16 Clinical Manifestations of Asthma

Cough
Hacking, paroxysmal, irritative, and nonproductive
Becomes rattling and productive of frothy, clear, gelatinous sputum

Respiratory-Related Signs
Shortness of breath
Prolonged expiratory phase
Wheezing
May have a malar flush and red ears
Lips deep, dark red color
May progress to cyanosis of nail beds or circumoral cyanosis
Restlessness
Apprehension
Prominent sweating as the attack progresses
Older children sitting upright with shoulders in a hunched-over position, hands on the bed or chair, and arms braced (tripod)
Speaking with short, panting, broken phrases

Chest
Hyperresonance on percussion
Coarse, loud breath sounds
Wheezes throughout the lung fields
Prolonged expiration
Crackles
Generalized inspiratory and expiratory wheezing; increasingly high pitched

With Repeated Episodes
Barrel chest
Elevated shoulders
Use of accessory muscles of respiration
Facial appearance—flattened malar bones, dark circles beneath the eyes, narrow nose, prominent upper teeth

Expiration is prolonged. Coarse rhonchi can be heard, as can generalized inspiratory and expiratory wheezing that becomes more high pitched as obstruction progresses. With minimum obstruction, wheezing may be mild or even absent.

With severe spasm or obstruction, breath sounds and crackles may be inaudible. Cough is ineffective despite repeated hacking maneuvers. This represents a lack of air movement and may be misinterpreted as improvement by unknowing examiners. With repeated asthmatic episodes the thoracic cavity becomes fixed in a hyperaerated state (barrel chest), with a depressed diaphragm, elevated shoulders, and increased use of accessory muscles of respiration.

! NURSING ALERT

Shortness of breath with air movement in the chest restricted to the point of absent breath sounds (silent chest) accompanied by a sudden rise in respiratory rate is an ominous sign indicating ventilatory failure and imminent respiratory arrest.

DIAGNOSTIC EVALUATION

The diagnosis is determined primarily based on clinical manifestations, history, physical examination, and, to a lesser extent, laboratory tests. Generally, chronic cough in the absence of infection or diffuse wheezing during the expiratory phase of respiration is sufficient to establish a diagnosis.

Pulmonary function tests (PFTs) provide an objective method of evaluating the presence and degree of lung disease and the response to therapy. Spirometry can generally be performed reliably on children by 5 or 6 years old and includes either the traditional and simple mechanical spirometer often used in clinics, offices, and the home or new computerized versions. The National Asthma Education and Prevention Program (2007) recommends that spirometry testing be done at the time of initial assessment of asthma, after treatment is initiated and symptoms have stabilized, and at least every 1 to 2 years to assess the maintenance of airway function.

Bronchoprovocation testing (e.g., direct exposure of the mucous membranes to a suspected antigen in increasing concentrations) helps identify inhaled allergens. Exposure to methacholine (methacholine challenge), histamine, or cold or dry air may be performed to assess airway responsiveness or reactivity. Exercise challenges may be used to identify children with exercise-induced bronchospasm (EIB) (Liu et al., 2020). Although these tests are highly specific and sensitive, they place the child at risk for an asthmatic episode and should be done under close observation in a qualified laboratory or clinic.

The peak expiratory flow rate (PEFR) can be measured using a peak expiratory flow meter (PEFM). The PEFR is the maximum flow of air that can be forcefully exhaled in 1 second and is measured in liters per minute. Three zones of measurement, patterned after a traffic light, are typically used to interpret the PEFR. The reliability of the PEFM is controversial because it relies on the child's ability to use the PEFM and willingness to participate. The child's technique on doing the PEFR should be examined on an ongoing basis and reeducation provided when needed. Families are encouraged to record PEFR at regular intervals and to bring the recorded results to the medical appointment for health care providers to review trends. Each child needs to establish his or her personal best value during a 2- to 3-week period when the child's asthma is stable. After the personal best value has been established, the child's current PEFR on any occasion can be compared with the personal best value. PEFR monitoring can be used for short-term monitoring, managing exacerbations, and daily long-term monitoring. However, the PEFM should not be used to diagnose asthma severity. The Expert Panel (National Asthma Education and Prevention Program, 2007) recommends either PEFM or symptom monitoring or a combination of both.

NURSING CARE GUIDELINES

Interpreting Peak Expiratory Flow Rates[a]

- **Green (80% to 100% of personal best)** signals all clear. Asthma is under reasonably good control. No symptoms are present, and the routine treatment plan for maintaining control can be followed.
- **Yellow (50% to 79% of personal best)** signals caution. Asthma is not well controlled. An acute exacerbation may be present. Maintenance therapy may need to be increased. Call the practitioner if the child stays in this zone.
- **Red (<50% of personal best)** signals a medical alert. Severe airway narrowing may be occurring. A short-acting bronchodilator should be administered. Notify the practitioner if the peak expiratory flow rate (PEFR) does not return immediately and stay in yellow or green zones.

[a]These zones are guidelines only. Specific zones and management should be individualized for each child.
Modified from American Lung Association. (2017). Measuring your peak flow rate. Retrieved from http://www.lung.org/lung-health-and-diseases/lung-disease-lookup/asthma/living-with-asthma/managing-asthma/measuring-your-peak-flow-rate.html

A variety of easy-to-use, inexpensive PEFMs are available for use in the home and at school to assess changes in pulmonary function. In general, children 5 years of age and older can use a PEFM successfully. However, young children need to be supervised while they are learning to use the PEFM. Children should use the same PEFM over time, and they should bring it for use at every follow-up visit. Using the same brand of meter is recommended because different brands can give significantly different values. The use of a PEFM provides objective monitoring of the severity of asthma and can decrease asthma episodes, health care visits, and missed school days. Similarly, studies show that PEFM use can improve quality of life and asthma health outcomes in children with asthma (Walter, Sadeque-Igbal, Ulysse, et al., 2015).

Skin testing is useful in identifying specific allergens, and those obtained by the puncture technique correlate better than intracutaneous tests with symptoms and measurements of specific IgE antibody. Since the allergen-specific IgE testing also accurately determines allergic sensitization status to specific allergens, it was selected in a recent study instead of skin testing because of the objectivity of the in vitro test and the lack of the need to discontinue antihistamines (Nagarajan, Ahmad, Quinn, et al., 2018). It is recommended that all patients with year-round asthma symptoms be tested with skin tests or laboratory blood analysis to determine sensitization to perennial allergens (e.g., house dust mites, cats, dogs, cockroaches, molds, and fungus) (Liu et al., 2020; National Heart, Lung, and Blood Institute, 2014; Onell, Whiteman, Nordlund, et al., 2017).

In addition to these tests, other tests include laboratory tests (e.g., complete blood count with differential, allergen-specific IgE) and chest radiographs. Eosinophilia greater than 500/mm^3 suggests the presence of an allergic or inflammatory disorder. Frontal and lateral radiographs may show infiltrates and hyperexpansion of the airways, with the anteroposterior diameter on physical examination indicating an increased diameter (suggestive of barrel chest). Radiography may also assist in ruling out a respiratory tract infection.

THERAPEUTIC MANAGEMENT

The overall goals of asthma management are to maintain normal activity levels, maintain normal pulmonary function, prevent chronic symptoms and recurrent exacerbations, provide optimum drug therapy with minimum or no adverse effects, and assist the child in living as normal and happy a life as possible. This includes facilitating the child's social adjustments in the family, school, and community and normal participation in recreational activities and sports. To accomplish these goals, several treatment principles need to be followed (Pinfield et al., 2015):

- Regular contact with the health care provider is necessary to control symptoms and prevent exacerbations. Registered nurse (RN) care coordinators or case managers can often assist with this and troubleshoot symptoms via phone.
- Prevention of exacerbations includes avoiding triggers, avoiding allergens, and using medications as needed.
- Therapy includes efforts to reduce underlying inflammation and relieve or prevent symptomatic airway narrowing.
- Therapy includes patient and family education, environmental control, pharmacologic management, and the use of objective measures to monitor the severity of disease and guide the course of therapy.

Allergen Control

Nonpharmacologic therapy is aimed at the prevention and reduction of exposure to airborne allergens and irritants. House dust mites and other components of house dust are frequent agents identified in

children who are allergic to inhalants. The cockroach, another common household inhabitant, is an important allergen in many locations. Exterminating live cockroaches, carefully cleaning kitchen floors and cabinets, putting food away after eating, and taking trash out in the evening are essential measures to control cockroaches. Other animal-related allergens include mice (especially in the homes of inner-city children) and cat and dog dander. Sensitized persons should carefully evaluate having such pets in the household, but there are inconclusive data on the effects of cat or dog dander on asthma development (Kanchongkittiphon, Mendell, Gaffin, et al., 2015). Additional sources of respiratory irritants include particulate matter produced by tobacco smoke, wood-burning stoves, lead, pesticides, mold spores, and nitrogen dioxide; these are believed to contribute to asthma morbidity in children and should be avoided or minimized (Kanchongkittiphon et al., 2015; Liu et al., 2020). Exposure to tobacco smoke is a significant contributing factor in the development and triggering of asthma in infants and children (Makadia et al., 2017; Skaaby, Taylor, Jacobsen, et al., 2017). Living in damp homes also can be a factor in the development of asthma in infants and small children (Kanchongkittiphon et al., 2015).

Skin testing can identify specific allergens. Steps should be taken to eliminate or avoid them. Often simply removing the offending environmental allergens or irritants (e.g., removing carpeting from the home of a child sensitive to mold and dust particles) decreases the frequency of asthma episodes. Dehumidifiers or air conditioners may control nonspecific factors such as extremes of temperature that trigger an episode. Avoiding known outdoor allergens such as tree, grass, and weed pollen during seasonal elevation may reduce asthma exacerbations as well.

Additional suggestions include the following:

- Cover pillows and mattresses with dustproof covers.
- Wash bedding in hot water once a week. Dry completely.
- Avoid using feather- or down-filled pillows and mattresses.
- Keep child indoors while lawn is being mowed, bushes and trees are being trimmed, or pollen count is high.
- Keep windows and doors closed during pollen season; use air conditioner if possible, or go to places that are air conditioned, such as libraries and shopping malls, when the weather is hot.
- The child should not be present during cleaning activities.
- Wet-mop bare floors weekly; wet-dust and clean child's room weekly.
- Vacuum carpet and fabric-covered furniture every week to reduce dust buildup, using a high-efficiency particulate air filter.
- Limit or prevent child's exposure to tobacco and wood smoke; do not allow cigarette smoking in the house or car; select places such as play and shopping areas that are smoke free.
- Use air conditioners with high-efficiency particulate air filters.
- Use indoor air purifiers with high-efficiency particulate air filters.
- Choose stuffed toys that can be washed in hot water. Dry completely before the child plays with the toy

Drug Therapy

Pharmacologic therapy is used to prevent and control asthma symptoms, reduce the frequency and severity of asthma exacerbations, and reverse airflow obstruction. A stepwise approach is recommended based on the severity of the child's asthma. Because inflammation is considered an early and persistent feature of asthma, therapy is directed toward long-term suppression of inflammation. The National Asthma Education and Prevention Program (2012) highlights that asthma control has two domains:

- Reducing impairment (associated with the frequency and intensity of symptoms and functional limitations experienced by the patient)
- Reducing risk (preventing future attacks, ED visits, and decline in lung function, as well as watching for medication side effects)

Asthma medications are categorized into two general classes: long-term control medications (preventive medications) to achieve and maintain control of inflammation and quick-relief medications (rescue medications) to treat symptoms and exacerbations.

Quick-relief and long-term medications are often used in combination. Inhaled corticosteroids, cromolyn sodium and nedocromil, long-acting β_2-agonists (LABAs), methylxanthines, and leukotriene modifiers are used as long-term control medications. Short-acting β_2-agonists, anticholinergics, and systemic corticosteroids are used as quick-relief medications. Bronchodilators that relax bronchial smooth muscle and dilate the airways include β_2-agonists, methylxanthines, and anticholinergics that can be used as both quick-relief and long-term medications.

Many asthma medications are given by inhalation with a nebulizer or a metered-dose inhaler (MDI). The MDI should always be attached to a spacer when an inhaled corticosteroid is administered to prevent yeast infections in the mouth. Spacers are also important for children who have difficulty coordinating or learning proper inhalation technique. The spacer and holder can be equipped with a mask or a mouthpiece. MDIs that contain propellant chlorofluorocarbons (CFCs) have been banned in the United States due to their linkage with depletion of the Earth's ozone level. An alternative propellant, hydrofluoroalkane, does not cause ozone depletion, delivers more fine particles of the medication, and has less oral deposition. The Diskhaler and Aerosolizer are similar, but with the Aerosolizer, the medication must be loaded into the inhaler before use. Infants and young children who have difficulty using MDIs or other inhalers can receive their asthma medications via a handheld nebulizer. When this device is used, the medication is mixed with saline (also available in premixed form) and nebulized with compressed air. Children are instructed to breathe normally with the mouth open to provide a direct route to the trachea.

Corticosteroids are antiinflammatory drugs used to treat reversible airflow obstruction, control symptoms, and reduce bronchial hyperresponsiveness in chronic asthma. Inhaled corticosteroids are used as first-line therapy in children older than 5 years of age. Clinical studies of corticosteroids have indicated significant improvement of all asthma parameters, including decreases in symptoms, ED visits, hospitalizations, and medication requirements (Bekmezian, Fee, & Weber, 2015; Falk, Hughes, & Rodgers, 2016).

Corticosteroids may be administered parenterally, orally, or by inhalation. Oral medications are metabolized slowly, with an onset of action up to 3 hours after administration and peak effectiveness occurring within 6 to 12 hours. Oral systemic steroids may be given for short periods (e.g., 3- or 10-day "bursts") to gain prompt control of inadequately controlled persistent asthma or to manage severe persistent asthma. These drugs should be given in the lowest effective dose. They have few side effects (cough, dysphonia, and oral thrush), and there is evidence that they improve the long-term outcomes for children of all ages with mild or moderate persistent asthma. Evidence from clinical trials that monitored children for 6 years indicates that the use of inhaled corticosteroids at recommended dosages does not have long-term significant effects on growth, bone mineral density, or suppression of the adrenal-pituitary axis (Falk et al., 2016; Liu et al., 2020). However, primary care providers should frequently monitor (at least every 3 to 6 months) the growth of children and adolescents taking corticosteroids to assess the systemic effects of these drugs and make appropriate reductions in dosages or changes to other types of asthma therapy when necessary. Inhaled corticosteroids include budesonide and fluticasone.

β-Adrenergic agonists (short acting) (primarily albuterol, levalbuterol [Xopenex], and terbutaline) are used for treatment of acute exacerbations and for the prevention of EIB. These drugs bind with the β-receptors on the smooth muscle of airways, where they activate adenylate cyclase and convert adenosine monophosphate (AMP) to cyclic AMP (cAMP). The increased cAMP enhances binding of intracellular calcium to the cell membrane, reducing the availability of calcium and thus allowing smooth muscle to relax. Other effects of the drug help stabilize mast cells to prevent release of mediators. Most β-adrenergics used in asthma therapy affect predominantly the β_2-receptors, which help eliminate bronchospasm. β_1-receptor effects, such as increased heart rate and GI disturbances, have been minimized. Albuterol is given orally or via nebulizer or inhaler, whereas levalbuterol is given only via inhaler or nebulizer. The inhaled drugs have a more rapid onset of action than oral forms. Levalbuterol is more expensive than albuterol but reportedly causes fewer side effects than albuterol. There continues to be some discussion about the administration of β_2-agonists via an MDI versus a nebulizer. However, administration via an MDI is as effective to delivery of medication by a small-volume nebulizer in reversing bronchospasm (Mitselou, Hedlin, & Hederos, 2016).

LABAs are approved as single-ingredient products (Serevent and Foradil) and in combination products containing inhaled corticosteroids (Advair and Symbicort). The National Asthma Education and Prevention Program (2007) recommends use of a LABA with low- or medium-dosage inhaled corticosteroid to improve lung function and asthma symptoms, as well as reduce use of short-acting β_2-agonists. They are used for patients whose symptoms cannot be adequately controlled on asthma controller medications.

LABAs must be added to antiinflammatory therapy and never used as monotherapy (Liu et al., 2020). Inhaled β-adrenergic agents should not be taken more than three or four times daily for acute symptoms without medical supervision. LABAs can increase the risk of severely worsening asthma symptoms, potentially leading to hospitalizations and death. The US Food and Drug Administration has required LABA manufacturers to conduct studies to evaluate the safety of using them with inhaled corticosteroids versus inhaled corticosteroids alone. Salmeterol and Foradil are not used for patients younger than 4 years of age.

Theophylline (a methylxanthine drug) was used for decades to relieve symptoms and prevent asthma attacks; however, it is now used primarily when the child is not responding to maximum therapy (Liu et al., 2020). Therapeutic levels should be obtained with this drug because it has a narrow therapeutic window. Theophylline is not recommended for acute asthma exacerbations.

Cromolyn sodium is a medication used in maintenance therapy for asthma in children older than 2 years of age. It stabilizes mast cell membranes; inhibits activation and release of mediators from eosinophil and epithelial cells; and inhibits the acute airway narrowing after exposure to exercise, cold dry air, and sulfur dioxide. It does not result in immediate relief of symptoms and has minimal side effects (occasional coughing on inhalation of the powder formulation). It is now only available as an oral preparation or via nebulizer. Cromolyn or nedocromil inhaler preparations were discontinued in 2010.

Leukotrienes are mediators of inflammation that cause increases in airway hyperresponsiveness. Leukotriene modifiers (e.g., zafirlukast [Accolate], zileuton [Zyflo], montelukast sodium [Singulair]) block inflammatory and bronchospasm effects. These drugs are not used to treat acute episodes but are given orally in combination with β-agonists and steroids to provide long-term control and prevent symptoms in mild persistent asthma. Montelukast is approved to treat asthma in children 12 months of age and older, whereas zafirlukast is approved for children 5 years of age and older.

Anticholinergics (atropine and ipratropium [Atrovent]) help relieve acute bronchospasm. However, these drugs have adverse side effects that include drying of respiratory secretions, blurred vision, and cardiac and CNS stimulation. The primary anticholinergic drug used is ipratropium, which does not cross the blood-brain barrier and therefore elicits no CNS effects. Ipratropium, when used in combination with albuterol, can be effective during acute severe asthma in significantly improving lung function in children and reducing hospitalizations and ED visits (Liu et al., 2020).

Omalizumab (Xolair) is a monoclonal antibody that is used for patients with moderate to severe persistent allergic asthma whose asthma symptoms are not controlled by inhaled corticosteroids. It blocks the binding of IgE to mast cells to inhibit the inflammation associated with asthma. Many patients with asthma are atopic and possess specific IgE antibodies to allergens responsible for airway inflammation. Xolair has been approved for use in children 12 years of age and older. IgE levels are measured before beginning treatment. Dosage and frequency of administration of Xolair are dependent on the serum total IgE level and body weight. The drug is administered once or twice a month by subcutaneous injection. Efficacy of omalizumab is not immediate and takes 12 to 16 weeks. In early 2007, the US Food and Drug Administration (2007) added a "black box warning" to omalizumab that highlighted the risk of anaphylaxis. Anaphylaxis was observed in 0.14% of patients receiving omalizumab in clinical trials, and 60% of these instances occurred within 2 hours of administration; therefore recommendations include observing the recipient for 2 hours after the first three doses are administered and for 30 minutes thereafter for subsequent doses (Thomson & Chaudhuri, 2012). Some children with severe asthma and a history of severe life-threatening episodes may need a prescription for an EpiPen (subcutaneous injectable epinephrine).

Magnesium sulfate, a potent muscle relaxant that acts to decrease inflammation and improves pulmonary function and peak flow rate, may be used in pediatric patients treated in the ED or ICU with moderate to severe asthma. Studies on the use of IV and inhaled magnesium sulfate offer significant benefits for children with acute asthma exacerbations (Griffiths, Kew, & Normansell, 2016; Schuh, Sweeney, Freedman, et al., 2016).

Exercise

Exercise-induced bronchospasm (EIB) is an acute, reversible, usually self-terminating airway obstruction that develops during or after vigorous activity, reaches its peak 5 to 10 minutes after stopping the activity, and usually stops in another 20 to 30 minutes. Patients with EIB have cough, shortness of breath, chest pain or tightness, wheezing, and endurance problems during exercise, but an exercise challenge test in a laboratory is necessary to make the diagnosis.

The problem occurs rarely in activities that require short bursts of energy (e.g., baseball, sprints, gymnastics, skiing) but more commonly during endurance exercises (e.g., soccer, basketball, distance running). Swimming is well tolerated by children with EIB because they are breathing air fully saturated with moisture and because of the type of breathing required in swimming.

Parents, teachers, and practitioners often exclude children with asthma from exercise, and the children themselves are reluctant to participate because it may provoke an attack. However, doing so can seriously hamper peer interaction and physical health. Exercise is advantageous for children with asthma, and most children can participate in activities at school and in sports with minimal difficulty, provided their asthma is under control. Evaluate participation on an individual basis. Appropriate prophylactic treatment with β-adrenergic agents or cromolyn sodium before exercise usually permits full participation in strenuous exertion.

Breathing Exercises

Breathing exercises and physical training help produce physical and mental relaxation, improve posture, strengthen respiratory musculature, and develop more efficient breathing patterns. For motivated child, breathing exercises and controlled breathing help prevent overinflation and improve efficiency of the cough. However, these exercises are not recommended during acute asthma exacerbations.

Hyposensitization

The role of hyposensitization in childhood asthma is somewhat controversial. In the past, allergen immunotherapy was used for seasonal allergies and when single substances were identified as the offending allergen. It is not recommended for allergens that can be eliminated, such as foods, drugs, and animal dander.

The National Asthma Education and Prevention Program (2007) guidelines recommend allergen immunotherapy for asthma patients in the following situations:

- When there is evidence of a relationship between asthma symptoms and unavoidable exposure to an allergen to which the patient is sensitive
- When symptoms occur all year or at least during a major portion of the year
- When symptom control is difficult with drug therapy because multiple medications are required, the patient is not responsive to available drugs, or the patient refuses to take the medications

Injection therapy is usually limited to clinically significant allergens. The initial dose of the offending allergen(s), based on the size of the skin reaction, is injected subcutaneously. The amount is increased at weekly intervals until a maximum tolerance is reached, after which a maintenance dose is given at 4-week intervals. This may be extended to 5- or 6-week intervals during the off-season for seasonal allergens. Successful treatment is continued for a minimum of 3 years and then stopped. If no symptoms appear, acquired immunity is assumed; if symptoms recur, treatment is reinstituted. Hyposensitization injections should be administered only with emergency equipment and medications readily available in the event of an anaphylactic reaction.

Status Asthmaticus

Status asthmaticus is a medical emergency that can result in respiratory failure and death if unrecognized and untreated. Children who continue to display respiratory distress despite vigorous therapeutic measures, especially the use of sympathomimetics (e.g., albuterol, epinephrine), are in status asthmaticus. The condition may develop gradually or rapidly, often coincident with complicating conditions, such as pneumonia or a respiratory virus, that can influence the duration and treatment of the exacerbation.

! NURSING ALERT

A child with asthma who sweats profusely, remains sitting upright, and refuses to lie down is in severe respiratory distress. Also, a child who suddenly becomes agitated or an agitated child who suddenly becomes quiet may have serious hypoxia and requires immediate intervention.

Therapy for status asthmaticus is aimed at improving ventilation, decreasing airway resistance, relieving bronchospasm, correcting dehydration and acidosis, allaying child and parent anxiety related to the severity of the event, and treating any concurrent infection. Humidified oxygen is recommended and should be given to maintain an oxygen saturation greater than 90%. Inhaled aerosolized short-acting β_2-agonists are recommended for all patients. Three treatments of β_2-agonists spaced 20 to 30 minutes apart are usually given as initial therapy, and continuous administration of β_2-agonists via nebulizer may be initiated. A systemic corticosteroid (oral, IV, or IM) is given to decrease the effects of inflammation. An anticholinergic agent (such as ipratropium bromide) may be added to the aerosolized solution of the β_2-agonist. Anticholinergics have resulted in additional bronchodilation in patients with severe airflow obstruction. An IV infusion is often initiated to provide a means for hydration and to administer medications. Correction of dehydration, acidosis, hypoxia, and electrolyte disturbance is guided by frequent determination of arterial pH, blood gases, and serum electrolytes.

Additional therapies in acute asthma attacks may include the use of IV magnesium sulfate, a potent muscle relaxant that decreases inflammation and improves pulmonary function and peak flow rate among patients with moderate to severe asthma when treated in the ED or ICU. Heliox (a mixture of 70% to 80% helium and 20% to 30% oxygen) may be administered to decrease airway resistance and thereby decrease the work of breathing; it can be delivered via a nonrebreathing face mask from premixed tanks, which may be blended in a standalone unit or within a ventilator. It may be used in acute exacerbations as an adjunct to β_2-agonist and IV corticosteroid therapy to improve pulmonary function until the two latter medications have time to take full effect in decreasing bronchospasm; the effects of heliox are usually seen within 20 minutes of administration, whereas other drugs may take longer to exert the desired effect. Ketamine, a dissociative anesthetic, is believed to cause smooth muscle relaxation and decrease airway resistance caused by severe bronchospasm in acute asthma; it may be administered as an adjunct to other therapies mentioned previously. Antibiotics should not be used to treat stable asthma except when a bacterial infection is present.

A child suspected of having status asthmaticus is usually seen in the ED and is often admitted to a pediatric ICU for close observation and continuous cardiorespiratory monitoring. A key component in the prevention of morbidity is helping the child, parents, teachers, coaches, and other adults recognize features of deteriorating respiratory status, use the correct rescue drugs effectively, and immediately place the child with deteriorating respiratory status into the care of health care professionals instead of waiting to see if the asthma gets better on its own. For the child going into early status asthmaticus, immediate medical care is required to prevent irreversible respiratory failure and possible death (see Next-Generation NCLEX® Examination-Style Unfolding Case Study).

Prognosis

Although deaths from asthma have been relatively uncommon since the 1980s, the rate of death from asthma increased steadily in the United States until it peaked in the mid-1990s and then slowly decreased over the next 10 years. In 2016, 209 children younger than 18 years old died from asthma (Centers for Disease Control and Prevention, 2018b). In 2011, 14% of all children in the United States were diagnosed with asthma, and 70% of these children had recurrent asthma (Liu et al., 2020). There has been a significant increase in asthma-related ED visits and hospitalizations. Mortality and morbidity rates for asthma are especially high among African American children, whose hospitalization and death rates are two to seven times higher than non–African American children (Fitzpatrick, Gillespie, Mauger, et al., 2019; Liu et al., 2020). Most asthma deaths in children occur in the home, school, or community before life-saving medical care can be administered.

Some children's asthma symptoms may improve at puberty, but up to two-thirds of children with asthma continue to have symptoms through puberty and into adulthood. The prognosis for control or disappearance of symptoms varies in children from those who have rare and infrequent attacks to those who are constantly wheezing or are subject to status asthmaticus. Risk factors that may predict the persistence of symptoms into childhood (from infancy) include atopy, male gender, exposure to environmental tobacco, and maternal history of asthma. Many children

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

The Child With Acute Asthma Exacerbation

Day 1, 10:00 am

7. A 15-year-old male presents to the Emergency Department with a history of asthma and symptoms that are not resolving with his current rescue medications. His asthma symptoms have been controlled with use of a long-acting inhaler twice daily, but an increase in seasonal allergies and a recent upper respiratory infection (URI) have caused an exacerbation of his symptoms. The patient rarely uses his peak expiratory flow meter (PEFM); instead, he waits until his symptoms become severe before starting to use his rescue medications. The nurse completes a history and physical assessment and finds the following. **Highlight the assessment findings that require follow-up by the nurse.**
   - A. Temperature = 98.6° F (37° C)
   - B. Heart Rate = 114 beats/min
   - C. Respirations = 28 breaths/min
   - D. SpO_2 = 88% on room air
   - E. Blood Pressure = 110/64 mmHg
   - F. Wheezing auscultated in both lungs
   - G. Unable to lie down on the stretcher
   - H. Peak expiratory flow meter results are <50% of baseline

8. Based on these findings, what are the most important subjective and objective data that should be considered as the defining characteristics of an acute asthma exacerbation? **Select all that apply.**
   - A. Dyspnea
   - B. Moist cough
   - C. Shortness of breath
   - D. High blood pressure
   - E. Increased respiratory rate
   - F. Profuse thick secretions
   - G. Chest tightness or chest pain
   - H. Use of accessory muscles (retractions)
   - I. Diminished breath sounds and/or adventitious breath sounds (wheezing)

Day 1, 10:15 am

9. A 15-year-old male with a history of asthma is in the Emergency Department for immediate treatment. The physician has examined the patient and written orders. Which nursing interventions are of **highest priority** for this adolescent with an asthma exacerbation? **Use an X to indicate whether the nursing actions listed below are Emergent (appropriate or immediately necessary) or Not Emergent (not appropriate or not immediately necessary) for the patient's care at this time.**

Nursing Action	Emergent	Not Emergent
Administer humidified oxygen to keep the oxygen saturation (SpO_2) above 90%.		
Administer methylprednisolone per the physician order.		
Administer albuterol per hospital protocol.		
Place the patient in a comfortable standing, sitting upright or learning forward position.		
Discuss possible allergens in the home that might have triggered the attack.		
Review how to use the metered dose inhaler.		

10. Indicate which nursing action number listed in the far-left column is most appropriate for each potential complication listed in the middle column. **Place the number in the far-right column. Note that not all actions will be used.**

Nursing Action	Potential Complication	Nursing Action to Prevent Complication
1. Allow patient to assume position of comfort.	To minimize drying of nasal mucous membranes	
2. Administer rescue medications (as prescribed) that can include inhalers, nebulization, and/or oral or intravenous (IV) steroids.	To prevent airway obstruction	
3. Administer humidified oxygen to maintain oxygen saturation (SaO_2) above 90%.	Decreased patient's awareness of factors that exacerbate asthma	
4. Assess patient's response to rescue medications.	To prevent constricted airways and decreased air exchange	
5. Assist patient in recognizing factors that trigger asthma symptoms.	Lack of awareness of need for more aggressive interventions	
6. Assure respirations will be easy and nonlabored at a rate within normal limits for age.		
7. Teach the patient how to use the peak expiratory flow meter (PEFM).		
8. Evaluate the use of the PEFM.		

Day 2, 11:00 am

11. A 15-year-old male with a history of asthma was admitted yesterday for acute asthmatic care. He has responded well to treatment and will be discharged. The nurse will be discussing discharge plans that are essentials aspects of asthma care and prevention. What would the nurse include in the teaching plan? **Select all that apply.**
   - A. Avoiding smoke and other irritants
   - B. Avoiding Tylenol containing products
   - C. Encouraging daily albuterol use.
   - D. Identifying early signs of an asthma exacerbation
   - E. Identifying specific asthmatic triggers in the environment
   - F. Reviewing home medications, dosing and precautions
   - G. Recommending physical exercise and mental training
   - H. Avoiding exposure to excessive cold, wind and other extremes of weather

Continued

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—cont'd

Day 2, 2:00 pm

12. A 15-year-old male with a history of asthma who is in the Emergency Department for immediate treatment. He has responded well to treatment and no longer needs oxygen and plans are being discussed for discharge. Since there is a history of this adolescent not using the PEFM the nurse will meet with him and his mother to review how to use the PEFM. The nurse realizes that the adolescent and his mother must understand how to interpret the peak expiratory flow rates using the peak expiratory flow meter (PEFM). **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.** The PEFR measures the maximum _____1_____ that can be forcefully exhaled in _____2_____. Asthma is under reasonably good control when the PEFR indicates _____3_____ of the patient's personal best value is obtained. This value is established by obtaining a PEFR over a _____4____ period of time.

Options for 1	Options for 2	Options for 3	Options for 4
flow of air	5 seconds	80-100%	4-5 week
flow of oxygen	10 seconds	50-70%	2-3 week
flow of water	1 second	60-80%	1-2 day

who outgrow their exacerbations continue to have airway hyperresponsiveness and cough as adults. Furthermore, airway hyperresponsiveness in adults appears to be associated with decreased lung function.

The adolescent age-group appears to be the most vulnerable, with the greatest increase in mortality from the condition occurring in children 10 to 14 years of age. No reliable data exist to explain this increase. Factors that have been postulated include exposure of atopic persons to more allergens (particularly in large urban centers), change in severity of the disease, abuse of drug therapy (toxicity), failure of families and practitioners to recognize the severity of asthma, and psychologic factors, such as denial and refusal to accept the disease. Risk factors for asthma-related deaths include early onset, frequent attacks, difficult-to-manage disease, adolescence, history of respiratory failure, psychologic problems (refusal to take medications), dependency on or misuse of asthma drugs (high use), presence of physical stigmata (barrel chest, intercostal retractions), and abnormal PFTs.

Nursing Care Management

Acute Asthma Care

Children who are admitted to the hospital with acute asthma are ill, anxious, and uncomfortable. Continual observation and assessment are essential. Pediatric Quality Indicators for appropriate asthma medication implications are shown in Table 21.3.

When β_2-agonists, corticosteroids, and supplemental oxygen are given, the child is monitored closely and continuously for relief of respiratory distress and signs of side effects or toxicity (e.g., tachycardia, restlessness, irritability, hyperactivity). Pulse oximetry is monitored along with rate and depth of breathing, auscultation of air movement, adventitious sounds, and any signs of respiratory distress (e.g., nasal flaring, tachypnea, retractions). The child on supplemental oxygen requires intermittent or continuous oxygenation monitoring depending on severity of respiratory compromise and initial oxygenation status. The child in status asthmaticus should be placed on continuous cardiorespiratory (including blood pressure) and pulse oximetry monitoring. Oral fluid intake may be limited during the acute phase; IV fluid replacement may be required to provide adequate tissue hydration.

Children with acute asthma may be apprehensive and anxious. The calm, efficient presence of a nurse helps reassure children that they are safe and will be cared for during this stressful period. Assure children that they will not be left alone and that their parents can remain with them. Parents need reassurance and want to be informed of their child's condition and therapies. They may believe that they have in some way contributed to the child's condition or could have prevented the episode. Reassurance regarding their efforts expended on the child's behalf and their parenting capabilities can help alleviate their stress. Efforts to reduce parental apprehension will also reduce the child's distress. Anxiety is easily communicated to the child from parents and other family members.

Provide Long-Term Asthma Care

The nursing care of the child with asthma begins with a review of the child's health history; the home, school, and play environment; the parents' and child's attitudes about the child's condition; and a comprehensive physical assessment with focus on the respiratory system. Physical assessment of asthma involves the same observations and techniques described in Chapter 4. In addition, the nurse identifies and evaluates physical characteristics of chronic respiratory involvement, including chest configuration (e.g., barrel chest), posturing (tripod), and type of breathing. A history of the current and previous episodes and precipitating factors or events provides important information. An asthma scoring system may be used to determine severity of symptoms. The nursing assessment should include questions about nighttime waking related to symptoms, frequency of use of the quick-acting bronchodilator, ability to participate in school or other activities, PEFR scores, any medication side effects, and other visits to a provider related to asthma symptoms.

Nursing care of children with asthma involves both acute and long-term care. Nurses who are involved with children in the home, hospital, school, outpatient clinic, or practitioner's office play an important role in helping children and their families learn to live with the condition. The disease can be managed so that it does not require ED visits or hospitalization, or interfere with family life, physical activity, or school attendance. The nursing process in the care of the child with asthma is outlined in the Next-Generation NCLEX® Examination-Style Unfolding Case Study box.

Nurses may perform a variety of vital functions in asthma care, including asthma education in the primary care setting and in schools and other community settings and care of the child with asthma in the acute care setting, ambulatory care, and intensive care. Nurses also obtain information on how asthma affects the child's everyday

TABLE 21.3 Pediatric Quality Indicator[a]

Appropriate Medications for Asthma

Measure	Asthma patients who were identified as having moderate to severe persistent asthma and had a ratio of controller medications to total asthma medications of 0.50 or greater during the measurement year.
Numerator	The number of patients who have a medication ratio of at least 0.50 during the measurement year who were identified as having moderate to severe persistent asthma.
Denominator	All patients during the measurement year who were identified as having moderate to severe persistent asthma.

[a]Endorsed by the National Quality Forum NQF #1800 and 2019 Core Set of Children's Health Care Quality Measures for Medicaid and CHIP, https://www.medicaid.gov/federal- policy-guidance/downloads/cib112018.pdf.

activities and self-concept, the child's and family's adherence to the prescribed therapy, and their personal treatment goals. Every effort is made to build a partnership between the child and family and the health care team, and effective communication is an essential part of this partnership. Assess the child and family's satisfaction with asthma control and with the quality of care, their perception of the severity of the disease, and their level of social support.

One of the major emphases of nursing care is outpatient management by the family. Parents are taught how to recognize and respond to symptoms of bronchospasm, to maintain health and prevent complications, and to promote normal activities. The child's asthma action plan should be reviewed periodically at least every 6 months in children with moderate to severe disease; precipitating factors, illness management, and medication use should be discussed. The nurse determines any cultural or ethnic beliefs or practices that influence self-management and may necessitate modifications in educational approaches to meet the family's needs.

Avoid Allergens

One goal of asthma management is avoidance of an exacerbation. Parents and children need to know how to avoid allergens that precipitate asthma episodes. The nurse educates the parent and child on how to modify the environment to reduce contact with the offending allergen(s). Caution parents to avoid exposing a sensitive child to extremes of weather (e.g., excessive cold, wind) and other irritants (e.g., smoke, sprays, scents). Foods known to provoke symptoms should be eliminated from the diet.

Approximately 2% to 6% of children with asthma are sensitive to aspirin; therefore nurses should caution parents to use other analgesic or antipyretic drugs for discomfort or fever and to read package labeling. Parents are taught to avoid administering aspirin to *any* child because of its association with Reye syndrome unless specifically recommended by and under the supervision of a health practitioner. Salicylate compounds are contained in other common medicines such as Pepto-Bismol, which should be avoided. Children with aspirin-induced asthma may also be sensitive to nonsteroidal antiinflammatory drugs (NSAIDs) and tartrazine (yellow dye number 5, a common food coloring).

! NURSING ALERT

Acetaminophen is the analgesic of choice for asthmatic children.

Relieve Bronchospasm

Teach parents and older children to recognize early signs and symptoms of an impending attack so that it can be controlled before symptoms become distressing. Most children can recognize prodromal symptoms well before an attack (about 6 hours) and implement preventive therapy. Objective signs that parents may observe include rhinorrhea, cough, low-grade fever, irritability, itching (especially in front of the neck and chest), apathy, anxiety, sleep disturbance, abdominal discomfort, and loss of appetite.

Children who use a nebulizer, MDI, Diskus, or Turbuhaler to deliver drugs need to learn how to use the device correctly (Fig. 21.8). The MDI device (Fig. 21.9) delivers medication directly to the airways; therefore the child needs to learn to breathe slowly and deeply for better distribution to narrowed airways (see Family-Centered Care box).

FAMILY-CENTERED CARE

Use of a Metered-Dose Inhaler[a]

Steps for Checking How Much Medicine Is in the Canister

1. If the canister is new, it is full.
2. Check product label to see how many inhalations should be in each canister.
3. The most accurate way to determine how many doses remain in a metered-dose inhaler (MDI) is to count and record each dose as it is used.
4. Many dry powder inhalers have a dose-counting device or dose indicator on the canister to specify when the canister is empty.
5. Placing dry powder inhalers or MDIs with hydrofluoroalkanes in water will destroy them.

Steps for Using the Inhaler With Mouthpiece

1. Remove the cap and hold inhaler upright
2. Shake the inhaler.
3. Attach spacer, as appropriate.
4. Tilt the head back slightly and breathe out slowly.
5. With the inhaler in an upright position, insert the mouthpiece about 3 to 4 cm (1 to 1½ inches) from the mouth or into the mouth, forming an airtight seal between the lips and mouthpiece.
6. At the end of a normal expiration, depress the top of the inhaler canister firmly to release the medication (into the mouth) and breathe in slowly (about 3 to 5 seconds). Relax the pressure on the top of the canister.
7. Hold the breath for at least 5 to 10 seconds to allow the aerosol medication to reach deeply into the lungs.
8. Remove the inhaler and breathe out slowly through the nose.
9. Wait 1 minute between puffs (if an additional puff is needed) when using a bronchodilator.
10. Replace the cap on the MDI.
11. If using a corticosteroid, rinse mouth or take a drink to remove residual medication (which can cause a yeast infection to develop).

Steps for Using the Inhaler With an AeroChamber (see Fig. 21.9)

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Attach AeroChamber
4. For AeroChamber with a mouthpiece, place the inhaler in an upright position, then insert the mouthpiece into the mouth, forming an airtight seal between the lips and mouthpiece.
5. For AeroChamber with a mask, apply AeroChamber mask to child's face and make sure that there is a good seal.
6. Have child breathe slow, regular breaths. Depress the top of the inhaler canister firmly to release the medication (into the AeroChamber) as the child breathes slowly in and out. Relax the pressure on the top of the canister.
7. Hold the AeroChamber in place over the child's face until six breaths have been taken. Give one puff at a time and wait 1 minute in between puffs when using a bronchodilator.
8. Remove the inhaler and AeroChamber. Apply to cap to the MDI. The AeroChamber should be washed weekly using soap and water.

Common Problems for Children Using Inhalers

- Child refuses or resists treatment.
- Inhalation is too rapid.
- Child is unable to coordinate the spray with inhalation.
- Breath is not held long enough after inhalation.

[a]Inhaled dry powder such as budesonide (Pulmicort) requires a different inhalation technique. To use a dry powder inhaler, the base of the device is turned until a click is heard. It is important to close the mouth tightly around the mouthpiece of the inhaler and inhale rapidly.

Fig. 21.8 Children with asthma may take a nebulized aerosol treatment with (A) a mask or (B) a mouthpiece. (Courtesy Texas Children's Hospital, Houston, TX.)

Fig. 21.9 Child using metered-dose inhaler (MDI) with spacer and face mask.

Young children and those who are unable to manipulate the MDI or hold their breath for 10 seconds should use a spacer. A spacer is a 4- to 8-inch tube that fits on the end of the MDI mouthpiece. These devices allow the parent or child to deliver the medication from the MDI into the spacer, from which the child then inhales the medication while taking slow, steady breaths at his or her own pace. Spacers also help prevent yeast infections in the mouth when corticosteroids are inhaled via an MDI.

! NURSING ALERT

Long-acting β_2-agonist (LABA) inhalers (salmeterol) should be used only as directed (usually every 12 hours) and not more frequently. They are not intended to relieve acute asthmatic symptoms.

The nurse also needs to caution the child and parents about the adverse effects of prescribed drugs and the dangers of overuse of β_2-agonists. They should know that it is important to use these drugs when needed but not indiscriminately or as a substitute for avoiding the symptom-provoking allergen. Caution parents against purchasing over-the-counter preparations because these medications can place the children at risk for increased dosage of a drug and toxicity. Educate parents on how to read labels on prepared foods and snacks to determine the presence of allergens.

The family should obtain a PEFM and learn to use this device to monitor the child's asthma. A written asthma action plan that includes the three peak flow meter zones and the child's asthma medications may be obtained from the child's primary care provider. A written asthma action plan can significantly reduce ED visits, hospital stay days, school absence days, and the risk of asthma death (Lakupoch, Manuyakorn, Preutthipan, et al, 2018; Liu et al., 2020). Medications used for asthma exacerbations are also included in the asthma plan. This action plan should be used to make decisions about asthma management at home and at school. The nurse may assist the child and family in preparing this plan, emphasizing that the child and family determine the success of the plan, not the health professionals.

The child should be protected from a respiratory tract infection that can trigger an attack or aggravate the asthmatic state, especially in young children whose airways are mechanically smaller and more reactive. Annual influenza vaccinations are recommended for all children older than 6 months of age. Pneumococcal conjugate vaccine (PCV13) regimen for protection against pneumococcal infection is part of the routine childhood vaccination schedule that is recommended for all children from 2 to 59 months of age. Also, an additional pneumococcal polysaccharide vaccine (PPSV23) is recommended for high-risk children, including asthmatic children on prolonged high-dose corticosteroids (American Academy of Pediatrics, Committee on Infectious Diseases, 2018). Equipment used for the child, such as nebulizers, must be kept absolutely clean to decrease the chances of contamination with bacteria and fungi.

Teach and encourage breathing exercises and controlled breathing for motivated children, and provide information on activities that promote diaphragmatic breathing, side expansion, and improved mobility of the chest wall. Play techniques that can be used for younger children to extend

their expiratory time and increase expiratory pressure include blowing cotton balls or a ping-pong ball on a table, blowing a pinwheel, blowing bubbles, or preventing a tissue from falling by blowing it against the wall.

Self-care and asthma self-management programs are important in helping the child and family cope with asthma. Most asthma self-management programs for children convey several principles. First, asthma is a common disease that can be controlled with appropriate drug therapy, environmental control, education, and management skills. Second, it is much easier to prevent than to treat an asthma episode; adherence to a therapeutic program is necessary to prevent exacerbations. Third, children with asthma can live full and active lives. Although a visit to the ED or hospital due to an asthma exacerbation is undesirable, it also presents an opportunity to assess the child's and family's current knowledge about asthma, its triggers, prevention, and treatment to prevent future visits. The technique used for MDI or nebulizer administration should be observed and education provided when needed.

Asthma camps provide an opportunity for children with asthma to engage in physical activity while learning about their disease in a controlled environment with their peers and health professionals. Children who attend asthma camps often demonstrate improved asthma self-management skills.

Self-contained programs and brochures for patient education are available from the Asthma and Allergy Foundation of America[b] and the American Lung Association.[c] The National Heart, Lung, and Blood Institute[d] provides educational materials for asthma education in the school setting. Practice parameters and guidelines designed for health care practitioners are available from the American Academy of Allergy Asthma and Immunology website.[e]

Child and Family Support

The nurse working with children with asthma can provide support in a number of ways. Many children voice frustration because their exacerbations interfere with their daily activities and social lives. These children need reassurance from the health team that they can learn to control and cope with their asthma and live a normal life.

Children in disruptive family situations (e.g., divorce, separation, violence, custodial battles) may disregard their daily asthma medication regimen or be at higher risk as a result of neglect by adults who are in charge of their care. Adolescents struggling with a sense of identity and body image often regard asthma as a condition that will "go away," especially if there is a time lapse between symptoms, and may abandon the therapeutic regimen. Referral for counseling and guidance is appropriate where the child's or adolescent's life is potentially in danger and the therapeutic regimen for asthma is abandoned due to personal or family crises.

The short- and long-term adaptation of children with asthma often depends on the family's acceptance of the disorder. The task of living day to day with affected children undergoing periodic asthmatic crisis involves the entire family. Throughout the stressful crisis, encourage parents to promote as normal a life as possible for their children.

CYSTIC FIBROSIS

Cystic fibrosis (CF) is a condition characterized by exocrine (or mucus-producing) gland dysfunction that produces multisystem involvement, especially in the pulmonary and digestive systems. The affected child inherits the autosomal recessive defective gene from both parents, with an overall 25% risk with each pregnancy of acquiring the defective genes. The condition has a frequency of 1 in 3500 live births among mostly whites; the incidence in other ethnic groups varies, affecting African Americans in 1 in 15,000 live births and Hispanics in 1 in 9200 live births (Egan, Schecter, & Voynow, 2020). The mutated gene responsible for CF is located on the long arm of chromosome 7. This gene codes a protein of 1480 amino acids called the cystic fibrosis transmembrane conductance regulator (CFTR). The CFTR protein is related to a family of membrane-bound glycoproteins. The glycoproteins constitute a cAMP-activated chloride channel and regulate other chloride and sodium channels at the surfaces of the epithelial cells.

Pathophysiology

With the discovery of the CFTR gene, research is continuing to determine its multisystem effects on the body. Several clinical features characterize CF: increased viscosity of mucous gland secretions, a striking elevation of sweat electrolytes, an increase in several organic and enzymatic constituents of saliva, and abnormalities in autonomic nervous system function. Although both sodium and chloride are affected, the defect appears to be primarily a result of abnormal chloride movement; the CFTR appears to function as a chloride channel.

Children with CF demonstrate decreased pancreatic secretion of bicarbonate and chloride and an increase in sodium and chloride in both saliva and sweat. This last characteristic is the basis for the sweat chloride diagnostic test. The sweat electrolyte abnormality is present from birth, continues throughout life, and is unrelated to the severity of the disease or the extent to which other organs are involved. The sodium and chloride content of sweat in 98% to 99% of children with CF is two to five times greater than that of children without CF.

The primary factor, and the one responsible for many of the clinical manifestations of the disease, is mechanical obstruction caused by the increased viscosity of mucous gland secretions (Fig. 21.10). Instead of forming a thin, freely flowing secretion, the mucous glands produce a thick mucoprotein that accumulates and dilates them. Small passages in organs such as the pancreas and bronchioles become obstructed as secretions precipitate or coagulate to form concretions in glands and ducts.

In the pancreas of many patients, thick secretions block the ducts, leading to pancreatic fibrosis caused by cystic dilations of the acini (small lobes of the gland) that undergo degeneration and progressive diffuse fibrosis. The blockage prevents essential pancreatic enzymes from reaching the duodenum, which causes marked impairment in the digestion and absorption of nutrients, especially fats and proteins. The disturbed absorption is reflected in bulky stools that are frothy from undigested fat (steatorrhea) and foul smelling from putrefied protein (azotorrhea).

The incidence of diabetes mellitus (cystic fibrosis–related diabetes [CFRD]) is greater in children with CF than in the general population, which may be caused by changes in pancreatic architecture and diminished blood supply over time. CFRD is reported to be the most common complication associated with CF. Approximately 40% to 50% of people with CF will develop diabetes by age 30 years, which is associated with increased morbidity and mortality.

However, as age increases the likelihood of developing CFRD and survival improves, the proportion of CF adults with CFRD may exceed the current 40% to 50% estimate (Kayani, Mohammed, & Mohiaddin, 2018). Severe insulin deficiency occurs as a result of β-islet cell dysfunction, and insulin resistance may occur, especially during acute illness. Therefore CFRD has characteristics of both type 1 diabetes mellitus and type 2 diabetes mellitus. Adequate insulin appears to be a key factor in maintaining nutritional status that correlates with optimal lung function. Adult studies have shown that

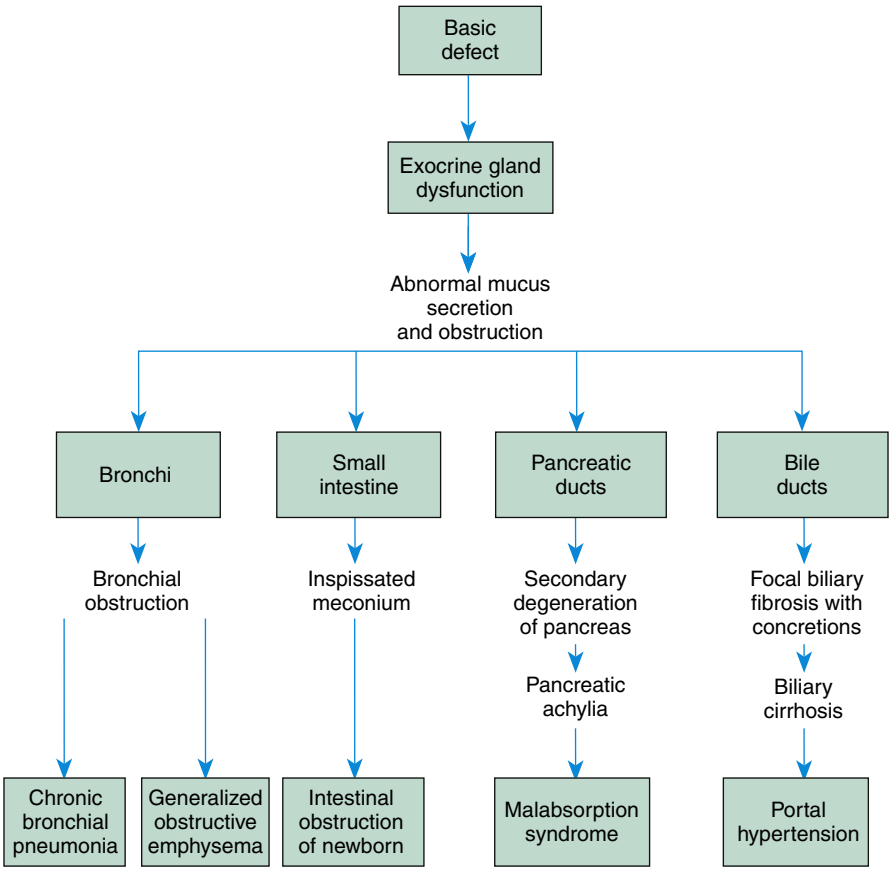

Fig. 21.10 Various effects of exocrine gland dysfunction in cystic fibrosis (CF).

reduced insulin (a potent anabolic hormone) contributes to a shift toward an inflammatory catabolic state, potentially compromising lung function (Kayani et al., 2018).

In the liver, focal biliary obstruction (e.g., cholelithiasis) and fibrosis are common and become more extensive with time, eventually giving rise to a distinctive type of multilobular biliary cirrhosis. Some children develop extensive liver involvement with fatty infiltration despite adequate nutrition.

Pulmonary complications are present in almost all children with CF, but the onset and extent of involvement are variable. Symptoms are produced by stagnation of mucus in the airways, with eventual bacterial colonization leading to destruction of lung tissue. The abnormally viscous and tenacious secretions are difficult to expectorate and gradually obstruct the bronchi and bronchioles, causing scattered areas of bronchiectasis, atelectasis, and hyperinflation. The stagnant mucus also offers a favorable environment for bacterial growth. Recurrent pulmonary infections in the child with CF result in greater and progressive damage to the airways. In severe, progressive lung involvement, compression of pulmonary blood vessels and progressive lung dysfunction frequently lead to pulmonary hypertension, cor pulmonale, respiratory failure, and death.

The most common pathogens responsible for pulmonary infections are *P. aeruginosa, Burkholderia cepacia,* methicillin-resistant *Staphylococcus aureus* (MRSA), *Burkholderia dolosa, S. aureus, H. influenzae, Escherichia coli,* and *Kiebsiella pneumoniae. P. aeruginosa* and *B. cepacia* are particularly pathogenic for children with CF, and infections with these organisms are difficult to eradicate. *P. aeruginosa* infection is not specific for CF but occurs much more frequently in CF than in other diseases characterized by chronic airway obstruction. Methicillin-sensitive *S. aureus* is the most common organism to colonize the respiratory tract and is likely to occur with coinfection of *P. aeruginosa, Aspergillus fumigatus,* or *H. influenzae* (Sobin, Kawai, Irace, et al., 2017). Children with CF who are chronically colonized with these organisms have poorer survival rates than children who are not colonized. Fungal colonization with *Candida* or *Aspergillus* organisms in the respiratory tract is also common in patients with CF.

The reproductive systems of both males and females with CF are adversely affected with CF. The glands of the uterine cervix are often filled with mucus, and copious amounts of mucus may block the cervical canal and prevent sperm entry. More than 95% of males with CF are sterile due to obliteration or atresia of the epididymis, vas deferens, and seminal vesicles, resulting in decreased or absent sperm production (Egan et al., 2020).

Growth and development are often affected in children with moderate to severe forms of CF. Physical growth may be restricted as a result of decreased absorption of nutrients, including vitamins and fat; increased oxygen demands for pulmonary function; and delayed bone growth. The usual pattern is one of growth failure (failure to thrive) with increased weight loss despite an increased appetite and gradual deterioration of the respiratory system. Clinical manifestations of CF are listed in Box 21.17.

Diagnostic Evaluation

Traditionally, the diagnosis of CF was based on a positive sweat chloride test, absence of pancreatic enzymes, radiography, chronic obstructive pulmonary disease, and family history. The addition of the positive newborn screen plus laboratory confirmation of an abnormality in the CFTR gene or protein makes it possible to diagnose CF in early infancy, so that therapies can be implemented to increase the child's overall survival and quality of life.

BOX 21.17 Clinical Manifestations of Cystic Fibrosis

Meconium Ileus[a]
Abdominal distention
Vomiting
Failure to pass stools
Rapid development of dehydration

Gastrointestinal Manifestations
Large, bulky, loose, frothy, extremely foul-smelling stools
Voracious appetite (early in disease)
Loss of appetite (later in disease)
Weight loss
Marked tissue wasting
Growth failure
Distended abdomen
Thin extremities
Sallow skin
Evidence of deficiency of fat-soluble vitamins A, D, E, and K
Anemia

Pulmonary Manifestations
Initial signs:
- Wheezy respirations
- Dry, nonproductive cough

Eventually:
- Increased dyspnea
- Paroxysmal cough
- Evidence of obstructive emphysema and patchy areas of atelectasis

Progressive involvement:
- Overinflated, barrel-shaped chest
- Cyanosis
- Clubbing of fingers and toes
- Repeated episodes of bronchitis and bronchopneumonia

[a]In about 10% of cases.

Universal newborn screening for CF is available in all 50 states in the United States. The newborn screening test consists of an immunoreactive trypsinogen (IRT) analysis performed on a dried spot of blood, which may be followed by direct analysis of DNA for the presence of the ΔF508 mutation or other mutations on the same dried blood spot. A positive screen indicates persistent hypertrypsinogenemia and does not diagnose CF but identifies infants at risk of CF. Further testing is needed to confirm or rule out CF. Benefits of newborn screening and detection include earlier nutritional intervention and preservation of lung function for identified infants. Perceived disadvantage of newborn screening is parental anxiety associated with a false-positive result. Children who were identified and treated early in infancy with aggressive nutritional support had improved height and weight well into adolescence (Egan et al., 2020). Although the technology is available to conduct carrier screening for the general population, this issue remains controversial, and widespread implementation of carrier screening programs is not recommended. An in-utero diagnosis of CF is also possible based on detection of two CF mutations in the fetus.

The consistent finding of abnormally high sodium and chloride concentrations in the sweat is a unique diagnostic characteristic of CF. Parents may report that their infant tastes "salty" when they kiss him or her. The quantitative sweat chloride test (pilocarpine iontophoresis) remains a diagnostic tool for CF and involves stimulating the production of sweat with a special device (involves stimulation with 3-mA electric current), collecting the sweat on filter paper, and measuring the sweat electrolytes. The quantitative analysis requires a sufficient volume of sweat (>75 mg). Two separate samples are collected to ensure the reliability of the test. Normally, sweat chloride content is less than 40 mEq/L, with a mean of 18 mEq/L. A chloride concentration greater than 60 mEq/L is diagnostic of CF; in infants younger than 3 months, a sweat chloride concentration greater than 40 mEq/L is highly suggestive of CF. In some situations, DNA testing may be substituted for the sweat test. The presence of a mutation known to cause CF on each CFTR gene predicts with a high degree of certainty that the individual has CF; however, multiple CFTR mutations may also be present and detected with DNA assay. More than 2000 mutations have now been identified in the CFTR gene, not all of which result in CF (Cystic Fibrosis Mutation Database, 2011).

Chest radiography reveals characteristic patchy atelectasis and obstructive emphysema. PFTs are sensitive indices of lung function, providing evidence of abnormal small airway function in CF. Radiographs, including contrast enema, are used for diagnosis of meconium ileus.

Other diagnostic tools that may aid in diagnosis include stool fat or enzyme analysis. Stool analysis requires a 72-hour sample with accurate recording of food intake during that time. In some cases, CF may go undiagnosed until the child is older and is seen with clinical manifestations that previously were not acute.

Therapeutic Management

Improved survival among patients with CF during the past 2 decades is attributable largely to antibiotic therapy and improved nutritional and respiratory management. Goals of CF therapy are to prevent or minimize pulmonary complications, ensure adequate nutrition for growth, encourage appropriate physical activity, and promote a reasonable quality of life for the child and the family. A multidisciplinary approach to treatment is needed to accomplish these goals.

Management of Pulmonary Problems

Management of pulmonary problems is directed toward prevention and treatment of pulmonary infection by improving ventilation, removing mucopurulent secretions, and administering antimicrobial agents. Many children develop respiratory symptoms by 3 years old. The large amounts and viscosity of respiratory secretions in children with CF contribute to the likelihood of respiratory tract infections. Recurrent pulmonary infections in children with CF result in greater damage to the airways; small airways are destroyed, causing bronchiectasis.

CPT has been the cornerstone of airway clearance therapy (ACT) in the prevention of pulmonary infection for many years. Several other ACT strategies are now available to assist with removal of secretions, including percussion and postural drainage, positive expiratory therapy (PEP), active cycle of breathing technique, autogenic drainage, oscillatory PEP, high-frequency chest compressions, and exercise. The decision of which technique to use is based on the child and the family. Several techniques may be used, and they are usually adapted over time. It is important to foster adherence to ACTs from a young age. They are usually performed on average twice daily (on rising and in the evening) and more frequently if needed, especially during pulmonary infection. Percussion and postural drainage are especially useful for infants and young children but are often not adequate for older children.

PEP is performed by breathing out with a moderate force through a device. This creates resistance and a positive pressure in the airways, helping keep them open. It allows airflow to get around the mucus and moves it toward the larger airways, where it can be expectorated. Three

Fig. 21.11 *Top,* Flutter device components showing the pipe stem, cone with steel ball, and perforated top. *Bottom,* The acapella device. (From Marks, J. H. [2007]. Airway clearance devices in cystic fibrosis. *Paediatric Respiratory Reviews, 8*[1], 17–23.)

devices that help accomplish this are PEP valves, flutters, and acapellas. The PEP valve allows air to be inhaled through a one-way valve and blown out through a hole or resistance. The Flutter mucus clearance device is a small handheld plastic pipe with a stainless-steel ball on the inside that facilitates removal of mucus (Fig. 21.11). An acapella provides high-frequency oscillation as well as PEP.

The active cycle of breathing technique is a series of breathing techniques to help clear secretions. Examples include forced expiration, or "huffing," with the glottis partially closed; thoracic expansion exercises; and relaxation and breathing control. Young children can be taught games with breathing that can develop into these techniques as they get older.

Autogenic drainage involves a variety of breathing techniques that the older children can use to force mucus in lower lobes up into the airways so that it can be successfully expelled. Handheld percussors or electronic chest vibrators may be used to loosen secretions but may not be as effective as some of the other techniques described.

High-frequency chest compression (HFCC) is accomplished by use of a mechanical chest device that is worn for periodic treatments during the day. HFCC provides rapid entry and exit of air in the lungs and assists with mucus breakdown and clearance. It is a common ACT used in patients with CF. Nebulization therapies are generally administered during the vest therapy. Some studies have reported more effective mucus clearance with this treatment than with other conventional treatments.

Patients with CF have been found to regress when conventional ACT is discontinued. Although it is time consuming for the child and family, it is an essential part of care.

Physical exercise is an important adjunct to daily ACT. Exercise stimulates mucus excretion and provides a sense of well-being and increased self-esteem. Any aerobic exercise that the patient enjoys should be encouraged. The ultimate aim of exercise is to increase lung vital capacity, remove secretions, increase pulmonary blood flow, and maintain healthy lung tissue for effective ventilation.

Bronchodilator medication delivered in an aerosol opens bronchi for easier expectoration and is administered before or during ACTs when the patient exhibits evidence of reactive airway disease or wheezing. Another aerosolized medication is recombinant human deoxyribonuclease (DNase, known generically as dornase alfa [Pulmozyme]), which decreases the viscosity of mucus. It is well tolerated and has no major adverse effects; minor reactions are voice alterations and laryngitis. This medication, given once or twice daily via nebulization, generally has resulted in improvements in spirometry, PFTs, dyspnea scores, and perceptions of well-being and has reduced the viscosity of sputum (Yang, Chilvers, Montgomery, et al., 2016).

Nebulized hypertonic saline (6% to 7%) has shown some effectiveness in improving airway hydration and increases mucus clearance in patients with CF who are 6 years of age and older; this treatment, however, causes bronchospasm and may not be recommended for patients with severe disease (Goralski & Donaldson, 2014).

Pulmonary infections are treated as soon as they are recognized. In patients with CF, characteristic signs of pulmonary infection—fever, tachypnea, and chest pain—may be absent. Therefore a careful history and physical examination are essential. The presence of anorexia, weight loss, and decreased activity alerts the practitioner to pulmonary infection and the need for an antibiotic regimen. Aerosolized tobramycin is beneficial for patients with frequent pulmonary exacerbations (Egan et al., 2020). This medication is usually administered by jet or ultrasonic nebulizers after ACT is performed. This type of delivery system allows for direct antimicrobial application with little systemic absorption. It is not uncommon for the child with CF to be placed on as many as two or three antibiotics and one antifungal medication to treat coexisting pulmonary infections.

Colonization with *P. aeruginosa* and *B. cepacia* signals progressive involvement. Although the bacteria are impossible to eradicate, they can be successfully controlled. Patients with CF metabolize antibiotics more rapidly than normal; therefore drug dosage is often higher than would be expected. Depending on its sensitivity, *P. aeruginosa* is usually treated with piperacillin-tazobactam, ceftazidime, cefepime, imipenem-cilastin, meropenem or ticarcillin-clavulanate, ciprofloxacin, levofloxacin, tobramycin, or amikacin. Antibiotic treatment of *B. cepacia* and *S. aureus* should be based on susceptibility and synergy testing. The duration of therapy depends on the patient's response, which is measured by clinical indicators, including cough, fatigue, and exercise intolerance, in addition to tests such as PFTs, chest radiography, and oxygen measurements.

IV antibiotics may be administered at home as an alternative to hospitalization. The use of peripherally inserted central catheters (PICCs) for the administration of antibiotics in children with CF is a viable option with limited complications and fewer needle punctures to obtain blood specimens and to maintain often lengthy treatment with parenteral antibiotics. Alternatively, an implanted vascular access device offers the advantage of access for blood draws and antibiotic infusion. Patients may receive antibiotic therapy at home and continue daily activities with minimal disruptions. However, when pulmonary function does not improve with outpatient management, hospitalization may be recommended for continued antibiotic therapy and vigorous ACT. Oxygen administration is used for children with acute episodes but must be used cautiously because many children with CF have chronic carbon dioxide retention, and the unsupervised use of oxygen can be harmful (see Chapter 20, Oxygen Therapy). With repeated infection and inflammation, bronchial cysts and emphysema may develop. These cysts may rupture, resulting in a pneumothorax.

! NURSING ALERT

Signs of a pneumothorax are usually nonspecific and include tachypnea, tachycardia, dyspnea, pallor, and cyanosis. A subtle drop in oxygen saturation (measured by pulse oximetry) may be an early sign of pneumothorax.

Blood streaking of the sputum is usually associated with increased pulmonary infection or advanced lung disease. Hemoptysis greater than 250 ml/24 h for the older child (less for a younger child) indicates a potentially life-threatening event and needs to be treated immediately. Sometimes bleeding can be controlled with bed rest, IV antibiotics, replacement of acute blood loss, IV conjugated estrogens (Premarin) or vasopressin (Pitressin), and correction of any coagulation defects with vitamin K or fresh-frozen plasma. If hemoptysis persists, the site of bleeding should be localized via bronchoscopy and cauterized or embolized.

Nasal polyposis can develop in two-thirds of patients with CF and occur due to chronic inflammation. Treatment of nasal polyps includes intranasal corticosteroids, oral antihistamines, decongestants and sometimes prescribed nasal irrigations. If these measures are ineffective, surgical interventions may be necessary.

Because pulmonary damage in patients with CF is believed to be caused by the inflammatory process that occurs with frequent infections, the use of corticosteroids has been studied. However, treatment with corticosteroids for prolonged periods found only a modest efficacy and numerous side effects, including linear growth restriction, glucose tolerance abnormalities, and cataract formation. Antiinflammatory medications (NSAIDs) have been shown to slow the rate of decline in pulmonary function and to decrease the need for IV antibiotics in young patients with mild pulmonary involvement. Although this therapy is generally well tolerated, careful monitoring for adverse effects (GI bleeding) is essential.

Lung transplantation is a final therapeutic option for many CF patients with severe disease. Heart-lung and double-lung procedures have been performed successfully in children with advanced pulmonary vascular disease and hypoxia; however, whether such procedures significantly improve quality of life and survival rates in children with CF is debated in the current literature. Some experts state that infections such as *B. cepacia,* diabetes, and older age represent a negative factor for long-term survival after transplant (Egan et al., 2020).

Management of Gastrointestinal Problems

The principal treatment for pancreatic insufficiency is replacement of pancreatic enzymes, which are administered with meals and snacks to ensure that digestive enzymes are mixed with food in the duodenum. Enteric-coated products prevent the neutralization of enzymes by gastric acids, thus allowing activation to occur in the alkaline environment of the small bowel. The amount of enzyme depends on the severity of the insufficiency, the child's response to enzyme replacement, and published guidelines. A dosing schedule is based on grams of consumed fat or body weight. Usually one to five capsules are administered with a meal, and fewer are taken with snacks. To avoid overdosing, enzyme replacement should not exceed 2500 units lipase/kg/meal for children older than 12 months of age (Egan et al., 2020). Capsules can be swallowed whole or taken apart and the contents sprinkled on a small amount of food to be taken at the beginning of the meal. The amount of enzyme is adjusted to achieve normal growth and a decrease in the number of stools to one or two per day. Pancreatic enzymes should be taken within 30 minutes of eating. The enteric-coated beads should not be chewed or crushed because destroying the enteric coating can lead to inactivation of the enzymes and excoriation of oral mucosa. The powder form is used with infants and young children but should be used cautiously because inhalation of the powder may precipitate acute bronchospasm. The powder may also start to predigest the food, making it unpalatable. Enzymes are mixed into cereal or fruit such as applesauce for small children or into a small amount of breast milk or formula for infants. Enzyme dosing may need to be adjusted by the provider if abdominal side effects such as flatus, pain, loose stools, bloating, or steatorrhea occur.

Children with CF require a well-balanced, high-protein, high-caloric diet (because of their impaired intestinal absorption). In fact, a group of experts recommend that children and adolescents with CF who are 2 to 20 years of age should have an energy intake of 110% to 200% of standards for healthy persons (Turck, Braegger, Colombo, et al., 2016).

Regular nutritional monitoring should be a standard part of the medical care of the child with CF and should occur every month from birth to 6 months, then every 2 months until 12 months of age. During the second year of life, growth assessments should take place every 2 to 3 months, and between 2 and 18 years of age, they should take place every 3 months (Turck et al., 2016). The weight-for-length goal for growth in the first 2 years of life should be above the 50th percentile on World Health Organization standard growth charts, and in children 2 to 18 years of age a body mass index (BMI) above the 50th percentile should be the goal for growth (Turck et al., 2016). Breastfeeding with enzyme supplementation should be continued for as long as possible and, when necessary, supplemented with a higher-calorie-per-ounce (e.g., 24 kcal/oz) formula to achieve adequate growth. For formula-fed infants, commercial cow's milk–based formulas may be adequate to achieve desired growth. Because the uptake of fat-soluble vitamins is decreased, water-miscible forms of these vitamins (A, D, E, and K) are given along with multivitamins and the enzymes. When high-fat foods are eaten, the child is encouraged to add extra enzymes.

Growth failure despite adequate nutritional support may indicate deterioration of pulmonary status. Patients with CF may experience frequent anorexia as a result of the copious amounts of mucus produced and expectorated, persistent cough, effects of medications, fatigue, and sleep disruption. They may be placed on oral nutritional supplements, nighttime (or continuous) supplemental NG or gastrostomy feedings, or, rarely, parenteral alimentation in an effort to build up nutritional reserves if there has been a history of inability to maintain weight. An enzyme supplement is encouraged with enteric feedings; these may be given at the initiation of the infusion, at bedtime, and at the conclusion of the feeding infusion.

Meconium ileus and meconium ileus equivalent, or total or partial intestinal obstruction, can occur at any age. Constipation is often the result of a combination of malabsorption (either from inadequate pancreatic enzyme dosage or a failure to take the enzymes), decreased intestinal motility, and abnormally viscous intestinal secretions. These problems usually do not require surgical interventions and may be treated with Miralax or Colyte (osmotic solutions given orally or by NG tubes), other laxatives, stool softeners, or rectal administration of diatrizoate meglumine (Gastrografin).

Rectal prolapse occurs in a small number of infants with CF, due to steatorrhea, malnutrition, and repetitive coughing (Egan et al., 2020). The first episode of rectal prolapse is frightening to both the parents and child. Its reduction usually requires immediate intervention, which is managed by simply guiding the rectum back into place with a gloved, lubricated finger with the child in a side-lying position. Further management usually involves attempting to decrease the bulk of daily stools through enzyme replacement.

Children with CF often experience transient or chronic gastroesophageal reflux, which should be treated with the appropriate histamine-receptor antagonist and GI motility drug, dietary modifications, and an upright position after feedings or meals.

Management of Endocrine Problems

The management of CFRD is critical in the therapeutic treatment of the child with CF. CFRD presents a combination of insulin resistance

and insulin deficiency, with unstable glucose homeostasis in the presence of acute lung infection and treatment. Children with CF may be at increased risk for glucose management problems as a result of decreased nutrient absorption, anorexia, and severity of pulmonary illness. Diagnosis of CFRD is made using an oral glucose tolerance test. Children with CFRD require close monitoring of blood glucose and administration of insulin, diet and exercise management, and quarterly glycosylated hemoglobin (A1c) measurements. The prevalence of CFRD increases with age, and there is increased morbidity and mortality among children with CFRD compared to those without (Castellani & Assael, 2017). Microvascular complications, such as retinopathy and nephropathy, may occur in children and adolescents with CFRD (O'Riordan, Dattani, & Hindmarsh, 2010). However, ketoacidosis is reported to be rare in individuals with CFRD (Egan et al., 2020).

Children with CFRD on an insulin regimen should perform blood glucose checks three times daily, preferably before meals. With mild CFRD, a single daily dose of long-acting insulin may be sufficient for glycemic control. During illness exacerbations, hyperglycemia may be prevalent.

Bone health is of concern in children and adults with CF. The pancreatic insufficiency of CF and chronic steroid use present potential risks for less than optimum bone growth in such children. Assessment of bone health by history and bone mass density evaluation should be considered in assessing the child's (≤8 years old) health status to detect and prevent osteoporosis and osteopenia.

The administration of recombinant human growth hormone is being used for children with CF who have growth delay to achieve optimum growth. A Cochrane review reported that human growth hormone benefits for children with CF are increased height, weight, and lean tissue mass and improved lung functioning (Thaker, Haagensen, Carter, et al., 2015). However, there is no evidence that it improves clinical status or health-related quality of life.

Prognosis

The median survival age for the patient with CF is 37 years (Egan et al., 2020). Despite considerable progress and a recent surge in new treatment modalities, CF remains a progressive and incurable disease. Lung, heart, pancreas, and liver transplantation have increased survival rates among some CF patients. Heart-lung and double-lung procedures have been successfully performed in children with advanced pulmonary vascular disease and hypoxia. The obstacles surrounding this technique are availability of donated organs; complications from surgery; pulmonary infections; and recurrence of obstructive bronchiolitis, which decreases transplanted lung function.

CFTR modulator therapies are available to patients who have specific mutations in the CFTR gene. The US Food and Drug Administration (2016) approved CFTR pharmacotherapy, namely ivacaftor (Kalydeco), which is available for children ages 2 years and older, and lumacaftor/ivacaftor (Orkambi), which is available for children ages 6 years and older. The medications last 12 hours, so twice-daily dosing is required (Bulloch, Hanna, & Giovane, 2017; Ren, Morgan, Oermann, et al., 2018). These medications regulate the flow of sodium and fluids in cell linings in the affected organs, reducing the likelihood of the development of sticky mucus in organs. Recommendations for the use of CFTR modulators in patients with CF were developed to help CF clinicians, patients, and their families in their decisions on the use of these medications (Ren et al., 2018).

Clinical trials are in progress to examine the effects of inhaled dry powder mannitol for improving mucociliary clearance in CF by rehydrating the airway. Initial reports showed significant improvement in lung function and sputum (De Boeck, Haarman, Hull, et al., 2017).

Current research and modern technologies are exploring methods to attack the genetic defect. For example, a number of clinical trials are underway to examine the feasibility of correcting the underlying genetic defect using gene therapy where patients inhale the CF gene monthly via a nebulizer.

With advances in technology, parents and adolescents are challenged to set future goals that may include college, careers, social relationships, and marriage. Concurrently, they are faced with increasing morbidity and higher rates of CF complications as they grow older.

Nursing Care Management

Assessment of the child with CF involves comprehensive assessment of all affected systems with special focus on the pulmonary and GI systems. Pulmonary assessment is the same as described for asthma, with special attention to lung sounds, observation of cough, and evidence of decreased activity or fatigue. Gastrointestinal assessment primarily involves observing the frequency and nature of the stools and abdominal distention. The nurse should be alert to evidence of growth failure or failure to thrive (e.g., weight loss, muscle wasting, pallor, anorexia, decreased activity [from baseline norm]). Family members are interviewed to determine the child's eating and elimination habits and confirm a history of frequent respiratory tract infections or bowel obstruction in infancy.

The nurse assesses the newborn for feeding and stooling patterns, which may indicate a potential problem, such as meconium ileus. The nurse also participates in diagnostic testing, such as the initial newborn screening, immunoreactive trypsinogen, DNA analysis, or sweat chloride test.

The uncertainty, fear, and initial shock associated with the diagnosis are overwhelming to parents. They must face the impact of the chronic, life-threatening nature of the disease and the prospect of intensive treatment, for which they must assume a major part of the responsibility and for which they may be ill prepared. They often fear that they will be unable to provide the care the child needs. They need careful explanations of the disease, how it might affect their family, and what they can do to provide the best possible care for their child. One of the most difficult aspects of the diagnosis is the implications inherent in its etiology (i.e., the recognition that each parent contributed the gene responsible for the defect).

Hospital Care

Most patients with CF require hospitalization for treatment of pulmonary infection (exacerbation of their pulmonary symptoms), uncontrolled diabetes, or a coexisting medical problem that cannot be treated on an outpatient basis. Patients with CF may require contact isolation for their own protection and should wear a mask in communal areas of the hospital.

When the child with CF is hospitalized for diagnosis or treatment of pulmonary complications, aerosol therapy, chest percussion therapy, and postural drainage are instituted or continued. Respiratory therapists often initiate, supervise, and provide these treatments; however, it is the nurse's responsibility to monitor the patient's tolerance to the procedure and evaluate the effectiveness of the procedure in relation to treatment goals. The nurse may at times administer aerosol therapy, perform chest percussion and postural drainage, assist with ACTs such as the mechanical vest, and teach breathing exercises. Planning ACT so that it does not coincide with meals is difficult in the hospital setting but is essential for the effectiveness of this treatment.

Nursing assessments, including observation of respiratory pattern, work of breathing, and lung auscultation, are vital. Noninvasive pulse oximetry provides valuable data about the patient's oxygenation status.

Supplemental oxygen therapy is administered to the child with mild or moderate respiratory distress.

One of the nursing challenges in the care of the child with CF is encouraging compliance with the therapeutic regimen, which often involves taking a significant number of medications, including pancreatic enzymes; vitamins A, D, E, and K; oral antifungals for *Candida* infection; antihistamines; antiinflammatory agents; and oral antibiotics. This may be overwhelming to the child. Factor in multiple inhaled bronchodilators, ACT and aerosol treatments, potential blood glucose monitoring and insulin administration, various other medications, and increased mucus production during the acute phase, and it is common for the child with CF to rebel and be uncooperative with the prescribed regimen. Gentle coaxing, positive reinforcement, and frank negotiation may be required to enlist cooperation for effective therapy compliance.

The diet for the child with CF represents another challenge; careful planning using a pediatric dietitian with the family and child's input may help decrease the loss of appetite and weight loss that are often part of the condition. With infection and increased lung involvement, the child's appetite tends to diminish, and eventually it can become a challenge to provide appropriate nutrition due to failing appetites. Age-appropriate nutrition education with specific nutritional goals for patients with CF may increase compliance with prescribed enzyme therapy and nutritional supplements.

When dietary intake fails to meet the child's needs for growth, enteral feedings or supplements may be considered. These feedings may be administered via an enteric tube during the night to minimize the disruption of daily activities, including school. A low-profile gastrostomy tube affords the child few activity restrictions and minimum disruption of body image in comparison to an NG tube or conventional gastrostomy tube. The child and parents are encouraged to perceive this therapy not as a last-ditch effort but as an adjunct therapy to maintain optimum growth and prevent excessive weight loss. In some cases, the nurse shows adolescents how to insert a NG tube for nighttime supplemental feedings; the tube may then be removed in the morning.

The child needs support during the many treatments and tests that are a part of the hospitalization. Vascular access (e.g., blood test, IV fluids and medications) are almost always a part of the acute care treatment, and the child soon associates hospitalization with these stress-provoking procedures. Depression, anxiety, and disturbed self-image may occur in children and adolescents with CF. Older adolescents and young adults are especially prone to depression due to the realization of the poor prognosis and unmet life expectations and goals.

Providing support to both the child and the family is essential. The progressive nature of the disease makes each illness requiring hospitalization a potentially life-threatening event. Skilled nursing care and sympathetic attention to the emotional needs of the child and family help them cope with the stresses associated with repeated respiratory tract infections and hospitalizations.

Home Care

Most children and adolescents with CF can be managed at home. The goals of care include normalization of daily activities, including school and peer involvement. The care plan should be flexible so that family activities are disrupted as little as possible. Parents may initially require assistance in finding and contacting durable medical equipment companies that will provide home care equipment. They also need opportunities to learn how to use the equipment and to solve problems they may encounter while delivering therapy at home (see Chapter 19).

Patients and family members need education about the preferred diet of nutritious meals with tolerated fat, increased protein and carbohydrate, and the administration of pancreatic enzymes and nutritional supplements. It is important to stress to parents that the enzymes, in the amount regulated to the child's needs, should be administered at the beginning of all meals and snacks. For enteral feeds administered overnight, enzymes are generally administered at the start and finish of the feeds.

One of the most important aspects of educating parents for home care is teaching ACTs. The success of a therapy program depends on conscientious performance of these treatments regularly as prescribed. The number of times these therapies are performed each day is determined on an individual basis, and often parents readily learn to adjust the number and intensity of the treatments to the child's needs. For pulmonary infection, home IV antibiotics may be prescribed. Home IV care may be preferred for willing and competent families; however, this option depends on a number of factors, including availability of an agency with adequate staff to perform multiple home antibiotic infusions, willingness of the family to assist with infusions, and adherence to therapy at home. With use of venous access devices such as PICC lines or vascular access devices, the parents and child learn the correct technique of direct administration into the IV line. Families also need information about medications and possible side effects.

The child diagnosed with CFRD should be educated on self–blood glucose monitoring, insulin therapy, diet control, and possible related complications. Follow-up with a pediatric endocrinologist is recommended.

Children and adolescents with CF should receive routine primary care with special attention to diet, growth and development, and immunizations. Primary care providers should be alert to any weight loss or flattening in the growth curve associated with loss of appetite, which could indicate a pulmonary exacerbation in children with CF. Anticipatory guidance concerning issues of discipline, how to incorporate aspects of the treatment regimen into the school environment, and delayed pubertal development is also an important consideration for the primary care provider. Home palliative care for the child or adolescent with CF who is in the terminal stages may be carried out with the assistance of hospice (see Chapter 17).

The nurse can assist the family in contacting resources that provide help to families with affected children. Various special child health services, many local clinics, private agencies, service clubs, and other community groups often offer equipment and medications either free or at reduced rates. The Cystic Fibrosis Foundation[f] has chapters throughout the United States that provide education and services to families and professionals.

Family Support

One of the most challenging aspects of providing care for a child or adolescent with CF is meeting the emotional needs of the child and family. The diagnosis, treatment, and prognosis for CF are often associated with many problems and frustrations. The diagnosis can evoke feelings of guilt and self-recrimination in parents.

The long-range problems for an infant, child, or adolescent with CF are those encountered in any chronic illness (see Chapter 17). Both the child and the family must make many adjustments, the success of which depends on their ability to cope and on the quality and quantity

[f]4550 Montgomery Avenue, Suite 1100N, Bethesda, MD 20814; 301-951-4422 or 800-344-4823; http://www.cff.org. In Canada: Canadian Cystic Fibrosis Foundation, 2323 Yonge St., Suite 800, Toronto, ON M4P 2C9; 800-378-2233 (toll-free in Canada only); http://www.cysticfibrosis.ca.

of support they receive from outside sources. The combined efforts of various health professionals are needed to provide the most comprehensive services to families. It is often the nurse who assesses the home situation, organizes and coordinates these services, and collects the data needed to evaluate the effectiveness of the services.

The persistent need for treatment several times a day places tremendous strain on the family. Children often balk at these treatments, and parents are placed in the position of insisting on adherence. The stress and anxiety related to this routine may produce feelings of resentment in both the child and the family members. When possible, occasional trusted respite care should be available to allow parents to leave the situation for short periods without undue anxiety about the child's welfare.

The affected child or adolescent may become resentful about the disease, its relentless routine of therapy, and the necessary curtailment it places on activities and relationships. The child's activities are interrupted or built around treatments, medications, and diet. This imposes hardships and influences the child's quality of life. The nurse should encourage the child to attend school and join age-appropriate peer groups to live as normally and productively as possible. Sports are often an important part of the child's and adolescent's life; interaction with peers includes valuable life experiences, especially for adolescents. The child or adolescent with CF should be encouraged to participate in sports activities in as much as physical and pulmonary health allows. Exercise is encouraged to increase pulmonary vital capacity, promote muscle development, and enhance cardiovascular function.

The nurse should monitor adolescents with CF for signs of eating disturbances. The need for high calorie consumption along with early satiety and a potential body image disorder leave adolescents vulnerable to eating disorders (Quick, Byrd-Bredbenner, & Neumark-Sztainer, 2013). In addition, depression in CF patients has been associated with worse health outcomes, less adherence, and decreased quality of life (Smith, Georgiopoulos, & Quittner, 2016). As the disease progresses, however, family stress should be expected, and the patient may become angry and noncompliant. It is important for the nurse to recognize the family's changing needs and the grief they may experience as the CF worsens. Families should be made aware of resources for counseling. Patients need to be guided toward activities that enable them to express anger, sorrow, and fear without guilt.

Transition to Adulthood

As life expectancy continues to rise for children and adolescents with CF, issues related to marriage, sexuality, childbearing, and career choice become more pressing. Males must be informed at some point that they will often be unable to produce offspring. It is important that the distinction be made between sterility and impotence. Normal sexual relationships can be expected. Female patients may be able to bear children but should be informed of the possible deleterious effects on the respiratory system created by the burden of pregnancy. Women with CF who become pregnant have an increased incidence of premature labor and delivery and low birth weight in the infant. However, favorable nutritional status and pulmonary function are positively correlated with favorable pregnancy outcomes, therefore adequate nutritional status and pulmonary status should be reinforced during pregnancy. Women with CF also need to know that their children will be carriers of the CF gene; therefore genetic counseling for those planning to have children is essential. Adolescent females may need counseling on the use of oral contraceptives and other contraceptive options.

Adolescents with CF are encouraged to take personal ownership and management of the illness to maximize their life's potential. Many adolescents and young persons with the illness enroll in college or vocational and technical training school and complete degrees either by distance learning or by attending a local school. Young people should set life goals and live normal lives to the extent that their illness allows.

Life as an independent adult should be encouraged for children with CF. From the time that children can take partial responsibility for their own care (e.g., ACT, taking pancreatic enzymes), independence and accountability should be fostered. Although the prognosis for these children has improved, many will need continued support as they cope with the demands of surviving with CF.

Anticipatory grieving and other aspects related to care of a child with a terminal illness are also part of nursing care. It is important to prepare the child and family members for end-of-life decisions and care when appropriate. Families may need information about specific interventions such as hospice (see Chapter 17).

OBSTRUCTIVE SLEEP-DISORDERED BREATHING

Pediatric obstructive sleep-disordered breathing reportedly affects approximately 600,000 children 5 to 19 years old in the United States (Weiss & Owens, 2018). Sleep-disordered breathing problems in this spectrum range from partial obstruction of the upper airway to continuous episodes of complete upper airway obstruction, with the most severe form being obstructive sleep apnea (OSA) (Owens, 2020).

Obstructive sleep apnea is defined by the American Thoracic Society (1996) as a disorder of breathing during sleep with prolonged partial upper airway obstruction and/or complete obstruction that disrupts normal respiration during sleep and normal sleep patterns. Adenotonsillar hypertrophy is a common cause of OSA, but tonsil size does not correlate with the degree of OSA (Owens, 2020). Other causes of OSA include allergies associated with chronic rhinitis or nasal obstruction, craniofacial abnormalities, gastroesophageal reflux, nasal septal deviation, and cleft palate repair (Owens, 2020).

Common OSA symptoms include nightly snoring, breathing pauses, choking or gasping on arousal, disturbed sleep patterns, secondary enuresis, daytime sleepiness, and daytime neurobehavioral problems (Owens, 2020). OSA is to be distinguished from primary snoring, which is snoring without obstructive apnea, or abnormalities in gas exchange. If left untreated, OSA may result in complications such as growth failure, cor pulmonale, hypertension, poor attention span, behavioral problems (impulsiveness, hyperactivity, rebelliousness, and aggression), attention-deficit/hyperactivity disorder, hypertension, cardiac ventricle dysfunction, and death.

The diagnosis of OSA is made by an overnight sleep study (polysomnography), which provides evidence of sleep disturbance, respiratory pauses, and changes in oxygenation. The six-channel polysomnography can be performed in children of all ages with videotaping or audiotaping. Polysomnography can distinguish between OSA and primary snoring (Owens, 2020).

Adenotonsillectomy is a common treatment for OSA in children with adenotonsillar hypertrophy (Owens, 2020). However, evidence indicates that this procedure may not be as successful in children with obesity as previously reported (Boudewyns, Abel, Alexopoulos, et al., 2017).

CPAP and BiPAP (cycles between high and low pressure) may be helpful in older children with OSA whose condition persists after surgical intervention or in children who are not good candidates for surgical intervention. These long-term therapies require frequent assessments to evaluate the required amount of pressure and the overall effectiveness of the intervention.

Nursing care of the child with OSA involves early detection by observation of the infant's or child's sleep patterns, active participation

in the diagnostic polysomnography, observation of oxygenation and vital signs, application of CPAP when indicated, and monitoring the patient's response to diagnostic therapy. Counseling families of children with OSA may involve dietary counseling for exercise programs and weight management, use of the CPAP or BiPAP equipment, and direct postoperative care after the surgical intervention of tonsillectomy or adenoidectomy. Some children may resist wearing the CPAP or BiPAP devices. Gentle coaxing, patience, reassurance, and gradually building up the duration of time on the therapies may help the child's adjustment to these devices.

RESPIRATORY EMERGENCY

RESPIRATORY FAILURE

Effective pulmonary gas exchange requires clear airways, normal lungs and chest wall, and adequate pulmonary circulation. Anything that affects these functions or their relationships can compromise respiration. In general, the term respiratory insufficiency is applied to two conditions: when there is increased work of breathing, but gas exchange function remains near normal and when normal blood gas tensions cannot be maintained, and hypoxemia and acidosis develop secondary to carbon dioxide retention.

Respiratory failure is the inability of the respiratory system to maintain adequate gas exchange. This process involves pulmonary dysfunction that generally results in impaired alveolar-capillary gas exchange, which can lead to hypoxemia or hypercapnia. Respiratory arrest is the complete cessation of respiration. Respiratory failure is the most common cause of cardiopulmonary arrest in children.

Apnea is generally defined as cessation of breathing for more than 20 seconds or for a shorter period when associated with hypoxemia or bradycardia (Kline-Tilford, Sorce, Levin, et al., 2013; Krishnan, Raghunandhan, Kumar, et al., 2014). Apnea can be (1) central, in which both airflow and chest wall movement are absent; (2) obstructive, in which airflow is absent but chest wall motion is present; and (3) mixed, in which both central and obstructive components are present.

Respiratory dysfunction may have an abrupt or an insidious onset. Conditions that predispose to respiratory failure are obstructive lung disease (increase resistance to airflow), restrictive lung disease (impaired lung expansion), primary inefficient gas transfer (respiratory control dysfunction or diffusion defect), or a combination of these disorders. Respiratory failure can occur as an emergency or may be preceded by gradual and progressive deterioration of respiratory function. Most clinical manifestations are nonspecific and are affected by variations among individual patients and differences in the severity and duration of inadequate gas exchange.

Recognition of Respiratory Failure

Respiratory failure that occurs as a result of acute obstruction of a major airway or cardiac arrest is sudden and readily apparent. Gradual and more covert development of signs and symptoms is less easily recognized. Evaluation of respiratory adequacy is based on both clinical assessment and laboratory studies.

Unless respiratory arrest occurs suddenly, signs of hypoxemia and hypercapnia are usually subtle in their development, becoming more obvious as respiratory failure progresses. In clinical situations in which impaired ventilation can be anticipated or clinical manifestations indicate impending hypoxemia, serial measurements of blood gases should be obtained and monitored to detect impending respiratory failure, and therapy should be implemented before respiratory acidosis becomes extreme.

BOX 21.18 Clinical Manifestations of Respiratory Failure

Cardinal Signs
- Restlessness
- Tachypnea
- Tachycardia
- Diaphoresis

Early but Less Obvious Signs
- Mood changes, such as euphoria or depression
- Headache
- Altered depth and pattern of respirations
- Hypertension
- Exertional dyspnea
- Anorexia
- Increased cardiac output and renal output
- Central nervous system symptoms (e.g., decreased efficiency, impaired judgment, anxiety, confusion, restlessness, irritability, depressed level of consciousness)
- Nasal flaring
- Retractions
- Expiratory grunt
- Wheezing or prolonged expiration

Signs of More Severe Hypoxia
- Depressed respirations
- Hypotension or hypertension
- Altered vision
- Bradycardia
- Arrhythmias
- Somnolence
- Stupor
- Coma
- Dyspnea
- Cyanosis, peripheral or central

Nursing observation and judgment are vital to the recognition and successful management of respiratory failure. Nurses must be able to assess a situation and initiate appropriate action within moments. Clinical manifestations of respiratory failure are listed in Box 21.18.

Therapeutic Management

The interventions used in the management of respiratory failure are often dramatic, requiring special skills and emergency procedures. If respiratory arrest occurs, the primary objectives are to recognize the situation and immediately initiate resuscitative measures, such as opening the airway and positioning, administering supplemental oxygen and positive pressure ventilation, suctioning if needed, performing cardiopulmonary resuscitation (CPR), and intubating if the child's status continues to deteriorate.

When the situation is not an arrest, the suspicion of respiratory failure is confirmed by assessment, and the severity is defined by capillary or arterial blood gas analysis. Interventions such as opening the airway, administering supplemental oxygen, positioning, stimulation, suctioning, CPAP, BiPAP, or early intubation may avert an arrest. When the severity is established, an attempt is made to determine the underlying cause by thorough evaluation.

The principles of management are to (1) maintain ventilation and maximize oxygen delivery, (2) correct hypoxemia and hypercapnia, (3) treat the underlying cause, (4) minimize extrapulmonary organ

failure, (5) apply specific and nonspecific therapy to control oxygen demands, and (6) anticipate complications. Monitoring the patient's condition closely is critical.

Nursing Care Management

Nursing observation and judgment are vital to successful management of respiratory failure. The nurse monitors the child to anticipate respiratory failure, determine a course of action, and assess the patient's response to treatment. Often the child is transferred to a pediatric ICU. The child is kept as comfortable as possible, and observation is geared toward general appearance, responsiveness, pulse oximetry, and vital signs. The child is positioned to allow maximum lung expansion and comfort, such as sitting upright or leaning forward (depending on respiratory status). The nurse closely monitors the child's cardiac and respiratory status by observation and by electronic means.

Children who are in respiratory distress often relax after an airway is established and their respiratory effort is assisted. However, they are anxious and frightened when they are unable to communicate; therefore it is important to effectively manage the child's anxiety. This may be accomplished initially with mild sedation until the child's ventilatory status has improved. Assistive communication devices should be offered as appropriate to age and development (e.g., electronic pads, paper and pen, picture boards).

Parents are often concerned about the life-threatening implications generated by the need for the breathing tube (endotracheal tube or tracheostomy) and the possible long-term residual effects on the brain and on the child's psychologic status. For families whose child has a respiratory arrest, support focuses on keeping the family informed of the child's status and helping them cope with a near-death experience or an actual death (see Chapter 17). Knowing that their child requires CPR is a frightening and often overwhelming experience for parents. Uncertainty about the outcome regarding morbidity and mortality is a primary concern.

Regardless of whether an institution permits parental presence during CPR, nurses must consider the needs, fears, and concerns of family members during this situation. If family presence is not permitted during CPR, nurses should arrange for someone to remain with the family. After the child's recovery or death, the family will continue to need support and thorough medical information regarding life-saving measures, the prognosis if the child survives, and the cause of death if the child dies.

CARDIOPULMONARY RESUSCITATION

Cardiac arrest in children occurs more frequently due to prolonged hypoxemia secondary to inadequate oxygenation, ventilation, and circulation (shock) than due to a cardiac condition. Some causes of cardiac arrest are injuries, suffocation (e.g., FB aspiration), smoke inhalation, anaphylaxis, apparent life-threatening event, or infection. Respiratory arrest is associated with a better survival rate than cardiac arrest. After cardiac arrest occurs, the outcome of resuscitative efforts is poor.

Apnea signals the need for rapid, vigorous action to prevent cardiac arrest. In such situations, nurses must initiate action immediately and notify emergency personnel. In the hospital, emergency equipment must be available and easily accessible in all patient care areas. The status of emergency equipment must be checked at least once daily.

Outside the hospital, the first action in an emergency is to quickly assess the extent of any injury and determine whether the child is unconscious. A child who is struggling to breathe but conscious should be transported immediately to an advanced life support (ALS) facility, with the child maintaining whatever position affords the most comfort. Transportation by an emergency medical service (EMS) is recommended, as the service can institute ALS immediately or en route to a medical facility.

An unconscious child is managed with care to prevent additional trauma if a head or spinal cord injury has been sustained (see Chapter 30, Spinal Cord Injuries).

Resuscitation Procedure

Historically, the sequence for CPR was A-B-C (airway, breathing or ventilation, and chest compressions [or circulation]), but the 2010 American Heart Association guidelines changed this recommended sequence to C-A-B to reduce the amount of time to the initiation of chest compressions (Fig. 21.12). Modifications were also made to the depth of compressions, which should be at least one-third of the anteroposterior diameter of the chest (4 cm in infants and 5 cm in older children). The American Heart Association stipulates that having rescuers stop to detect a pulse is not reliable and wastes time. Instead, rescuers should start CPR if the child is unresponsive and not breathing or not breathing normally or if they failed to detect a pulse within 10 seconds. The "look, listen, and feel for breathing" practice is no longer recommended. In 2015 the American Heart Association implemented a few changes in CPR guidelines. Chest compressions should be at a rate of 100 to 120 per minute and chest compression depth should be at least 2 inches (5 cm) but not more than 2.4 inches (6 cm). Each breath should be delivered at a rate of 1 breath every 6 seconds. The American Heart Association updated the recommendation for lay rescuer or bystander compression-only CPR to include chest compressions with rescue breaths for infants and children in cardiac arrest since most pediatric arrests have an asphyxial basis that necessitates ventilation. However, if bystanders are unwilling or unable to deliver rescue breaths, the recommendation is that rescuers provide chest compressions for infants and children (American Heart Association, 2017). The American Heart Association stipulates that a manual defibrillator is preferred to an automatic external defibrillator (AED) for defibrillation of infants. The AED is used as a part of the treatment of cardiorespiratory arrest in children older than 1 year of age. If a manual defibrillator is not available, an AED equipped with a pediatric dose attenuator is preferred. If neither is available, an AED without a pediatric dose attenuator may be used (American Heart Association, 2015; Travers, Rea, Bobrow, et al., 2010). There is still limited evidence to support the safety of AED use in infants, but it may be safe and effective in this group. Appropriate-size pediatric pads must be used for small children. Health care providers are advised to give children age 1 year and older a defibrillatory shock after providing approximately five cycles of CPR (≈2 minutes of cycles of 30 compressions and 2 ventilations by the lone rescuer), provided the AED is sensitive to pediatric rhythms, the device is capable of delivering a pediatric dose of 2 to 4 joules/kg, and a shockable rhythm (usually ventricular fibrillation) is present. In a hospital situation in which weight-based defibrillation dosing is possible, manual defibrillation is the mode of choice instead of AED. When using an AED, health care providers are advised to give adults and children older than 8 years of age a defibrillatory shock within 5 minutes of collapse outside the hospital and within 3 minutes in the hospital.

If two rescuers are present, one rescuer should begin CPR while the second rescuer activates the EMS system by calling 9-1-1 and obtaining an AED. Pediatric rescuers provide five cycles of basic life support (≈2 minutes) before activating EMS; each cycle consists of 30 chest compressions and 2 ventilations. Because pediatric arrests are most commonly caused by respiratory arrest, maintaining ventilation is key.

Component	RECOMMENDATIONS		
	Adults	Children	Infants
Recognition	Unresponsive (for all ages)		
	No breathing or no normal breathing (i.e., only gasping)	No breathing or only gasping	
	No pulse palpated within 10 seconds for all ages (HCP only)		
CPR sequence*	C-A-B		
Compression rate	100 to 120 per minute		
Compression depth	At least 2 inches (5 cm) but not more than 2.4 inches (6 cm)	At least ⅓ AP diameter About 2 inches (5 cm)	At least ⅓ AP diameter About 1½ inches (4 cm)
Chest wall recoil	Allow complete recoil between compressions HCPs rotate compressors every 2 minutes		
Compression interruptions	Minimize interruptions in chest compressions Attempt to limit interrruptions to <10 seconds		
Airway	Head tilt/chin lift (HCP suspected trauma: jaw thrust)		
Compression-to-ventilation ratio (until advanced airway placed)	30:2 1 or 2 rescuers	30:2 Single rescuer 15:2 2 HCP rescuers	
Ventilations: when rescuer untrained or trained and not proficient	Compressions only		
Ventilations with advanced airway (HCP)	1 breath every 6 seconds (10 breaths/min) Asynchronous with chest compressions About 1 second per breath Visible chest rise		
Defibrillation	Attach and use AED as soon as available. Minimize interruptions in chest compressions before and after shock; resume CPR beginning with compressions immediately after each shock.		

*Excluding the newly born, in whom the etiology of an arrest is nearly always asphyxial.
NOTE: Newborn/neonatal information not included.

Fig. 21.12 Summary of basic life support maneuvers for infants, children, and adults. *AED,* Automatic external defibrillator; *AP,* anterior-posterior; *C-A-B,* chest compressions (or circulation), airway, breathing or ventilation; *CPR,* cardiopulmonary resuscitation; *HCP,* health care provider. [2018]. *Red book: 2018 report of the Committee on Infectious Diseases* [31st ed.]. Itaca, IL: American Academy of Pediatrics)

Pulse Check

During an emergent situation, palpating the pulse can be a challenge. The patient should be reassessed for a pulse after every 2 minutes of CPR. The pulse should not be assessed for longer than 10 seconds. The carotid is the most central and accessible artery in children older than 1 year of age, but the femoral pulse may also be used. An infant's short and often fat neck makes the carotid pulse difficult to palpate. Therefore, in an infant, it is preferable to use the brachial pulse, located on the inner side of the upper arm midway between the elbow and the shoulder (Fig. 21.13). Absence of a carotid or brachial pulse is considered sufficient indication to begin external cardiac massage. Lay rescuers are not taught to check the pulse but are taught to look for signs of circulation (e.g., normal breathing, coughing, air movement) in response to rescue breaths.

Chest Compression

External chest compression consists of serial, rhythmic compressions of the chest to maintain circulation to vital organs until the child achieves spontaneous vital signs or ALS can be provided. Chest compressions are always interspersed with ventilation of the lungs; however, laypersons who witness an adult cardiac arrest should perform continuous chest compressions without ventilations (American Heart Association, 2015, 2017; Berg, Hemphill, Abella, et al., 2010). For optimal compressions, it is essential that the child's spine is supported on a firm surface during compressions of the sternum and that sternal pressure is forceful but not traumatic. The child's head is positioned for optimal airway opening using the head tilt/chin lift maneuver if the cervical spine is stable and no neck injuries are present. It is essential to prevent overextension of the head of small infants because this tends to close the flexible trachea.

The placement of the fingers for compression in infants is at a point on the lower sternum just below the intersection of the sternum and an imaginary line drawn between the nipples (Fig. 21.14). Compressions on the child 1 to 8 years old are applied to the lower half of the sternum (Fig. 21.15). Sternal compression to infants is applied with two fingers on the sternum, exerting a firm downward thrust; for children, pressure is applied with the heel of one hand or two hands, depending on the child's size. American Heart Association guidelines include the addition of the

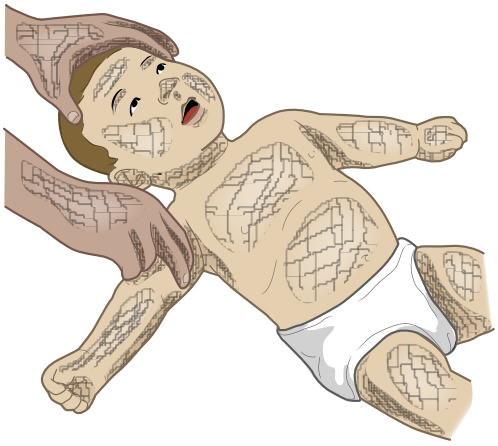

Fig. 21.13 Locating the brachial pulse in an infant. (From Proctor, B. D., Niedzwiecki, B., Pepper, J., Madero, P., & Garrels, M. [2017]. *Kinn's the medical assistant* [13th ed.]. St. Louis, MO: Elsevier.)

Fig. 21.14 Combining chest compressions with breathing in an infant.

two-thumb-encircling hands technique for chest compressions for infants when two health care providers are present (American Heart Association, 2015, 2017; Travers et al., 2010). In the two-thumb-encircling technique, one of the two rescuers places both thumbs side by side over the lower half of the infant's sternum; the remaining fingers encircle the infant's chest and support the back. The two-thumb-encircling technique is not taught to lay rescuers and is not practical for a health care provider working alone.

Lone-rescuer CPR is continued at the ratio of 2 breaths to 30 compressions for all ages until signs of recovery appear. These signs include palpable peripheral pulses, return of pupils to normal size, the disappearance of mottling and cyanosis, and possibly return of spontaneous respiration. When two rescuers are present, they should deliver 2 breaths to each 15 compressions.

Open the Airway

For effective CPR, the victim is placed on the back on a firm, flat surface using appropriate precautions. With loss of consciousness, the tongue, which is attached to the lower jaw, may relax and fall back, obstructing the airway. To open the airway, the head is positioned with a head tilt/chin lift maneuver (if stable cervical spine) by the lay rescuer. Health professionals should open the airway using either a head tilt/chin lift or a jaw thrust maneuver if an unstable cervical spine is suspected. A head tilt is accomplished by placing one hand on the victim's forehead and applying firm, backward pressure with the palm to tilt back the head. The fingers of the free hand are placed under the bony portion of the lower jaw near the chin to lift and bring the chin forward (chin lift). This supports the jaw and helps tilt the head back (Fig. 21.16).

The jaw thrust is accomplished by grasping the angles of the victim's lower jaw and lifting with both hands, one on each side, displacing the mandible upward and outward. The jaw thrust is recommended only for health care workers. In suspected neck injuries, the jaw thrust method should be used while the cervical spine is completely immobilized. After

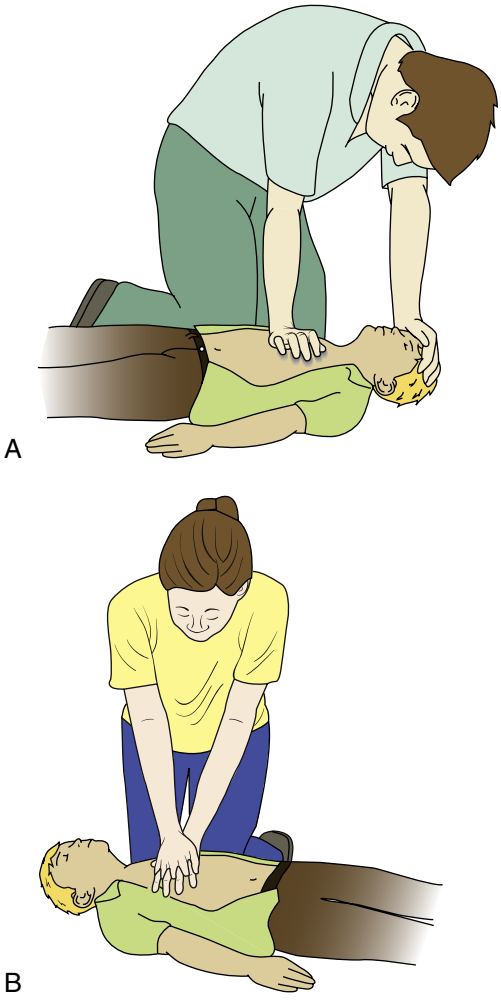

Fig. 21.15 Chest compressions in a child: **(A)** one hand for a smaller child and **(B)** two hands for a larger child.

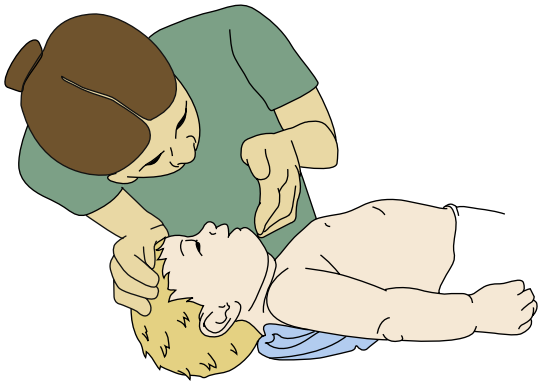

Fig. 21.16 Open the airway using the head tilt/chin lift maneuver, and check breathing.

a patent airway has been restored by removal of foreign material and secretions (if indicated) and if the child is not breathing, maintenance of the airway is continued, and rescue breathing is initiated.

Give Breaths

To ventilate the lungs in the infant (from birth to 1 year old), the bag valve mask (BVM) or operator's mouth is placed in such a way that both the mouth and the nostrils are covered (Fig. 21.17) using the E-C technique. With the BVM, the thumb and index finger of the nondominant

Fig. 21.17 Mouth-to-mouth and nose breathing for an infant.

hand secure the mask on the patient's face (forming a C), while the first three fingers of the same hand are used to lift the jaw (forming an E). If no BVM is available, children (older than 1 year old) are ventilated through the mouth while the nostrils are pinched for airtight contact.

The volume of air in an infant's lungs is small, and the air passages are considerably smaller, with resistance to flow potentially higher than in adults. The rescuer should deliver small puffs of air and assess the rise of the chest to ensure that overinflation does not occur. A gentle rise of the chest is a sufficient indicator of adequate inflation and indicates that the airway is clear. Breaths should be given over 1 second with sufficient volume to make the chest rise. If the chest does not rise, reposition the head or jaw and try again.

Medications

Medications are an important adjunct to CPR, especially with cardiac arrest, and are used during and after resuscitation in children. Medications are used to (1) correct hypoxemia, (2) increase perfusion pressure during chest compression, (3) stimulate spontaneous or more forceful myocardial contraction, (4) accelerate cardiac rate, (5) correct metabolic acidosis, and (6) suppress ventricular ectopy. In 2015 the American Heart Association changed the guidelines to report that bystanders may administer naloxone for suspected life-threatening opioid-associated emergencies.

Appropriate fluid therapy is initiated immediately in the hospital or by EMS personnel during transport (see Chapter 20, Parenteral Fluid Therapy, and Chapter 23, Shock). A complete supply of emergency medications is maintained in all EMS vehicles and on all hospital units. The supply is checked on a regular basis (usually once a day at minimum). When administering drugs during CPR (or a "code"), use a saline flush or other compatible flush solution between medications to prevent drug interactions. Document all drugs, dosages, and the time and route of administration.

AIRWAY OBSTRUCTION

Attempts at clearing the airway should be considered for (1) children in whom aspiration of an FB is witnessed or strongly suspected, and (2) unconscious, nonbreathing children whose airways remain obstructed despite the usual maneuvers to open them. When aspiration is strongly suspected, the child is encouraged to continue coughing for as long as the cough remains forceful. In a conscious choking child, attempt to relieve the obstruction only if:

- The child is unable to make any sounds.
- The cough becomes ineffective.
- There is increasing respiratory difficulty with stridor.

! NURSING ALERT

Blind finger sweeps are avoided in all infants and children.

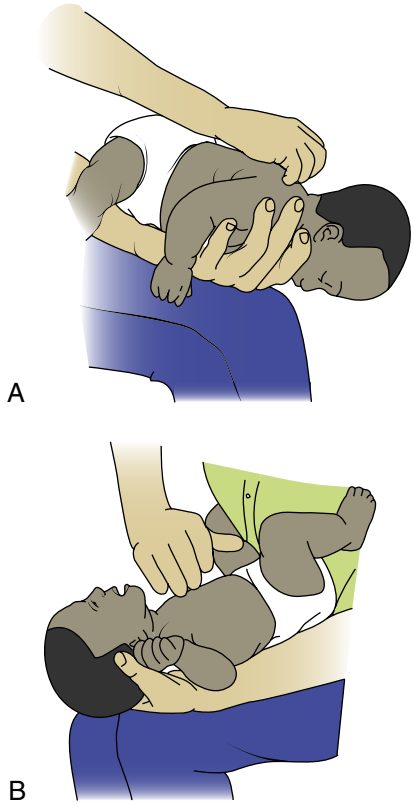

Fig. 21.18 Relief of foreign body (FB) obstruction in infant. **A,** Back blows. **B,** Chest thrusts.

Infants

A combination of back blows (over the spine between the shoulder blades) and chest thrusts (on the sternum, the same location as for chest compressions) is recommended to relieve an FB obstruction in infants (Fig. 21.18). A choking infant is placed face down over the rescuer's arm with the head lower than the trunk and the head supported. The rescuer should support the holding arm firmly against the thigh. Up to five quick, sharp back blows are delivered between the infant's shoulder blades with the heel of the rescuer's hand. Less force is required than would be applied to an adult. After delivery of the back blows, the rescuer's free hand is placed flat on the infant's back so that the infant is "sandwiched" between the two hands, making certain that the neck and chin are well supported. While the rescuer maintains support with the infant's head lower than the trunk, the infant is turned and placed supine on the rescuer's thigh, where up to five quick downward chest thrusts are applied in rapid succession in the same location as external chest compressions described for CPR. Back blows and chest thrusts are continued until the object is removed or the infant becomes unconscious. If the infant does lose consciousness, CPR should be initiated.

Children

A series of subdiaphragmatic abdominal thrusts (Heimlich maneuver) is recommended for children older than 1 year of age. The maneuver creates an artificial cough that forces air—and with it, the FB—out of the airway. The procedure is carried out with the child in a standing, sitting, or lying position (Fig. 21.19). In a conscious choking child, upward thrusts are delivered to the upper abdomen with the fisted hand at a point just below the rib cage. To prevent damage to the internal organs, the rescuer's hands should not touch the xiphoid process of the sternum or the lower margins of the ribs. Up to five thrusts are repeated in rapid succession until the FB is expelled.

Fig. 21.19 Abdominal thrusts in standing child for relief of foreign body (FB) obstruction.

The child may vomit after relief of the obstruction and should be positioned to prevent aspiration. After breathing is restored, the child should receive medical attention and be assessed for complications. If the child is coughing, allow him or her to relieve the obstruction this way.

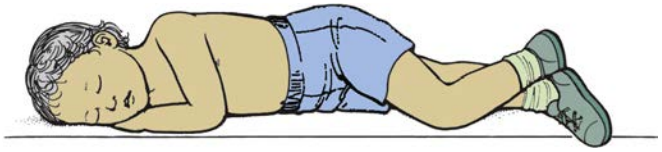

Fig. 21.20 Recovery position for a child after a respiratory emergency.

The success of the technique is primarily a result of the obstruction occurring at the end of a maximum respiration. The victim is most likely to choke on food during inspiration; therefore the tidal volume plus expiratory reserve volume is present in the lungs. When pressure is exerted on the diaphragm by the maneuver, the food bolus is ejected with considerable force by this trapped air.

If the victim is breathing or resumes effective breathing after emergency interventions, place him or her in the recovery position—move the head, shoulders, and torso simultaneously and turn onto the side. The leg not in contact with the ground may be bent and the knee moved forward to stabilize the victim (Fig. 21.20). The victim should not be moved in any way if trauma is suspected and should not be placed in the recovery position if rescue breathing or CPR is required.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A 12-year-old boy is in the urgent care clinic with a complaint of fever, headache, and sore throat. The nurse performs a complete history and physical and obtains a throat swab for rapid antigen testing. A diagnosis of group A beta-hemolytic streptococcus (GABHS) pharyngitis is confirmed. The nurse's assessment findings are listed below. **Select the assessment findings that reflect the diagnosis of GABHS. Select all that apply.**
   - **A.** Tonsils are inflamed and covered with exudate
   - **B.** Temperature 100.4° F (38° C)
   - **C.** Headache for the past 2 days
   - **D.** Small, <.5cm cervical lymph nodes
   - **E.** Constipation for the past 3 days
   - **F.** Throat pan increased when swallowing
   - **G.** Abdomen painful to touch

2. A 5-year-old girl is recovering from a tonsillectomy and adenoidectomy and is being discharged home with her mother. She is taking oral fluids but says it still hurts to swallow. She has no fever. The nurse is preparing to discharge the patient. Home care instructions for the mother would include which of the following? **Select all that apply.**
   - **A.** Observe the child for ability to swallow.
   - **B.** Encourage the child to take sips of cool, clear liquids.
   - **C.** Administer codeine elixir as necessary for throat pain.
   - **D.** Administer an analgesic such as acetaminophen for pain.
   - **E.** Observe the child for restlessness or difficulty breathing.
   - **F.** Encourage the child to cough every 4 to 5 hours to prevent pneumonia.

3. A 4-year-old girl is seen in the urgent care clinic with the following history and symptoms: sudden onset of severe sore throat after going to bed, drooling and difficulty swallowing, axillary temperature of 102.2°F (39°C), clear breath sounds, and absence of cough. The child appears anxious and is flushed. Her pulse if 149 beats/min and respirations are 36 breaths/min. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**
   Based on these symptoms and history, the nurse anticipates a diagnosis of:_____1_____ hat is most frequently caused by a _____2_____ infection. When considering the diagnosis, examination of the throat with a _____3_____ is contraindicated without experienced personnel and equipment available for immediate intubation or tracheostomy

Options for 1	Options for 2	Options for 3
Acute Laryngotracheobronchitis	Fungal	flashlight
Acute Tracheitis	Protozoic	tongue depressor
Acute Epiglottitis	Bacterial	microscope
Acute Spasmodic Laryngitis	Idiopathic	otoscope light

4. A 2-month-old, formerly healthy infant boy, born at term is seen in the urgent care clinic with intercostal retractions, respiratory rate of 62 breaths/min, heart rate of 128 beats/min, refusal to breastfeed, abundant nasal secretions, and a pulse oximeter reading of 88% in room air. The diagnosis of respiratory syncytial virus (RSV) is made, a bronchodilator is administered, and intravenous (IV) bolus of fluids is given. The infant's oxygen saturation (SpO_2) remains 95% on room air, and the respiratory rate is 54 breaths/min, with intercostal retractions; heart rate is 120 beats/min. After overnight observation the infant is being discharged home. The nurse provides which of the following home care instructions for this infant? **Select all that apply.**

A. Continue breastfeeding infant.
B. Keep the infant out of day care or nursery.
C. Discontinue breastfeeding and administer Pedialyte for 24 hours.
D. Observe infant for labored breathing or apnea (cessation of breathing).
E. Instil normal saline drops in both nares and suction before feeding and before placing to sleep.
F. Place infant to sleep on his side with the head of bed slightly elevated to facilitate breathing.

DISTRIBUTION OF BODY FLUIDS

The distribution of body fluids, or **total body water (TBW)**, involves the presence of **intracellular fluid (ICF)** and **extracellular fluid (ECF)**. Water is the major constituent of body tissues, and the TBW in an individual ranges from 45% (in late adolescence) to 75% (in term newborn) of total body weight.

The ICF refers to the fluid contained within the cells, whereas the ECF is the fluid outside the cells. The ECF is further broken down into several components: intravascular (contained within the blood vessels), interstitial (surrounding the cell; the location of most ECF), and transcellular (contained within specialized body cavities such as cerebrospinal, synovial, and pleural fluid). In the newborn, about 50% of the body fluid is contained within the ECF, whereas 30% of the toddler's body fluid is contained within the ECF.

Body water is important in body function not only because of its abundance but also because it is the medium in which body solutes are dissolved and all metabolic reactions take place. Because even small alterations in fluid composition affect these metabolic processes, precise regulation of the volume and composition of the fluid is essential. In healthy individuals, body water remains singularly constant, but marked alterations in either its volume or distribution, which occur in many disease states, can produce severely damaging physiologic consequences.

WATER BALANCE

Under normal conditions the amount of water ingested closely approximates the amount of urine excreted in a 24-hour period, and the water in food and from oxidation approximates the amount lost in feces and through evaporation. In this way, the body maintains equilibrium.

Mechanisms of Fluid Movement

Water is retained in the body in a relatively constant amount and, with few exceptions, is freely exchangeable among all body fluid compartments. The proximity of the extravascular compartment to the cells allows for continuous change in volume and distribution of fluids, largely determined by solutes (especially sodium) and physical forces. Transport mechanisms are the basis for all activity within the cells, and because the cells have limited ability to store materials, movement in and out of cells must be rapid. Internal control mechanisms are responsible for distribution and maintenance of fluid balance.

Maintaining Water Balance

Maintenance water requirement is the volume of water needed to replace obligatory fluid loss, such as that from insensible water loss (through the skin and respiratory tract), evaporative water loss, and losses through urine and stool formation. The amount and type of these losses may be altered by disease states such as fever (with increased sweating), diarrhea, gastric suction, and pooling of body fluids in a body space (often referred to as **third spacing**).

Nurses should be alert for altered fluid requirements in various conditions:

Increased requirements:

- Fever (add 12% per rise of 1°C)
- Vomiting, diarrhea
- High-output kidney failure
- Diabetes insipidus
- Diabetic ketoacidosis
- Burns
- Shock
- Tachypnea
- Radiant warmer (preterm infant)
- Phototherapy (infants)
- Postoperative bowel surgery (e.g., gastroschisis)

Decreased requirements:

- Heart failure
- Syndrome of inappropriate antidiuretic hormone
- Mechanical ventilation
- After surgery
- Oliguric renal failure
- Increased intracranial pressure

Basal maintenance calculations for required body water are based on the body's requirements for water in a normometabolic state, at rest; estimated fluid requirements are then increased or decreased from these parameters based on increased or decreased water losses, such as with elevated body temperature or congestive heart failure. Daily maintenance fluid requirements are listed in Table 22.1.

TABLE 22.1 Daily Maintenance Fluid Requirements[a]

Body Weight	Amount of Fluid per Day
1-10 kg	100 ml/kg
11-20 kg	1000 ml plus 50 ml/kg for each kg >10 kg
>20 kg	1500 ml plus 20 ml/kg for each kg >20 kg

[a]Not appropriate for neonatal use.

Maintenance fluids contain both water and electrolytes and can be estimated from the child's age, body weight, degree of activity, and body temperature. **Basal metabolic rate (BMR)** is derived from standard tables and adjusted for the child's activity, temperature, and disease state. For example, for afebrile patients at rest, the maintenance water requirement is approximately 100 ml for each 100 kcal expended. Children with fluid losses or other alterations require adjustment of these basic needs to accommodate abnormal losses of both water and electrolytes as a result of a disease state. For example, insensible losses increase when basal expenditure increases by fever or hypermetabolic states. Hypometabolic states, such as hypothyroidism and hypothermia, decrease the BMR.

CHANGES IN FLUID VOLUME RELATED TO GROWTH

The percentage of TBW varies among individuals, and in adults and older children it is related primarily to the amount of body fat. Consequently, females, who have more body fat than males, and obese persons tend to have less water content in relation to weight.

The fetus is composed primarily of water, with little tissue substance. As the organism grows and develops, a progressive decrease occurs in TBW, with the fastest rate of decline taking place during fetal life. The changes in water content and distribution that occur with age reflect the changes that take place in the relative amounts of bone, muscle, and fat making up the body. At maturity the percentage of TBW is somewhat higher in the male than in the female and is probably a result of the differences in body composition, particularly fat and muscle content.

Another important aspect of growth change as it corresponds to water distribution is related to the ICF and ECF compartments. In the fetus and prematurely born infant, the largest proportion of body water is contained in the ECF compartment. As growth and development proceed, the proportion within the ECF compartment decreases as the ICF and cell solids increase. The ECF diminishes rapidly from approximately 40% of body weight at birth to less than 30% at 1 year of age. The different effects on males and females become apparent at puberty.

Water Balance in Infants

Because of several characteristics, infants and young children have a greater need for water and are more vulnerable to alterations in fluid and electrolyte balance. Compared with older children and adults, they have a greater fluid intake and output relative to size. Water and electrolyte disturbances occur more frequently and more rapidly, and children adjust less promptly to these alterations.

The fluid compartments in the infant vary significantly from those in the adult, primarily because of an expanded extracellular compartment. The ECF compartment constitutes more than half of the TBW at birth and has a greater relative content of extracellular sodium and chloride. The infant loses a considerable amount of fluid in the first few days after birth and still maintains a larger amount of ECF than the adult until about 2 to 3 years of age. This contributes to greater and more rapid water loss during this age period.

Fluid losses create compartment deficits that reflect the duration of dehydration. In general, approximately 60% of fluid is lost from the ECF, and the remaining 40% comes from the ICF. The amount of fluid lost from the ECF increases with acute illness and decreases with chronic loss.

Fluid losses may be divided into insensible, urinary, and fecal losses and vary with the patient's age. Approximately two-thirds of **insensible water loss** occurs through the skin, and the remaining one-third is lost through the respiratory tract. Environmental heat and humidity, skin integrity, body temperature, and respiratory rate all influence insensible fluid loss. Infants and children have a much greater tendency to become highly febrile than do adults. Fever increases insensible water loss by approximately 7 ml/kg/24 h for each 1°F rise in temperature above 99°F (37.2°C). Fever and increased surface area relative to volume both contribute to greater insensible fluid losses in young patients.

Body Surface Area

The infant's relatively greater **body surface area (BSA)** allows larger quantities of fluid to be lost through the skin. It is estimated that the BSA of the premature neonate is five times more, and that of the newborn is two or three times more, than that of the older child or adult. The proportionately longer gastrointestinal (GI) tract in infancy is also a source of relatively greater fluid loss, especially from diarrhea.

Metabolic Rate

The rate of metabolism in infancy is significantly higher than in adulthood because of the larger BSA in relation to the mass of active tissue. Consequently, infants have a greater production of metabolic wastes that the kidneys must excrete. Any condition that increases metabolism causes greater heat production, with its concomitant insensible fluid loss and an increased need for water for excretion. The BMR in infants and children is higher to support cellular and tissue growth.

Kidney Function

The infant's kidneys are functionally immature at birth and are therefore inefficient in excreting waste products of metabolism. Of particular importance for fluid balance is the inability of the infant's kidneys to concentrate or dilute urine, to conserve or excrete sodium, or to acidify urine. Therefore the infant is less able to handle large quantities of solute-free water than is the older child and is more likely to become dehydrated when given concentrated formulas or overhydrated when given excessive free water or dilute formula.

Fluid Requirements

As a result of these characteristics, infants ingest and excrete a greater amount of fluid per kilogram of body weight than do older children. Because electrolytes are excreted with water and the infant has limited ability for conservation, maintenance requirements include both water and electrolytes. The daily exchange of ECF in the infant is much greater than that of older children, which leaves the infant little fluid volume reserve in dehydrated states. Fluid requirements depend on hydration status, size, environmental factors, and underlying disease.

DISTURBANCES OF FLUID AND ELECTROLYTE BALANCE

Disturbances of fluids and their solute concentration are closely interrelated. Alterations in fluid volume affect the electrolyte component, and changes in electrolyte concentration influence fluid movement. Because intracellular water and electrolytes move to and from the ECF compartment, any imbalance in the ICF is reflected by an imbalance in

the ECF. Disturbances in the ECF involve either an excess or a deficit of fluid or electrolytes. Of these, fluid loss occurs more frequently.

Sodium is the chief solute in ECF and the primary determinant of ECF volume. It is considered a unique electrolyte in that water balance determines sodium concentration; when water is lost and sodium concentration becomes elevated, compensatory mechanisms in the kidney stop antidiuretic hormone (ADH) secretion so that water is retained. The thirst mechanism (not fully functional in infants) is also stimulated so that water is replaced, thus increasing the total body water content and returning sodium to a normal level (Greenbaum, 2020). Sodium depletion in diarrhea occurs in two ways: out of the body in stool and into the ICF compartment to replace potassium to maintain electrical equilibrium. Potassium is found primarily inside the cell (intracellular), but small amounts are also found in ECF.

Depletion of ECF, usually caused by gastroenteritis, is one of the most common problems encountered in infants and children. Until modern techniques for fluid replacement were perfected, gastroenteritis was one of the chief causes of infant mortality. Fluid and electrolyte problems related to specific diseases and their management are discussed throughout the book where appropriate. The major fluid disturbances, their usual causes, and clinical manifestations are listed in Table 22.2; the most common fluid disturbances, dehydration and edema, are discussed in the following sections. Problems of fluid and electrolyte disturbance always involve both water and electrolytes; therefore replacement includes administration of both, calculated based on ongoing processes and laboratory serum electrolyte values.

In conditions that involve alterations in the amount and composition of body fluid compartments, nurses consider many factors

TABLE 22.2 Disturbances of Select Fluid and Electrolyte Balance

Mechanisms and Situations	Manifestations	Management and Nursing Care
Water Depletion		
Failure to absorb or reabsorb water Complete or sudden cessation of intake or prolonged diminished intake: • Neglect of intake by self or caregiver—confused, psychotic, unconscious, or helpless • Loss from gastrointestinal tract—vomiting, diarrhea, nasogastric suction, fistula Disturbed body fluid chemistry: inappropriate ADH secretion Excessive renal excretion: glycosuria (diabetes) Loss through skin or lungs: • Excessive perspiration or evaporation—febrile states, hyperventilation, increased ambient temperature, increased activity (basal metabolic rate) • Impaired skin integrity—transudate from injuries • Hemorrhage Iatrogenic: • Overzealous use of diuretics • Improper perioperative fluid replacement • Use of radiant warmer or phototherapy	General symptoms dependent to some extent on proportion of electrolytes lost with water Thirst Variable temperature—increased (infection) Dry skin and mucous membranes Poor skin turgor Poor perfusion (decreased pulse, slowed capillary refill time) Weight loss Fatigue Diminished urinary output Irritability and lethargy Tachycardia Tachypnea Altered level of consciousness, disorientation Laboratory findings: • High urine specific gravity • Increased hematocrit • Variable serum electrolytes • Variable urine volume • Increased blood urea nitrogen • Increased serum osmolality	Provide replacement of fluid losses commensurate with volume depletion. Provide maintenance fluids and electrolytes. Determine and correct cause of water depletion. Measure fluid intake and output. Monitor vital signs. Monitor urine specific gravity. Monitor body weight. Monitor serum electrolytes.
Water Excess		
Water intake in excess of output: • Excessive oral intake • Hypotonic fluid overload • Plain water enemas Failure to excrete water in presence of normal intake: • Kidney disease • Congestive heart failure • Malnutrition	Edema: • Generalized • Pulmonary (moist rales or crackles) • Intracutaneous (noted especially in loose areolar tissue) Elevated central venous pressure Hepatomegaly Slow, bounding pulse Weight gain Lethargy Increased spinal fluid pressure Central nervous system manifestations (seizures, coma) Laboratory findings: • Low urine specific gravity • Decreased serum electrolytes • Decreased hematocrit • Variable urine volume	Limit fluid intake. Administer diuretics. Monitor vital signs. Monitor neurologic signs as necessary. Determine and treat cause of water excess. Analyze serum electrolytes frequently. Implement seizure precautions.

TABLE 22.2 Disturbances of Select Fluid and Electrolyte Balance—cont'd

Mechanisms and Situations	Manifestations	Management and Nursing Care
Sodium Depletion (Hyponatremia)		
Prolonged low-sodium diet Decreased sodium intake Fever Excess sweating Increased water intake without electrolytes Tachypnea (infants) Cystic fibrosis Burns and wounds Vomiting, diarrhea, nasogastric suction, fistulas Adrenal insufficiency Renal disease Diabetic ketoacidosis (DKA) Malnutrition	Associated with water loss: • Same as with water loss—dehydration, weakness, dizziness, nausea, abdominal cramps, apprehension • Mild—apathy, weakness, nausea, weak pulse • Moderate—decreased blood pressure, lethargy Laboratory findings: • Sodium concentration <130 mEq/L (may be normal if volume loss) • Urine specific gravity depends on water deficit or excess	Determine and treat cause of sodium deficit. Administer IV fluids with appropriate saline concentration. Monitor fluid intake and output.
Sodium Excess (Hypernatremia)		
High salt intake—enteral or IV Renal disease Fever Insufficient breast milk intake in neonate (dehydration hypernatremia) High insensible water loss: • Increased temperature • Increased humidity • Hyperventilation • Diabetes insipidus • Hyperglycemia	Intense thirst Dry, sticky mucous membranes Flushed skin Temperature possibly increased Hoarseness Oliguria Nausea and vomiting Possible progression to disorientation, convulsions, muscle twitching, nuchal rigidity, lethargy at rest, hyperirritability when aroused Laboratory findings: • Serum sodium concentration ≤150 mEq/L • High plasma volume • Alkalosis	Determine and treat cause of sodium excess. Administer IV fluids as prescribed. Measure fluid intake and output. Monitor laboratory data. Monitor neurologic status. Ensure adequate intake of breast milk and provide lactation assistance with new mother-baby pair before hospital discharge.
Potassium Depletion (Hypokalemia)		
Starvation Clinical conditions associated with poor food intake Malabsorption IV fluid without added potassium Gastrointestinal losses—diarrhea, vomiting, fistulas, nasogastric suction Diuresis Administration of diuretics Administration of corticosteroids Diuretic phase of nephrotic syndrome Healing stage of burns Potassium-losing nephritis Hyperglycemic diuresis (e.g., diabetes mellitus) Familial periodic paralysis IV administration of insulin in DKA Alkalosis	Muscle weakness, cramping, stiffness, paralysis, hyporeflexia Hypotension Cardiac arrhythmias, gallop rhythm Tachycardia or bradycardia Ileus Apathy, drowsiness Irritability Fatigue Laboratory findings: • Decreased serum potassium concentration ≥3.5 mEq/L • Abnormal ECG—notched or flattened T waves, decreased ST segment, premature ventricular contractions	Determine and treat cause of potassium deficit. Monitor vital signs, including ECG. Administer supplemental potassium. Assess for adequate renal output before administration. For IV replacement, administer potassium slowly. Always monitor ECG for IV bolus potassium replacement. For oral intake, offer high-potassium fluids and foods. Evaluate acid-base status.

Continued

TABLE 22.2 Disturbances of Select Fluid and Electrolyte Balance—cont'd

Mechanisms and Situations	Manifestations	Management and Nursing Care
Potassium Excess (Hyperkalemia)		
Renal disease Renal failure Adrenal insufficiency (Addison disease) Associated with metabolic acidosis Too-rapid administration of IV potassium chloride Transfusion with old donor blood Severe dehydration Crushing injuries Burns Hemolysis Dehydration Potassium-sparing diuretics Increased intake of potassium (e.g., salt substitutes)	Muscle weakness, flaccid paralysis Twitching Hyperreflexia Bradycardia Ventricular fibrillation and cardiac arrest Oliguria Apnea—respiratory arrest Laboratory findings: • High serum potassium concentration ≤5.5 mEq/L • Variable urine volume • Flat P wave on ECG, peaked T waves, widened QRS complex, increased PR interval	Determine and treat cause of potassium excess. Monitor vital signs, including ECG. Administer exchange resin, if prescribed. Administer IV fluids as prescribed. Administer IV insulin (if ordered) to facilitate movement of potassium into cells. Monitor potassium levels. Evaluate acid-base status.
Calcium Depletion (Hypocalcemia)		
Inadequate dietary calcium Vitamin D deficiency Rapid transit through gastrointestinal tract Advanced renal insufficiency Administration of diuretics Hypoparathyroidism Alkalosis Calcium trapped in diseased tissues Increased serum protein (albumin) Cow's milk—tetany of the newborn (inappropriate calcium/phosphorus ratio in whole milk for newborn) Exchange transfusion with citrated blood Inadequate parenteral administration in diseased status	Neuromuscular irritability Tingling of nose, ears, fingertips, toes Tetany Laryngospasm Generalized convulsions May be changes in clotting Positive Chvostek and Trousseau signs Hypotension Cardiac arrest Laboratory findings: • Decreased serum calcium concentration (8.8-10.8 mEq/L) or increased serum protein levels • Prolonged QT interval	Determine and treat cause of calcium deficit. Administer oral calcium supplements as prescribed; administer IV slowly and diluted. Monitor IV site; calcium may cause vascular irritation. Monitor serum calcium, vitamin D, and parathyroid levels. Monitor serum protein levels. Avoid cow's milk in infants younger than 12 months.
Calcium Excess (Hypercalcemia)		
Acidosis Prolonged immobilization Conditions associated with increased bone catabolism Hypoproteinemia Kidney disease Hypervitaminosis D Hyperparathyroidism Hyperthyroidism Excessive IV or oral administration	Constipation Weakness, fatigue Nausea, vomiting Anorexia Dry mouth (thirst) Muscle hypotonicity Bradycardia or cardiac arrest Increased calcium concentration in urine, causing formation of kidney stones Laboratory findings: • Increased serum calcium levels or decreased serum protein levels • Prolonged QRS complex or PR interval, shortened QT interval	Determine and treat cause of calcium excess. Monitor serum calcium levels. Monitor ECG.

ADH, Antidiuretic hormone; *ECG,* electrocardiogram; *IV,* intravenous.

when planning management. The following discussion is concerned with the general concepts of two common fluid volume disturbances, dehydration and edema, which are features of a variety of conditions.

DEHYDRATION

Dehydration is a common body fluid disturbance encountered in the nursing care of infants and young children; it occurs whenever the total output of fluid exceeds the total intake, regardless of the underlying cause. Dehydration is also commonly referred to as volume depletion. Although dehydration can result from lack of oral intake (especially in elevated environmental temperatures), more often it is a result of abnormal losses, such as those that occur in vomiting or diarrhea, when oral intake only partially compensates for the abnormal losses. Other significant causes of dehydration are diabetic ketoacidosis and extensive burns.

NURSING ALERT

In a child with a history of fluid loss and potential or actual dehydration, direct nursing assessment toward the possibility of impending shock.

In early dehydration (during the first 2 days), fluid loss is derived from both the ECF and the ICF because the increased osmolality of the diminished ECF volume causes fluid from the ICF compartment to move into the ECF compartment. As dehydration becomes chronic, the cellular losses become greater.

Types of Dehydration

Because sodium is the primary osmotic force that controls fluid movement between the major fluid compartments, dehydration is often described according to plasma sodium concentrations (e.g., isonatremic, hyponatremic, or hypernatremic). Other osmotic forces, however, such as glucose in diabetic ketoacidosis and protein in nephrotic syndrome, may also play a dominant role. Consequently, dehydration is conventionally classified as isotonic, hypotonic, or hypertonic.

Isotonic (isosmotic or isonatremic) dehydration occurs in conditions in which electrolyte and water deficits are present in approximately balanced proportions. This is the primary form of dehydration occurring in children. The observable fluid losses are not necessarily isotonic, but losses from other avenues make adjustments so that the sum of all losses, or the net loss, is isotonic. Because no osmotic force is present to cause a redistribution of water between the ICF and ECF, the major loss is sustained from the ECF compartment. This significantly reduces the plasma volume and thus the circulating blood volume, with its effect on the skin, muscles, and kidneys. Shock is the greatest threat to life in isotonic dehydration, and the child with isotonic dehydration displays symptoms characteristic of hypovolemic shock. Plasma sodium remains within normal limits, between 130 and 150 mEq/L (Huether, 2019).

Hypotonic (hyposmotic or hyponatremic) dehydration occurs when the electrolyte deficit exceeds the water deficit. Because ICF is more concentrated than ECF in hypotonic dehydration, water transfers from the ECF to the ICF to establish osmotic equilibrium. This movement further increases the ECF volume loss, and shock is a frequent result. Because there is a greater proportional loss of ECF in hypotonic dehydration, the physical signs tend to be more severe with smaller fluid losses than in isotonic or hypertonic dehydration. Plasma sodium concentrations are typically less than 130 mEq/L (Huether, 2019).

Hypertonic (hyperosmotic or hypernatremic) dehydration results from water loss in excess of electrolyte loss and is usually caused by a proportionately larger loss of water or a larger intake of electrolytes. This type of dehydration is the most dangerous and requires much more specific fluid therapy. This sometimes occurs in infants with diarrhea who are given fluids by mouth that contain large amounts of solute or in children receiving high-protein nasogastric (NG) tube feedings that place an excessive solute load on the kidneys. In hypertonic dehydration, fluid shifts from the lesser concentration of the ICF to the ECF. Plasma sodium concentration is greater than 150 mEq/L (Huether, 2019).

Because the ECF volume is proportionately larger, hypertonic dehydration consists of a greater degree of water loss for the same intensity of physical signs. Shock is less apparent in hypotonic dehydration. However, neurologic disturbances, such as seizures, are more likely to occur. Cerebral changes are serious and may result in permanent damage. These include disturbance of consciousness, poor ability to focus attention, lethargy, increased muscle tone with hyperreflexia, and hyperirritability to stimuli (e.g., tactile, auditory, bright lights).

Degree of Dehydration

A determination of the type and degree of dehydration is necessary to develop an effective plan of therapy. The degree of dehydration has been described as a percentage of body weight dehydrated: mild—less than 3% in older children or less than 5% in infants; moderate—5% to 10% in infants and 3% to 6% in older children; and severe—more than 10% in infants and more than 6% in older children (Carson, Mudd, & Madati, 2017; Greenbaum, 2020). Water constitutes only 60% to 70% of the infant's weight. However, adipose tissue contains little water and is highly variable in individual infants and children. A more accurate means of describing dehydration is to reflect acute fluid loss (time frame of ≥48 hours) in milliliters per kilogram of body weight. For example, a loss of 50 ml/kg is considered to be a mild fluid loss, whereas a loss of 100 ml/kg produces severe dehydration.

Weight is the most important determinant of the percent of total body fluid loss in infants and younger children. However, often the pre-illness weight is unknown. Other predictors of fluid loss include a changing level of consciousness (irritability to lethargy), altered response to stimuli, decreased skin elasticity and turgor, prolonged capillary refill (>2 seconds), increased heart rate, and sunken eyes and fontanels.

Clinical signs provide clues to the extent of dehydration (Table 22.3). The earliest detectable sign is usually tachycardia, followed by dry skin and mucous membranes, sunken fontanels, signs of circulatory failure (coolness and mottling of extremities), loss of skin elasticity, and prolonged capillary filling time (see Table 22.4 for clinical manifestations of dehydration). There is evidence that the clinical signs of abnormal capillary refill, abnormal skin turgor, and abnormal respiratory pattern are the most useful in predicting dehydration of 5% or more in children (Carson, Mudd, & Madati, 2017).

Compensatory mechanisms attempt to maintain fluid volume by adjusting to these losses. Interstitial fluid moves into the vascular compartment to maintain the blood volume in response to hemoconcentration and hypovolemia, and vasoconstriction of peripheral arterioles helps maintain pumping pressure. When fluid losses exceed the body's ability to sustain blood volume and blood pressure, circulation is seriously compromised and the blood pressure falls. This results in tissue hypoxia with accumulation of lactic acid, pyruvate, and other acid metabolites, which contribute to the development of metabolic acidosis.

Renal compensation is impaired by reduced blood flow through the kidneys, and little urine is formed. Increased serum osmolality stimulates the secretion of **antidiuretic hormone (ADH)** to conserve fluid and initiates the renin-angiotensin mechanisms in the kidney, causing further vasoconstriction. Aldosterone is released to promote sodium retention and conserve water in the kidneys. If dehydration increases in severity, urine formation is greatly diminished and metabolites and hydrogen ions that are normally excreted by this route are retained.

Shock, a common manifestation of severe depletion of ECF volume, is preceded by tachycardia and signs of poor perfusion and tissue oxygenation (by pulse oximeter readings). Peripheral circulation is poor as a result of reduced blood volume; therefore the skin is cool and mottled with decreased capillary filling. Impaired kidney circulation often leads to **oliguria** and **azotemia**. Although low blood pressure may accompany other symptoms of shock, in infants and young children it is usually a late sign and may herald the onset of cardiovascular collapse (see Congestive Heart Failure in Chapter 23).

TABLE 22.3 Evaluating Extent of Dehydration

	LEVEL OF DEHYDRATION		
Clinical Signs	**Mild**	**Moderate**	**Severe**
Weight loss—infants	3%-5%	6%-9%	≤10%
Weight loss—children	3%-4%	6%-8%	10%
Pulse	Normal	Slightly increased	Very increased
Respiratory rate	Normal	Slight tachypnea (rapid)	Hyperpnea (deep and rapid)
Blood pressure	Normal	Normal to orthostatic (>10 mm Hg change)	Orthostatic to shock
Behavior	Normal	Irritable, more thirsty	Hyperirritable to lethargic
Thirst	Slight	Moderate	Intense
Mucous membranes[a]	Normal (moist)	Dry	Parched
Tears	Present	Decreased	Absent, sunken eyes
Anterior fontanel	Normal	Normal to sunken	Sunken
External jugular vein	Visible when supine	Not visible except with supraclavicular pressure	Not visible even with supraclavicular pressure
Skin[a]	Capillary refill >2 sec	Slowed capillary refill (2-4 sec [decreased turgor])	Very delayed capillary refill (>4 sec) and tenting; skin cool, acrocyanotic or mottled
Urine	Decreased	Oliguria	Oliguria or anuria

[a]These signs are less prominent in patients who have hypernatremia.
Data from Jospe, N., & Forbes, G. (1996). Fluids and electrolytes—Clinical aspects. *Pediatrics in Review, 17*(11), 395–403; and Steiner, M. J., DeWalt, D. A., & Byerly, J. S. (2004). Is this child dehydrated? *Journal of the American Medical Association, 291*(22), 2746–2754.

TABLE 22.4 Clinical Manifestations of Dehydration

Manifestation	Isotonic (Loss of Water and Salt)	Hypotonic (Loss of Salt in Excess of Water)	Hypertonic (Loss of Water in Excess of Salt)
Skin			
• Color	Gray	Gray	Gray
• Temperature	Cold	Cold	Cold or hot
• Turgor	Poor	Very poor	Fair
• Feel	Dry	Clammy	Thickened, doughy
Mucous membranes	Dry	Slightly moist	Parched
Tearing and salivation	Absent	Absent	Absent
Eyeball	Sunken	Sunken	Sunken
Fontanel	Sunken	Sunken	Sunken
Body temperature	Subnormal or elevated	Subnormal or elevated	Subnormal or elevated
Pulse	Rapid	Very rapid	Moderately rapid
Respirations	Rapid	Rapid	Rapid
Behavior	Irritable to lethargic	Lethargic or comatose; convulsions	Marked lethargy with extreme hyperirritability on stimulation

Diagnostic Evaluation

To initiate a therapeutic plan, several factors must be determined:

- The degree of dehydration based on physical assessment
- The type of dehydration based on the pathophysiology of the specific illness responsible for the dehydrated state
- Specific physical signs other than general signs
- Initial plasma sodium concentrations
- Serum bicarbonate concentration
- Any associated electrolyte (especially serum potassium) and acid-base imbalances (as indicated)

Initial and regular, ongoing evaluations assess the patient's progress toward equilibrium and the effectiveness of therapy.

In the examination of an infant or younger child, one of the most important determinants of the extent of dehydration is body weight because this can assist in determining the percentage of total body fluid lost; however, because the pre-illness weight is often unknown, clinical manifestations must be evaluated. Important clinical manifestations include changing sensorium (irritability to lethargy); decreased response to stimuli; integumentary changes (decreased elasticity and turgor); prolonged capillary refill; increased heart rate; sunken eyes; and, in infants, sunken fontanels. Using multiple predictors increases the sensitivity of assessing the fluid deficit, and studies have shown a reasonably high degree of agreement between experienced observers in assessment of the level

BOX 22.1 Model for Rehydration

- For mild to moderate dehydration, rehydration solution should consist of 50 mEq of sodium per liter. In infants who are breastfed, breastfeeding should continue.
- For mild to moderate dehydration, give 50 ml/kg of oral rehydration solution to children.
- For severe dehydration, give 30 ml/h of oral rehydration for infants, 60 ml/h for toddlers, and 90 ml/h for older children. There is a high likelihood for intravenous fluid when children cannot tolerate these oral intake requirements.
- Add 10 ml/kg of fluid for every loose stool or episode of vomiting.
- Reevaluate the need for further rehydration; initiate maintenance therapy using maintenance formulations.
- In children with diarrhea without significant dehydration, the maintenance phase may be initiated without the need for rehydration solution.
- As soon as adequate rehydration has been achieved, start a regular diet along with fluid therapy and wean intravenous fluids.

Modified from Churgay, C. A., & Aftab, A. (2012). Gastroenteritis in children: Part II, prevention and management. *American Family Physician, 85*(11), 1066–1070.

of dehydration. Objective signs of dehydration are present at a fluid deficit of less than 5%.

Therapeutic Management

Medical management is directed at correcting the fluid imbalance and treating the underlying cause. When the child is alert, awake, and not in danger, correction of dehydration may be attempted with oral fluid administration. Most cases of dehydration are mild and can be managed at home by this method. See Box 22.1 for a model for rehydration. Oral rehydration management consists of replacement of fluid loss over 4 to 6 hours, replacement of continuing losses, and provision for maintenance fluid requirements. In general, the mildly dehydrated child may be given 50 ml/kg of **oral rehydration solution (ORS)**, whereas the child with moderate dehydration may be given 100 ml/kg of ORS. The child with fluid losses from diarrhea may be given an additional 10 ml/kg for each stool (Greenbaum, 2020). Amounts and rates are determined from body weight and severity of dehydration and are increased if rehydration is incomplete or if excess losses continue, until the child is well hydrated and the basic problem is under control.

The child may not be thirsty even though dehydrated and may refuse oral fluids initially for fear of continued emesis (if occurring) or because of decreased strength, oral stomatitis, or thrush. In such children rehydration may proceed by administering 2 to 5 ml of ORS by a syringe or small medication cup every 2 to 3 minutes until the child is able to tolerate larger amounts; if the child has emesis, administering small amounts (5 ml) of ORS every 5 minutes or so may help overcome fluid deficit, and the emesis will often lessen over time (Hendrickson, Zaremba, Wey, et al., 2017). Evidence indicates that oral administration of ondansetron (Zofran) to children with acute gastroenteritis and vomiting reduces emesis and increases time to oral rehydration, thus preventing intravenous (IV) therapy (Carter & Fedorowicz, 2012; Hendrickson et al., 2017). Oral rehydration therapy (ORT) is effective for treating mild or moderate dehydration in children, is less expensive, and involves fewer complications than therapy (Carson et al., 2017; Kleinman & Greer, 2014). ORSs enhance and promote the reabsorption of sodium and water. These solutions greatly reduce vomiting and the need for IV infusions (Hendrickson et al., 2017). ORSs, including lower-osmolarity ORS (224 mmol/L), are available in the United States as commercially prepared solutions and are successful in treating the majority of infants with dehydration. See the Quality Patient Outcomes box.

QUALITY PATIENT OUTCOMES: Fluid Volume Deficit

- Moist mucous membranes
- Sodium and potassium within normal limits
- Voiding (>1 ml/kg/h)
- Capillary refill of 2 seconds or less
- Skin turgor brisk
- Fluid intake and output balanced

NURSING TIP: Enhance the flavor of an oral rehydration solution (ORS) such as Pedialyte (unflavored) by adding a teaspoon of unsweetened powder Kool-Aid to each 60 to 90 ml of ORS. Older children may take a small Popsicle orally instead of fluids that require drinking. Many commercially available Popsicles are relatively inexpensive, contain small amounts of sucrose, and contain approximately 40 to 50 ml of fluid. Frozen oral hydration may be accepted by some children when conventional ORS is rejected.

Parenteral Fluid Therapy

Parenteral fluid therapy is initiated whenever the child is unable to ingest sufficient amounts of fluid and electrolytes to meet ongoing daily physiologic losses, replace previous deficits, and replace ongoing abnormal losses. Patients who usually require IV fluids are those with severe dehydration, those with uncontrollable vomiting, those who are unable to drink for any reason (e.g., extreme fatigue, coma), or those with severe gastric distention.

Because dehydration (volume depletion) constitutes a great threat to life, the first priority is the restoration of circulation by rapid expansion of the ECF volume to treat or prevent shock. IV administration of fluid begins immediately, although the exact nature of the dehydration and the serum electrolyte values are not known. The solution selected is based on what is known regarding the probable type and cause of the dehydration. This usually involves an isotonic solution such as 0.9% sodium chloride or lactated Ringer, both of which are close to the body's serum osmolality of 285 to 300 mOsm/kg and do not contain dextrose (which is contraindicated in the early treatment stages of rehydration, but especially in diabetic ketoacidosis).

Parenteral rehydration therapy has three phases. The initial therapy is used to expand ECF volume quickly and to improve circulatory and renal function. During initial therapy, an isotonic electrolyte solution is used at a rate of 20 ml/kg, given as an IV bolus over 5 to 20 minutes, and repeated as necessary after assessment of the child's response to therapy. In a meta-analysis of 10 randomized clinical trials, isotonic fluids were found to be safer than hypotonic fluids in preventing severe hyponatremia following administration (Wang, Xu, & Xiao, 2014). Subsequent therapy is used to replace deficits, meet maintenance water and electrolyte requirements, and catch up with ongoing losses. Water and sodium requirements for the deficit, maintenance, and ongoing losses are calculated at 8-hour intervals, taking into consideration the amount of fluids given with the initial boluses and the amount administered during the first 24-hour period. With improved circulation during this phase, water and electrolyte deficits can be evaluated, and acid-base status can be corrected either directly through the administration of fluids or indirectly through improved renal function. Potassium is withheld until kidney function is restored and assessed and circulation has improved.

The final phase of therapy allows the patient to return to normal and begin oral feedings, with a gradual correction of total body deficits. The potassium loss in ICF is replaced slowly by way of the ECF. The body fat and protein stores are replaced through diet. If the child is unable to eat or if feeding aggravates a chronic condition, IV maintenance fluids are provided.

Although the initial phase of fluid replacement is rapid in both isotonic and hypotonic dehydration, it is contraindicated in hypertonic dehydration because of the risk of water intoxication, especially in the brain cells, specifically the central pontine cells. Central pontine myelinolysis may occur with an overcorrection of fluid deficit and an overly rapid correction of serum sodium concentration (Greenbaum, 2020). There is an apparent lag time for sodium to reach a steady state when diffusing in and out of brain cells, whereas water diffuses almost instantaneously. Consequently, rapid administration of fluid will cause equally rapid diffusion of water into the dehydrated brain cells, causing marked cerebral edema. Because ECF volume is maintained relatively well in hypertonic as opposed to the other types of dehydration, shock is not a usual manifestation.

WATER INTOXICATION

Water intoxication, or water overload, is observed less often than dehydration. However, it is important that nurses and others who care for children be alert to this possibility in certain situations. Children who ingest excessive amounts of electrolyte-free water develop a concurrent decrease in serum sodium accompanied by central nervous system (CNS) symptoms. There is a large urinary output, and because water moves into the brain more rapidly than sodium moves out, the child may also exhibit irritability, somnolence, headache, vomiting, diarrhea, or generalized seizures. The affected child usually appears well hydrated but may be edematous or even dehydrated.

Fluid intoxication can occur during acute IV water overloading, too-rapid dialysis, tap water enemas, feeding of incorrectly mixed infant formula, or excess water ingestion, or with too rapid reduction of glucose levels in diabetic ketoacidosis (Greenbaum, 2020). Patients with CNS infections occasionally retain excessive amounts of water. Administration of inappropriate hypotonic solutions (e.g., 0.45% sodium chloride) may cause a rapid reduction in sodium and result in symptoms of water overload.

Infants are especially vulnerable to fluid overload. Their thirst mechanism is not well developed; therefore they are unable to "turn off" fluid intake appropriately. A decreased glomerular filtration rate does not allow for repeated excretion of a water load, and ADH levels may not be maximally reduced. Consequently, infants are unable to excrete a water overload effectively.

Administration of inappropriately prepared formula is one of the more common causes of water intoxication in infants (Greenbaum, 2020). Families who cannot afford to buy enough formula may dilute the formula to increase the volume or even substitute water for the formula. A family may run out of formula and dilute the remaining amount to make it last until they are able to purchase more. In addition, water is sometimes used for pacification. Water intoxication can also occur in infants who receive overly vigorous hydration during a febrile illness.

A number of clinicians have reported water intoxication in infants after swimming lessons, in water births (Byard & Zuccollo, 2010), with excessive enema administration, and with gastric lavage (Manz, 2007). Although they hold their breath, some infants apparently swallow a large amount of water during repeated submersion. Anticipatory guidance to parents should include a discussion of swimming instruction and advice to stop a lesson if the child swallows unusual amounts of water or exhibits any symptoms of hyponatremia.

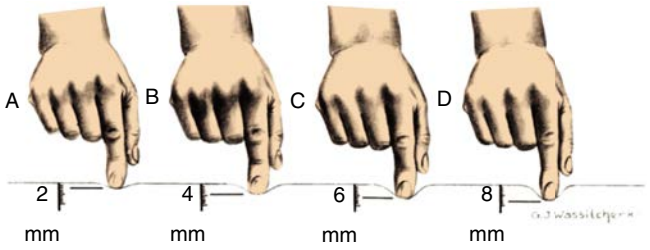

Fig. 22.1 Assessment of pitting edema. **A,** +1; **B,** +2; **C,** +3; **D,** +4.

EDEMA

Edema represents an abnormal accumulation of fluid within the interstitial tissue and subsequent tissue expansion and develops when a defect in the normal cardiovascular circulation or a failure in the lymphatic drainage to remove the increased amounts occurs. The processes responsible for fluid removal include venous hydrostatic pressure, oncotic pressure of intravascular and interstitial spaces, an intact semipermeable capillary wall, tissue tension, and lymphatic flow.

Assessment

Generalized edema resulting from any of the previously listed types is manifested by swelling in the extremities, face, perineum, and torso. Loss of normal skin creases may be assessed. Daily weights are more sensitive indicators of water gain or loss and should be obtained. Abdominal girth measurement changes may also be an indicator of edema in children. Pitting edema may occur and can be assessed by pressing the fingertip against a bony prominence for 5 seconds. If the tissue rebounds immediately on removing the finger, the patient does not have pitting edema. A quick way to determine the severity is to measure the degree of pitting edema (Fig. 22.1).

Therapeutic Management

The primary goal in the management of edema is treatment of the underlying disease process, which is discussed elsewhere in relation to the specific disorder. However, an essential aspect in the management of any fluid overload is early recognition, in which nurses play a vital role. The management of edema is discussed throughout the text with specific conditions. See the Quality Patient Outcomes box.

QUALITY PATIENT OUTCOMES: Fluid Volume Excess
- Fluid intake and output balanced
- No edema
- No weight gain
- No respiratory distress related to fluid volume excess

DISORDERS OF MOTILITY

DIARRHEA

Diarrhea is a symptom that results from disorders involving digestive, absorptive, and secretory functions. Diarrhea is caused by abnormal intestinal water and electrolyte transport. Worldwide, there are an estimated 1.7 billion episodes of diarrhea each year (Leung, Chisti, & Pavia, 2016). The incidence and morbidity of diarrhea are more prominent in low-income countries such as areas of Asia and Africa (Leung et al., 2016) and among children younger than 5 years of age (Leung et al., 2016).

The transport of fluid and electrolytes in the developing GI tract is related to the child's age. The intestinal mucosa of the young infant

is more permeable to water than that of an older child. Therefore in young infants with increased intestinal luminal osmolality caused by diarrhea, more fluid and electrolytes are lost than in older children. Diarrhea results from several pathophysiologic processes.

Types of Diarrhea

Diarrheal disturbances involve the stomach and intestines (gastroenteritis), the small intestine (enteritis), the colon (colitis), or the colon and intestines (enterocolitis). Diarrhea is classified as acute or chronic.

Acute diarrhea is defined as a sudden increase in frequency and a change in consistency of stools, often caused by an infectious agent in the GI tract. It may be associated with upper respiratory or urinary tract infections, antibiotic therapy, or laxative use. Acute diarrhea is usually self-limited (14 days' duration) and subsides without specific treatment. Acute infectious diarrhea (infectious gastroenteritis) is caused by a variety of viral, bacterial, and parasitic pathogens (Table 22.5).

Chronic diarrhea is an increase in stool frequency and increased water content with duration of more than 14 days. It is often caused by chronic conditions such as malabsorption syndromes, inflammatory bowel disease (IBD), immunodeficiency, food allergy, lactose intolerance, or chronic nonspecific diarrhea, or as a result of inadequate management of acute diarrhea.

TABLE 22.5 Infectious Causes of Acute Diarrhea

Agents	Pathology	Characteristics	Comments
Viral			
Rotavirus Incubation—48 hours Diagnosis—EIA	Fecal-oral transmission 8 groups (A-H)—Most group A virus replicates in mature villus epithelial cells of small intestine; leads to (1) imbalance in ratio of intestinal fluid absorption to secretion and (2) malabsorption of complex carbohydrates	Mild to moderate fever Vomiting followed by onset of watery stools Fever and vomiting generally abate in approximately 2 days, but diarrhea persists 5-7 days	Most common cause of diarrhea in children <5 years old; infants 6-12 months old most vulnerable; affects all ages; usually milder in children >3 years old Immunocompromised children at greater risk for complications Peak occurrences in winter months Important cause of nosocomial infections
Norovirus Incubation—12-48 hours Diagnosis—PCR assays	Fecal-oral; contaminated water Pathology similar to that of rotavirus; affects villus epithelial cells of small intestine, leading to (1) imbalance in ratio of intestinal fluid absorption to secretion and (2) malabsorption of complex carbohydrates	Abdominal cramps, nausea, vomiting, malaise, low-grade fever, watery diarrhea without blood; duration 2-3 days; tends to resemble so-called food poisoning symptoms with nausea predominating	Affects all ages Multiple strains often named for the location of outbreak (e.g., Norwalk, Sapporo, Snow Mountain, Montgomery)
Bacterial			
Escherichia coli Incubation—3-4 days; variable depending on strain Diagnosis—Sorbitol MacConkey (SMAC) agar positive for blood, but fecal leukocytes absent or rare	*E. coli* strains produce diarrhea as result of enterotoxin production, adherence, or invasion (enterotoxigenic-producing *E. coli*, enterohemorrhagic *E. coli*, enteroaggregative *E. coli*)	Watery diarrhea 1-2 days, then severe abdominal cramping and bloody diarrhea Can progress to hemolytic uremic syndrome	Foodborne pathogen Traveler's diarrhea Cause of nursery epidemics Symptomatic treatment Antibiotics may worsen course Avoid antimotility agents and opioids
***Salmonella* groups** (nontyphoidal) Gram-negative rods, nonencapsulated, nonsporulating Incubation—6-72 hours Diagnosis—Gram stain, stool culture	Invasion of mucosa in the small and large intestine, edema of the lamina propria, focal acute inflammation with disruption of the mucosa and microabscesses	Nausea, vomiting, colicky, abdominal pain, bloody diarrhea, fever; symptoms variable (mild to severe) May have headache and cerebral manifestations (e.g., drowsiness, confusion, meningismus, seizures) Infants may be afebrile and nontoxic May result in life-threatening septicemia and meningitis Nausea and vomiting typically of short duration; diarrhea may persist as long as 2-3 weeks Typically shed virus for average of 5 weeks; cases reported up to 1 year	Incidence highest in summer months; foodborne outbreaks common Usually transmitted person to person but may transmit via undercooked meats or poultry; about half the cases caused by poultry and poultry products In children, related to pets (e.g., dogs, cats, hamsters, turtles) Communicable as long as organisms are excreted Antibiotics not recommended in uncomplicated cases Antimotility agents also not recommended—prolong transit time and carrier state

Continued

TABLE 22.5 Infectious Causes of Acute Diarrhea—cont'd

Agents	Pathology	Characteristics	Comments
Salmonella typhi Produces enteric fever—systemic syndrome Incubation—usually 7-14 days but could be 3-30 days, depending on size of inoculum Diagnosis—positive blood cultures; also sometimes positive stool and urine cultures Late stage—positive bone marrow culture	Bloodstream invasion; after ingestion, organism attaches to microvilli of ileal brush borders, and bacteria invade the intestinal epithelium via Peyer patches Next, organism is transported to intestinal lymph nodes and enters bloodstream via thoracic ducts, and circulating organism reaches reticuloendothelial cells, causing bacteremia	Manifestations dependent on age Abdominal pain, diarrhea, nausea, vomiting, high fever, lethargy Must be treated with antibiotics	Incidence much lower in developed countries; about 400 cases/year in United States; 65% of US cases acquired via international cases Ingestion of foods and water contaminated with human feces is most common mode of transmission Congenital and intrapartum transmission possible Two vaccines available
***Shigella* groups** Gram-negative nonmotile anaerobic bacilli Incubation—1-7 days Diagnosis—stool culture loaded with polymorphonuclear leukocytes	Enterotoxins—invade the epithelium with superficial mucosal ulcerations	Children appear sick Symptoms begin with fever, fatigue, anorexia Crampy abdominal pain preceding watery or bloody diarrhea Symptoms usually subside in 5-10 days	Most cases in children <9 years old, with about one-third of cases in children ages 1-4 weeks old Antibiotics shorten illness and lower mortality All patients at risk for dehydration Acute symptoms may persist for ≤1 week Antidiarrheal medications not recommended because they may predispose patient to toxic megacolon
***Yersinia* enterocolitis** Incubation—dose dependent, 1-3 weeks Diagnosis—stool culture, ELISA Patients have leukocytosis, elevated sedimentation rate	Pathology poorly understood; possibly caused by production of enterotoxin	Mucoid diarrhea, sometimes bloody; abdominal pain suggestive of appendicitis; fever, vomiting	Seen more frequently in the winter months Transmitted by pets and food Antibiotics usually do not alter the clinical course in uncomplicated cases; antibiotics used in complicated infections and compromised hosts
Campylobacter jejuni Microaerophilic, motile, gram-negative bacilli Incubation—1-7 days Ability to cause illness appears dose related Diagnosis—stool culture, sometimes blood culture Commonly found in GI tract of wild or domestic animals	Not fully understood, possibly (1) adherence to intestinal mucosa by toxin, (2) invasion of the mucosa in the terminal ileum and colon, (3) translocation in which the organisms penetrate the mucosa and replicate in the lamina propria	Fever, abdominal pain, diarrhea that can be bloody, vomiting Watery, profuse, foul-smelling diarrhea Clinically similar to infection by *Salmonella* or *Shigella* organisms Fecal-oral transmission	Most infections in humans relate to consumption of contaminated foods or water, such as undercooked meats, particularly chicken Also acquired from contaminated household pets (e.g., dogs, cats, hamsters) Bimodal peaks in infants <1 year old and again at ages 15-29 years old Antibiotics do not prolong the carriage of bacteria and may eliminate organism more quickly Erythromycin is the drug of choice Antimotility agents not recommended because they tend to prolong symptoms
Vibrio cholerae Gram-negative, motile, curved bacillus living in bodies of salt water Incubation—1-3 days Diagnosis—stool culture	Enters via oral route in contaminated food or water; if survives acid stomach environment, travels to the small intestine, adheres to the mucosa, and produces toxin	Onset abrupt; vomiting, watery diarrhea without cramping or tenesmus Dehydration can occur quickly	More prevalent in developing countries Rehydration most important treatment Antibiotics can shorten diarrhea Despite continued efforts, still no vaccine
Clostridium difficile Gram-positive anaerobic bacillus with the ability to produce spores Diagnosis—by detecting *C. difficile* toxin in stool culture	Produces two important toxins (A and B) Toxin binds to the enterocyte surface receptor, resulting in alteration permeability, protein synthesis, and direct cytotoxicity	Mostly mild watery diarrhea lasting a few days Some prolonged diarrhea and illness May cause pseudomembranous colitis Some individuals extremely ill with high fever, leukocytosis, hypoalbuminemia	Associated with alteration of normal intestinal flora by antibiotics Adults tend to have more severe symptoms than children Treatment with antibiotics (metronidazole) in mildly to moderately symptomatic patients; for nonresponders, give vancomycin Resistant strains have developed Relapse common

TABLE 22.5 Infectious Causes of Acute Diarrhea—cont'd

Agents	Pathology	Characteristics	Comments
Clostridium perfringens Anaerobic, gram-positive, spore-producing bacilli Incubation—8-24 hours	Toxins produced in the intestine after ingestion of organism	Acute onset—watery diarrhea, crampy abdominal pain Fever, nausea, and vomiting are rare Duration of illness usually 24 hours	Transmitted by contaminated food products, most often meats and poultry Usually self-limiting and medical intervention not needed Oral rehydration usually sufficient Antibiotics serve no purpose and should not be used
Clostridium botulinum Gram-positive anaerobic spore-producing bacilli Incubation—12-26 hours (range, 6 hours to 8 days) Diagnosis—To detect toxin, submit blood and stool culture to special laboratory (usually state health department)	Botulism caused by binding of toxin to the neuromuscular junction	Clinical presentation related to age and the strain of the botulism GI—abdominal pain, cramping, and diarrhea Other strains—respiratory compromise, CNS symptoms	Transmitted in contaminated food products Can be acquired via wound infection Treatment is supportive care and neutralization of the toxin
***Staphylococcus* organisms** Gram-positive nonmotile, aerobic or facultative anaerobic bacteria Incubation—generally short, 1-8 hours Diagnosis—identify organism in food, blood, pus, aspirate	Direct tissue invasion and production of toxin	Clinical presentation dependent on site of entry In food poisoning, profuse diarrhea, nausea, and vomiting	Transmitted in inadequately cooked or refrigerated foods Self-limiting Symptomatic treatment

CNS, Central nervous system; *EIA,* enzyme immunoassay; *ELISA,* enzyme-linked immunosorbent assay; *GI,* gastrointestinal; *PCR,* polymerase chain reaction.

Intractable diarrhea of infancy is a syndrome that occurs in the first few months of life, persists for longer than 2 weeks with no recognized pathogens, and is refractory to treatment. The most common cause is acute infectious diarrhea that was not managed adequately.

Chronic nonspecific diarrhea (CNSD), also known as *irritable colon of childhood* and *toddlers' diarrhea,* is a common cause of chronic diarrhea in children 6 to 54 months of age. These children have loose stools, often with undigested food particles, and diarrhea lasting longer than 2 weeks. Children with CNSD grow normally and have no evidence of malnutrition, no blood in their stool, and no enteric infection. Poor dietary habits and food sensitivities have been linked to chronic diarrhea. The excessive intake of juices and artificial sweeteners such as sorbitol, a substance found in many commercially prepared beverages and foods, may be a factor.

Etiology

Most pathogens that cause diarrhea are spread by the fecal-oral route through contaminated food or water or are spread from person to person where there is close contact (e.g., daycare centers). Lack of clean water, crowding, poor hygiene, nutritional deficiency, and poor sanitation are major risk factors, especially for bacterial or parasitic pathogens. Infants are often more susceptible to frequent and severe bouts of diarrhea because their immune system has not been exposed to many pathogens and has not acquired protective antibodies. Worldwide, the most common causes of acute gastroenteritis are infectious agents, viruses, bacteria, and parasites.

Rotavirus is the most important cause of serious gastroenteritis among children, with 28% of all cases causing fatality (Lamberti, Ashraf, Walker, et al., 2016). The virus is spread through the fecal-oral route or by person-to-person contact, and almost all children are infected with rotavirus at least once by the age of 5 years (Bass, 2020). Rotavirus is the most common cause of diarrhea-associated hospitalization, with an estimated 80,000 hospitalizations occurring annually in the United States in children less than 5 years of age (Bass, 2020).

Salmonella, Campylobacter, Yersinia, and *Shigella* organisms are the most frequently isolated bacterial pathogens in the United States (Kotloff, 2017). These organisms are gram-negative bacteria and can be contracted through raw or undercooked food, contaminated food or water, or the fecal-oral route. Among children and adults in the United States annually, *Salmonella* occurs in approximately 8172 people; *Campylobacter* occurs in 8547 people; *Shigella* occurs in 2913 people; and *Yersinia* occurs in 302 people (Marder, Cieslak, Cronquist, et al., 2017). (See also Chapter 6, Intestinal Parasitic Diseases.)

Antibiotic administration is frequently associated with diarrhea because antibiotics alter the normal intestinal flora, resulting in an overgrowth of other bacteria. *Clostridium difficile* is the most common bacterial overgrowth with a 12-fold increases in pediatric incidence from 1991 to 2009 (McFarland, Ozen, Dinleyici, et al., 2016). Children acquire most *C. difficile* infections in health care facilities, but 41% are acquired from the community, such as day care centers (McFarland, Ozen, Dinleyici, et al., 2016).

Pathophysiology

Invasion of the GI tract by pathogens results in increased intestinal secretion as a result of enterotoxins, cytotoxic mediators, or decreased intestinal absorption secondary to intestinal damage or inflammation. Enteric pathogens attach to the mucosal cells and form a cuplike pedestal on which the bacteria rest. The pathogenesis of the diarrhea depends on whether the organism remains attached to the cell surface, resulting in a secretory toxin (noninvasive, toxin-producing, noninflammatory-type diarrhea), or penetrates the mucosa (systemic diarrhea). Noninflammatory diarrhea is the most common diarrheal illness, resulting from the action of enterotoxin that is released after attachment to the mucosa. The most serious and immediate physiologic disturbances associated with severe diarrheal disease are dehydration, acid-base imbalance with acidosis, and shock that occurs when dehydration progresses to the point that circulatory status is seriously impaired.

TABLE 22.6 Treatment of Acute Diarrhea

Degree of Dehydration	Signs and Symptoms	Rehydration Therapy[a]	Replacement of Stool Losses	Maintenance Therapy
Mild (5%-6%)	Increased thirst Slightly dry buccal mucous membranes	ORS, 50 ml/kg within 4 hours	ORS, 10 ml/kg (for infants) or 150 to 250 ml at a time (for older children) for each diarrheal stool	Breastfeeding, if established, should continue; give regular infant formula if tolerated. If lactose intolerance suspected, give undiluted lactose-free formula (or half-strength lactose-containing formula for brief period only); infants and children who receive solid food should continue their usual diet.
Moderate (7%-9%)	Loss of skin turgor, dry buccal mucous membranes, sunken eyes, sunken fontanel	ORS, 100 ml/kg within 4 hours	Same as above	
Severe (>9%)	Signs of moderate dehydration plus one of following: rapid thready pulse, cyanosis, rapid breathing, lethargy, coma	Intravenous fluids (lactated Ringer solution), 40 ml/kg until pulse and state of consciousness return to normal; then 50-100 ml/kg or ORS	Same as above	

[a]If no signs of dehydration are present, rehydration therapy is not necessary. Proceed with maintenance therapy and replacement of stool losses.
ORS, Oral rehydration solution.

Diagnostic Evaluation

Evaluation of the child with acute gastroenteritis begins with a careful history that seeks to discover the possible cause of diarrhea, to assess the severity of symptoms and the risk of complications, and to elicit information about current symptoms indicating other treatable illnesses that could be causing the diarrhea. The history should include questions about recent travel, exposure to untreated drinking or washing water sources, contact with animals or birds, daycare center attendance, recent treatment with antibiotics, or recent diet changes. History questions should also explore the presence of other symptoms such as fever and vomiting, frequency and character of stools (e.g., watery, bloody), urinary output, dietary habits, and recent food intake.

Extensive laboratory evaluation is not indicated in children who have uncomplicated diarrhea and no evidence of dehydration because most diarrheal illnesses are self-limiting. Laboratory tests are indicated for children who are severely dehydrated and receiving IV therapy. Watery, explosive stools suggest glucose intolerance; foul-smelling, greasy, bulky stools suggest fat malabsorption. Diarrhea that develops after the introduction of cow's milk, fruits, or cereal may be related to enzyme deficiency or protein intolerance. Neutrophils or red blood cells in the stool indicate bacterial gastroenteritis or IBD. The presence of eosinophils suggests protein intolerance or parasitic infection. Stool cultures should be performed only when blood, mucus, or polymorphonuclear leukocytes are present in the stool; when symptoms are severe; when there is a history of travel to a developing country; and when a specific pathogen is suspected. Gross blood or occult blood may indicate pathogens such as *Shigella, Campylobacter,* or hemorrhagic *Escherichia coli* strains. Providers may use an enzyme-linked immunosorbent assay (ELISA) to confirm the presence of rotavirus or *Giardia* organisms. If there is a history of recent antibiotic use, test the stool for *C. difficile* toxin. When bacterial and viral cultures are negative and when diarrhea persists for more than a few days, examine stools for ova and parasites. A stool specimen with a pH of less than 6 and the presence of reducing substances may indicate carbohydrate malabsorption or secondary lactase deficiency. Stool electrolyte measurements may help identify children with secretory diarrhea.

Determine urine specific gravity if dehydration is suspected. Obtain a complete blood count (CBC), serum electrolytes, creatinine, and blood urea nitrogen (BUN) in the child who has moderate to severe dehydration or who requires hospitalization. The hemoglobin, hematocrit, creatinine, and BUN levels are usually elevated in acute diarrhea and should normalize with rehydration.

Therapeutic Management

The major goals in the management of acute diarrhea include assessment of fluid and electrolyte imbalance, rehydration, maintenance fluid therapy, and reintroduction of an adequate diet. Treat infants and children with acute diarrhea and dehydration first with **oral rehydration therapy (ORT)**. ORT is one of the major worldwide health care advances. It is more effective, safer, less painful, and less costly than IV rehydration. The American Academy of Pediatrics, World Health Organization, and Centers for Disease Control and Prevention all recommend ORT as the treatment of choice for most cases of dehydration caused by diarrhea. **Oral rehydration solutions (ORSs)** enhance and promote the reabsorption of sodium and water. These solutions greatly reduce vomiting, duration of illness, and the need for IV infusions (Dekate, Jayashree, & Singhi, 2013). ORSs, including reduced-osmolarity ORS, are available in the United States as commercially prepared solutions and are successful in treating the majority of infants with dehydration. Guidelines for rehydration recommended by the American Academy of Pediatrics are given in Table 22.6 (See Quality Patient Outcomes box.)

QUALITY PATIENT OUTCOMES: Diarrhea
- Adequate hydration maintained during illness
- Appropriate diagnostic tests performed
- Antibiotics given only if appropriate
- No repeat visits to the emergency department or pediatrician during the course of the illness
- No tissue breakdown
- Normal elimination returns

After rehydration, ORS may be used during maintenance fluid therapy by alternating the solution with a low-sodium fluid such as breast milk, lactose-free formula, or half-strength lactose-containing formula. In older children, ORS can be given and a regular diet continued. Ongoing stool losses should be replaced on a 1:1 basis with ORS. If the stool volume is not known, approximately 10 ml/kg (4 to 8 oz) of ORS should be given for each diarrheal stool.

Solutions for oral hydration are useful in most cases of dehydration, and vomiting is not a contraindication. Give a child who is vomiting an ORS at frequent intervals and in small amounts. For young children, the caregiver may give the fluid with a spoon or small syringe in 5- to 10-ml increments every 1 to 5 minutes. An ORS may also be given via NG or gastrostomy tube infusion. Infants without clinical

signs of dehydration do not need ORT. They should, however, receive the same fluid recommended for infants with signs of dehydration in the maintenance phase and for ongoing stool losses. Probiotics when used in conjunction with ORS reduce the duration of antibiotic-associated diarrhea in children (Barnes & Yeh, 2015).

! NURSING ALERT

Encouraging intake of clear fluids by mouth, such as fruit juices, carbonated soft drinks, and gelatin, does not help diarrhea. These fluids usually have a high carbohydrate content, a very low electrolyte content, and a high osmolality. Have patients avoid caffeinated beverages because caffeine is a mild diuretic and may lead to increased loss of water and sodium. Chicken or beef broth is not given because it contains excessive sodium and inadequate carbohydrate. A BRAT diet (bananas, rice, applesauce, and toast or tea) is contraindicated for the child and especially for the infant with acute diarrhea because this diet has little nutritional value (low in energy and protein), is high in carbohydrates, and is low in electrolytes.

Early reintroduction of nutrients is desirable and has gained more widespread acceptance. Continued feeding or early reintroduction of a normal diet after rehydration has no adverse effects, lessens the severity and duration of the illness, and improves weight gain when compared with the gradual reintroduction of foods (Kotloff, 2020). Infants who are breastfeeding should continue to do so, and ORS should be used to replace ongoing losses in these infants. Formula-fed infants should resume their formula; if it is not tolerated, a lactose-free formula may be used for a few days. In toddlers there is no contraindication to continuing soft or pureed foods. In older children a regular diet, including milk, can generally be offered after rehydration has been achieved. In cases of severe dehydration and shock, IV fluids are initiated whenever the child is unable to ingest sufficient amounts of fluid and electrolytes to (1) meet ongoing daily physiologic losses, (2) replace previous deficits, and (3) replace ongoing abnormal losses. Patients who usually require IV fluids are those with severe dehydration, uncontrollable vomiting, inability to drink for any reason (e.g., extreme fatigue, coma), and severe gastric distention.

Select the IV solution on the basis of what is known regarding the probable type and cause of the dehydration. The type of fluid normally used is a saline solution containing 5% dextrose in water. Sodium bicarbonate may be added because acidosis is usually associated with severe dehydration. Although the initial phase of fluid replacement is rapid in both isotonic and hypotonic dehydration, rapid replacement is contraindicated in hypertonic dehydration because of the risk of water intoxication.

After the severe effects of dehydration are under control, begin specific diagnostic and therapeutic measures to detect and treat the cause of the diarrhea. Because of the self-limiting nature of vomiting and its tendency to improve when dehydration is corrected, the use of antiemetic agents is usually not needed; however, ondansetron has few side effects and may be administered if vomiting persists and interferes with ORT (Kotloff, 2020).

The use of antibiotic therapy in children with acute gastroenteritis is controversial. Antibiotics may shorten the course of some diarrheal illnesses (e.g., those caused by *Shigella* organisms). However, most bacterial diarrheas are self-limiting, and the diarrhea often resolves before the causative organism can be determined. Antibiotics may prolong the carrier period for bacteria such as *Salmonella*. Antibiotics may be considered, however, in patients who are younger than 3 months of age or on immunosuppressive medication, or who have clinical signs of shock, severe malnutrition, dysentery, suspected cholera, or suspected giardiasis (Wen, Best, & Nourse, 2017). (See Chapter 6, Intestinal Parasitic Diseases.)

Nursing Care Management

The management of most cases of acute diarrhea takes place in the home with education of the caregiver. Teach caregivers to monitor for signs of dehydration (especially the number of wet diapers or voidings) and the amount of fluids taken by mouth and to assess the frequency and amount of stool losses. Education relating to ORT, including the administration of maintenance fluids and replacement of ongoing losses, is important (see Critical Thinking Case Study box). ORS should be administered in small quantities at frequent intervals. Vomiting is not a contraindication to ORT unless it is severe. Information concerning the introduction of a normal diet is essential. Parents need to know that a slightly higher stool output initially occurs with continuation of a normal diet and with ongoing replacement of stool losses. The benefits of a better nutritional outcome with fewer complications and a shorter duration of illness outweigh the potential increase in stool frequency. Address parents' concerns to ensure adherence to the treatment plan.

CRITICAL THINKING CASE STUDY

Diarrhea

A mother brings her 8-month-old infant, Mary, to the primary care clinic. The mother reports that Mary has had a "cold" for about 2 days, and this morning she began to vomit and has had diarrhea for the past 8 hours. Mary's mother states that she is still breastfeeding, but Mary is not taking as much fluid as usual and she is having three times as many stools as usual (the stools are watery). When the nurse practitioner examines Mary, she notes that her temperature is 38°C (100.4°F), her pulse and blood pressure are in the normal range, her mucous membranes are slightly dry, but she has tears when she cries. The nurse practitioner also notes that Mary's weight has not changed from what it was when she was seen in the clinic 2 weeks ago for her well-child visit.

Initial Assessment. How would you classify the degree of dehydration that Mary is experiencing? Mild, moderate, or severe?

Clinical Reasoning. What interventions are appropriate for the degree of dehydration?

Teaching Points

- Infants or children with mild dehydration are managed with oral rehydration therapy (ORT) and early reintroduction of an adequate diet.
- Breastfeeding generally can be continued in mild dehydration.
- Antidiarrheal medications are not recommended for the treatment of acute infectious diarrhea. These medications have adverse effects such as slowed motility and can prolong the illness.

Critical Thinking Answers

Initial Assessment. Mary is experiencing mild dehydration based on the history and exam.

Clinical Reasoning. An appropriate nursing action is to continue oral rehydration at frequent intervals using small amounts. The mother should *not* administer any antidiarrheal medications.

If the child with acute diarrhea and dehydration is hospitalized, the nurse must obtain an accurate weight and carefully monitor intake and output. The child may be placed on parenteral fluid therapy with nothing by mouth (NPO) for 12 to 48 hours. Monitoring the IV infusion is an important nursing function. The nurse must ensure that the correct fluid and electrolyte concentration is infused, that the flow rate is

adjusted to deliver the desired volume in a given time, and that the IV site is maintained.

Accurate measurement of output is essential to determine whether renal blood flow is sufficient to permit the addition of potassium to the IV fluids. The nurse is responsible for examination of stools and collection of specimens for laboratory examination. (See Chapter 20, Collection of Specimens.) Take care when obtaining and transporting stools to prevent possible spread of infection. Use a clean tongue depressor to obtain specimens for laboratory examination or as an applicator for transfer to a culture medium. Transport stool specimens to the laboratory in appropriate containers and media according to hospital policy.

Diarrheal stools are highly irritating to the skin, and extra care is necessary to protect the skin of the diaper region from excoriation. (See Chapter 31, Diaper Dermatitis.) Avoid taking temperatures rectally because they stimulate the bowel, increasing passage of stool.

Support for the child and family involves the same care and consideration given to all hospitalized children (see Chapter 19). Keep parents informed of the child's progress and instruct them in the use of frequent and proper hand washing and the disposal of soiled diapers, clothes, and bed linens. Everyone caring for the child must be aware of "clean" areas and "dirty" areas, especially in the hospital, where the sink in the child's room is used for many purposes. Discard soiled diapers and linens in receptacles close to the bedside.

Prevention

The best intervention for diarrhea is prevention. The fecal-oral route spreads most infections, and parents need information about preventive measures such as personal hygiene, protection of the water supply from contamination, and careful food preparation.

! NURSING ALERT

To reduce the risk of bacteria transmitted via food, encourage parents to do the following:

- Quickly freeze or refrigerate all ground meat and other perishable foods.
- Never thaw food on the counter or let it sit out of the refrigerator for more than 2 hours.
- Wash hands, utensils, and work areas with hot, soapy water after contact with raw meat to keep bacteria from spreading.
- Check ground meat with a fork to make certain no pink is showing before taking a bite.
- Cook all dishes made with ground meat until brown or gray inside or to an internal temperature of 71°C (160°F).

Meticulous attention to perianal hygiene, disposal of soiled diapers, proper hand washing, and isolation of infected persons also minimize the transmission of infection. (See Chapter 20, Infection Control.)

Parents need information about preventing diarrhea while traveling. Caution them against giving their children adult medications that are used to prevent traveler's diarrhea. The best measure during travel to areas where water may be contaminated is to allow children to drink only bottled water and carbonated beverages (from the container through a straw supplied from home). Children should also avoid tap water, ice, unpasteurized dairy products, raw vegetables, unpeeled fruits, meats, and seafood.

Vaccines can protect children from some diarrhea-related diseases. The rotavirus vaccine was integrated into the national immunization program in the United States in 2006, and subsequently the rotavirus season was noted to be shorter, along with a 76% decline in diarrhea hospitalization rates among children younger than 5 years of age (Lamberti et al., 2016).

CONSTIPATION

Constipation is an alteration in the frequency, consistency, or ease of passing stool. It is defined as unsatisfactory defecation due to infrequent stools, difficult stool passage, or perceived incomplete defecation (Bruce, Bruce, Short, et al., 2016). The frequency of bowel movements varies by age, but children ages 4 years and older can be diagnosed with constipation if they have fewer than three stools per week (Poddar, 2016). Constipation is often associated with painful bowel movements, blood-streaked or retained stool, abdominal pain, lack of appetite, and stool incontinence (i.e., soiling) (Bruce et al., 2016). Having extremely long intervals between defecation is **obstipation**. Constipation with fecal soiling is **encopresis**.

Constipation may arise secondary to a variety of organic disorders or in association with a wide range of systemic disorders. Structural disorders of the intestine, such as strictures, ectopic anus, and Hirschsprung disease (HD), may be associated with constipation. Systemic disorders associated with constipation include hypothyroidism, hypercalcemia resulting from hyperparathyroidism or vitamin D excess, and chronic lead poisoning. Constipation is also associated with drugs such as antacids, diuretics, antiepileptics, antihistamines, opioids, and iron supplementation. Spinal cord lesions may be associated with loss of rectal tone and sensation. Affected children are prone to chronic fecal retention and overflow incontinence.

Most children have **idiopathic** or **functional constipation** because no underlying cause can be identified. Chronic constipation may occur as a result of environmental or psychosocial factors, or a combination of both. Transient illness, withholding and avoidance secondary to painful or negative experiences with stooling, and dietary intake with decreased fluid and fiber all play a role in the etiology of constipation.

Newborn Period

Normally, newborn infants pass a first meconium stool within 24 to 36 hours of birth. Any newborn that does not do so should be assessed for evidence of intestinal atresia or stenosis, HD, hypothyroidism, meconium plug, or meconium ileus. **Meconium plug** is caused by meconium that has reduced water content and is usually evacuated after digital examination but may require irrigations with a hypertonic solution or contrast medium. **Meconium ileus**, the initial manifestation of cystic fibrosis, is the luminal obstruction of the distal small intestine by abnormal meconium. Treatment is the same as for a meconium plug; early surgical intervention may be needed to evacuate the small intestine.

Infancy

The onset of constipation frequently occurs during infancy and may result from organic causes such as HD, hypothyroidism, and strictures. It is important to differentiate these conditions from functional constipation. Constipation in infancy is often related to dietary practices. It is less common in breastfed infants, who have softer stools than bottle-fed infants. Breastfed infants may also have decreased stools because of more complete use of breast milk with little residue. When constipation occurs with a change from human milk or modified cow's milk to whole cow's milk, simple measures such as adding or increasing the amount of vegetables and fruit in the infant's diet and increasing fluids such as sorbitol-rich juices usually correct the problem. When a bottle-fed infant passes a hard stool that results in an anal fissure, stool-withholding behaviors may develop in response to pain on defecation (see Critical Thinking Case Study box).

CRITICAL THINKING CASE STUDY

Constipation

Harry, an 8-month-old infant, is seen by the pediatric nurse practitioner for his well-child visit. Harry's mother states that he usually has one hard stool every 4 or 5 days, which causes discomfort when the stool is passed. He has also had one episode of diarrhea and two episodes of ribbonlike stools. Abdominal distention and vomiting have not accompanied the constipation, and Harry's growth has been appropriate for his age. Currently his diet consists of cow's milk–based formula only. Harry's mother reports that the infrequent passage of hard stools began approximately 6 weeks ago when she stopped breastfeeding.

Initial Assessment. What are the immediate concerns regarding Harry's symptoms?

Clinical Reasoning. What interventions are most appropriate for the degree of symptoms?

Teaching Points

- Functional constipation may occur with changes in the diet (e.g., the change from breastfeeding 6 weeks ago to bottle-feeding of cow's milk–based formula).
- Prune juice could be slowly introduced into Harry's diet.
- Offering fruits and vegetables each day may help prevent further constipation.
- Often, simple measures such as the introduction of solid foods or other dietary modifications help to remedy functional constipation.

Critical Thinking Answers

Initial Assessment. The immediate concern is constipation. The initial data seem to point to the conclusion that Harry has functional constipation. However, diarrhea and the passage of ribbonlike stools do not usually occur with functional constipation; therefore Harry should be monitored closely.

Clinical Reasoning. Constipation in infancy can be caused by medical conditions such as Hirschsprung disease, hypothyroidism, or strictures, or it can be simple functional constipation. In infancy, changes in dietary practices such as a change from human milk to cow's milk may precipitate functional constipation. Functional constipation is usually treated by dietary modifications such as increasing the amount of fluids, fruits, or vegetables in the infant's diet.

Childhood

Most constipation in early childhood is due to environmental changes or normal development when a child begins to attain control over bodily functions. A child who has experienced discomfort during bowel movements may deliberately try to withhold stool. Over time, the rectum accommodates to the accumulation of stool, and the urge to defecate passes. When the bowel contents are ultimately evacuated, the accumulated feces are passed with pain, thus reinforcing the desire to withhold stool.

Constipation in school-age children may represent an ongoing problem or a first-time event. The onset of constipation at this age is often the result of environmental changes, stresses, and changes in toileting patterns. A common cause of new-onset constipation at school entry is fear of using the school bathrooms, which are noted for their lack of privacy. Early and hurried departure for school immediately after breakfast may also impede bathroom use.

Therapeutic Management

Treatment of constipation depends on the cause and duration of symptoms. A complete history and physical examination are essential to determine appropriate management. It may be necessary to facilitate passage of the obstruction by irrigation with a hypertonic solution or water-soluble enema. If the constipation is due to HD, surgical treatment may include resection of the intestine and saline irrigations.

Management of the infant should include education of the parents concerning normal bowel habits. Short, transient periods of constipation usually require no intervention. Mild constipation usually resolves as solid food is introduced in the diet. Stool softeners such as malt extract or lactulose may be used for hard stools or anal fissures. The persistent use of rectal stimulation with thermometers or cotton-tipped applicators is discouraged because these methods often result in anal fissures and increased pain that may trigger stool withholding.

The management of simple constipation consists of a plan to promote regular bowel movements. Often this is as simple as changing the diet to provide more fiber and fluids, eliminating foods known to be constipating, and establishing a bowel routine that allows for regular passage of stool. Stool-softening agents such as docusate or lactulose may also be helpful. Polyethylene glycol (PEG) 3350 without electrolytes (MiraLax) is a chemically inert polymer that has been introduced as a new laxative in recent years. Children tolerate it well because it can be mixed in any beverage of choice. If other symptoms such as vomiting, abdominal distention, or pain and evidence of growth failure are associated with the constipation, investigate the condition further.

Management of chronic constipation requires an organized and ongoing approach. It is important for families to realize that it usually requires months or years to resolve, and relapse is common. The goals for management include restoring regular evacuation of stool, shrinking the distended rectum to its normal size, and promoting a regular toileting routine. This requires a combination of therapies and should include bowel cleansing, maintenance therapy to prevent stool retention, modification of diet, bowel habit training, and behavioral modification.

DRUG ALERT

Mineral Oil

Mineral oil must be given carefully to avoid the risk of aspiration. It should not be used in children younger than 1 year old (Poddar, 2016).

After the impaction is removed, maintenance therapy often lasting for 6 to 12 months is necessary to promote easy passage of stool and prevent stool retention. Maintenance therapy includes stool softeners and laxatives. Stool softeners are often ineffective for severe constipation; laxative therapy may be necessary to return the rectum to its normal size. Because of the minimal side effects, taste, and efficacy, PEG is a more favorable constipation intervention than lactulose (Poddar, 2016). PEG increases fluid in the colon. The additional volume of fluid stimulates the urge to defecate.

Changes in the diet may be helpful but are usually not effective alone. Encouraging the intake of fiber ultimately helps maintain regular elimination once the rectum returns to normal size and the laxatives are tapered. Recommended daily fiber intake is age in years plus 5 grams of fiber per day (Poddar, 2016). Effective counseling is an essential element of the treatment plan for children

with chronic constipation. Explain normal bowel function, the purpose of interventions, and the need for persistence to the child and family.

Retraining therapy involves habit training, reinforcement for sitting on the toilet and defecating, and emotional support. Parents should establish a regular toilet time once or twice a day, preferably after a meal. A reasonable amount of time (5 to 10 minutes) should be spent attempting to defecate completely. Biofeedback may be indicated as a form of behavior modification and as a means to teach children to relax the anal sphincter during defecation.

Nursing Care Management

Unfortunately, constipation tends to be self-perpetuating. A child who has difficulty or discomfort when attempting to evacuate the bowels has a tendency to retain the bowel contents, and thus constipation becomes a chronic problem. Nursing assessment begins with a history of bowel habits; diet; events that may be associated with the onset of constipation; drugs or other substances that the child may be taking; and the consistency, color, frequency, and other characteristics of the stool. If there is no evidence of a pathologic condition that requires further investigation, the nurse's major task is to educate the parents regarding normal stool patterns and to participate in the education and treatment of the child.

Dietary modifications are helpful in preventing constipation. Fiber is an important part of the diet. Parents benefit from guidance about foods that are high in fiber and ways to promote healthy food choices in children. If bran is added to the diet, creative ways to disguise the consistency, such as adding it to cereal, peanut butter, mashed potatoes, fruit shakes, and baked goods, are helpful. Beans are often found in Mexican dishes children enjoy and can be added to soups, salads, and stews. Beyond the age when foreign body aspiration is a hazard, a good source of fiber is corn and popcorn.

VOMITING

Vomiting is the forceful ejection of gastric contents through the mouth. It is a well-defined, complex, coordinated process that is under CNS control and is often accompanied by nausea and retching. In contrast, regurgitation is a simpler, more passive, and effortless phenomenon. Vomiting has many causes, including acute infectious diseases, increased intracranial pressure, toxic ingestions, food intolerances and allergies, mechanical obstruction of the GI tract, adrenal insufficiency, nephrologic disease, pregnancy, and psychogenic problems (Maqbool & Liacouras, 2020c). Vomiting is common in childhood, is usually self-limiting, and requires no specific treatment. However, complications can occur in children, including acute fluid volume loss (dehydration) and electrolyte disturbances, malnutrition, aspiration, and Mallory-Weiss syndrome (small tears in the distal esophageal mucosa).

Etiology

The child's age, pattern of vomiting, and duration of symptoms help determine the cause. For example, chronic and intermittent episodes of vomiting may indicate malrotation, whereas vomiting on a specific day at the same time before school is not likely to be a result of organic disease. The color and consistency of the emesis vary according to the cause. Green, bilious vomiting suggests bowel obstruction. Curdled stomach contents, mucus, or fatty foods that are vomited several hours after ingestion suggest poor gastric emptying or high intestinal obstruction. Gastric irritation by certain medicines, foods, or toxic substances may cause vomiting. Forceful vomiting is associated with pyloric stenosis.

Associated symptoms also help identify the cause. Fever and diarrhea accompanying vomiting suggest an infection. Constipation associated with vomiting suggests an anatomic or functional obstruction. Localized abdominal pain and vomiting often occur with appendicitis, pancreatitis, or peptic ulcer disease. A change in the level of consciousness or a headache associated with vomiting indicates a central nervous system or metabolic disorder.

Pathophysiology

The act of vomiting, including nausea and retching, is under the control of the CNS. Two areas of the medulla are involved as the vomiting center. The medullary center is also activated by impulses from a second center, the chemoreceptor trigger zone, which is located in the floor of the fourth ventricle. **Nausea** is a sensation that may be induced by visceral, labyrinthine (inner ear), or emotional stimuli. It is characterized by the desire to vomit, with discomfort felt in the throat or abdomen. Nausea is often associated with autonomic symptoms such as salivation, pallor, sweating, and tachycardia. Retching may occur with or without vomiting. **Retching** involves a series of spasmodic movements during inspiration, creating a negative intrathoracic pressure, and contraction of the abdominal muscles. Projectile vomiting is preceded and accompanied by vigorous peristaltic waves.

Vomiting is a well-recognized response to psychologic stress. During stress, adrenaline levels rise and may stimulate the chemoreceptor trigger zone. Nausea and vomiting are likely a protective mechanism to remove toxins from the system. Vomiting may follow GI infection or toxic ingestion, or it can be a learned behavioral response.

Cyclic vomiting syndrome is a rare disorder, affecting approximately 2% of children in the United States, and is characterized by bouts of vomiting that can last from hours to several days (Maqbool & Liacouras, 2020c). The cause of this syndrome is unknown, although a family history of migraines is usually present in at least 80% of the patients (Maqbool & Liacouras, 2020c).

Diagnostic Evaluation

The diagnostic evaluation includes a thorough history and physical examination. The description of the vomitus; relationship to meals or specific foods; behavior; and presence of pain, constipation, diarrhea, or jaundice are important components of the history. Physical examination should include an assessment of the hydration status and an abdominal examination.

Further evaluation may include analysis of urine for protein or blood, serum electrolytes, and radiographic studies. A plain radiograph of the chest or abdomen or ultrasonography may reveal anatomic abnormalities. Brain scans are used when tumors are considered. Endoscopy of the upper GI tract may be a valuable diagnostic procedure if the provider suspects esophagitis. A psychiatric evaluation may be indicated if cyclic vomiting, anorexia nervosa, bulimia, or self-poisoning is present. Self-induced vomiting and rumination may be a self-stimulation or gratification activity.

Therapeutic Management

Management is directed toward detection and treatment of the cause of the vomiting and prevention of complications, such as dehydration and malnutrition. Vomiting is often a symptom of a common infectious illness that is self-limiting and resolves with no specific treatment.

Further investigation is indicated if there is dehydration, progressively severe vomiting, or persistent vomiting for more than 24 hours, or if the history and physical examination fail to suggest a diagnosis. If vomiting leads to dehydration, oral rehydration or parenteral fluids may be required.

Antiemetic drugs may be indicated when the child is not able to tolerate anything orally or in cases of postoperative vomiting, chemotherapy-induced vomiting, cyclic vomiting syndrome, or acute motion sickness (Maqbool & Liacouras, 2020c). Ondansetron (Zofran) is an antiemetic with limited adverse effects and is beneficial when the child is not able to tolerate anything orally or in the case of postoperative vomiting, chemotherapy-induced vomiting, cyclic vomiting syndrome, or acute motion sickness (Maqbool & Liacouras, 2020c). Adverse effects with earlier-generation antiemetics (such as promethazine and metoclopramide) include somnolence, nervousness, irritability, and dystonic reactions, and they should not be routinely administered to children. For children who are prone to motion sickness, it is often helpful to administer an appropriate dose of dimenhydrinate (Dramamine) before a trip (see Translating Evidence Into Practice box).

TRANSLATING EVIDENCE INTO PRACTICE

Use of Antiemetics in Children With Acute Gastroenteritis

Ask the Question

In children with acute gastroenteritis (AGE), should antiemetics be used?

Search for the Evidence

Search Strategies

Search criteria included English-language publications within the years 2011 to 2017, research-based articles (level 3 or higher) regarding antiemetic use among children with AGE.

Databases Used

PubMed/Medline; CINAHL; Cochrane; National Guideline Clearinghouse (Agency for Healthcare Research and Quality); American Academy of Pediatrics; National Institute of Health and Clinical Excellence; European Society for Paediatric Gastroenterology, Hepatology, and Nutrition; Joanna Briggs Institute.

Critically Analyze the Evidence

There is **moderate evidence** with a **strong recommendation** (Balshem, Hefland, Schunemann, et al., 2011).

A review of the literature revealed two systematic reviews and three randomized control trials from 2011 to 2017 that evaluated the use of antiemetics in the treatment of children with AGE.

- A Cochrane review in 2011 revealed 7 randomized controlled trials (1020 patients) evaluating the safety and efficacy of antiemetics to treat gastroenteritis-induced vomiting in children (Fedorowicz, Jagannath, & Carter, 2011). Ondansetron was found more effective than placebo in studies evaluating hospital admission rates, need for intravenous (IV) rehydration therapy, and resolution of vomiting. When comparing placebo, dimenhydrinate was found more effective in one study, and metoclopramide was more effective in another single study.
- A systematic review from 1980 to 2012 revealed 10 studies (1479 participants) evaluating the evidence of safety and effectiveness of antiemetics (dexamethasone, dimenhydrinate, granisetron, metoclopramide, and ondansetron) for gastroenteritis-induced vomiting in children and adolescents (Carter & Fedorowicz, 2012). There is clear evidence from nine studies that ondansetron is more effective than placebo in resolving vomiting, reducing the need for IV rehydration therapy, and reducing the hospital admission rate. A single study showed a reduction in mean vomiting days among children receiving dimenhydrinate versus placebo and among granisteron versus placebo. Studies of metoclopramide were underpowered, and a single study of dexamethasone versus placebo showed no statistically significant difference in vomiting.
- A group of 144 children diagnosed with AGE were randomized to receive dimenhydrinate or placebo in a pediatric emergency department (Gouin, Vo, Roy, et al., 2012). No statistically significant difference in the frequency of vomiting was noted between the two groups.
- A group of 76 children diagnosed with AGE were randomized to receive an orally disintegrating ondansetron tablet or domperidone suspension (dosing based on body weight), then evaluated for vomiting for the next 24 hours (Rerksuppaphol & Rerksuppaphol, 2013). Sixty-two percent of patients in the ondansetron group and 44% of patients in the domperidone group had no vomiting after treatment, although no statistically significant difference was noted ($P = 0.16$).
- Another study randomized 356 children who failed oral rehydration in an emergency department to receive ondansetron ($n = 119$) versus domperiodone ($n = 119$) versus placebo ($n = 118$) for treatment of AGE (Marchetti, Bonati, Maestro, et al., 2016). Fourteen children (12%) needed IV rehydration in the ondansetron group compared with 30 children (25%) in the domperidone and 34 children (29%) in the placebo group.

Apply the Evidence: Nursing Implications

Ondansetron reduces the duration of vomiting in children with AGE, and ondansetron and domperidone relieves the incidence of vomiting in children with AGE. There is limited evidence for dimenhydrinate and metoclopramide and no evidence for other antiemetics in children with AGE who are vomiting. The number of children requiring IV rehydration and hospital admission for AGE is reduced with administration of ondansetron.

Nursing Care Management

The major emphasis of nursing care of the vomiting infant or child is on observation and reporting of vomiting behavior and associated symptoms and on the implementation of measures to reduce the vomiting. Accurate assessment of the type of vomiting, appearance of the emesis, and the child's behavior in association with the vomiting greatly aids in establishing a diagnosis.

The cause of the vomiting determines the nursing intervention. When the vomiting is a manifestation of improper feeding methods, establishing proper techniques through teaching and example ordinarily corrects the situation. If the vomiting is a probable sign of GI obstruction, the nurse usually withholds food or implements special feeding techniques. The nurse should direct efforts toward maintaining hydration and preventing dehydration in a vomiting child.

The thirst mechanism is the most sensitive guide to fluid needs, and ad libitum administration of a glucose-electrolyte solution to an alert child restores water and electrolytes satisfactorily. It is important to include carbohydrates to spare body protein and to avoid ketosis resulting from exhaustion of glycogen stores. Small, frequent feedings of fluids or foods are preferable and more effective. Once vomiting has abated, offer more liberal amounts of fluids, followed by gradual resumption of the regular diet.

Position the infant or child who is vomiting upright to prevent aspiration and observe him or her for evidence of dehydration. Carefully monitor fluid and electrolyte status to avoid the possibility of electrolyte imbalance. It is important to emphasize the need for the child to brush the teeth or rinse the mouth after vomiting to dilute the hydrochloric acid that comes in contact with the teeth.

HIRSCHSPRUNG DISEASE (CONGENITAL AGANGLIONIC MEGACOLON)

Hirschsprung disease (HD) is a congenital anomaly that results in mechanical obstruction from inadequate motility of part of the intestine. It accounts for about one-fourth of all cases of neonatal intestinal obstruction. The incidence is 1 in 5000 live births (Maqbool & Liacouras, 2020a). It is four times more common in males than in females and follows a familial pattern in a small number of cases. Mutations in the *RET* proto-oncogene have been found in children with HD (Maqbool & Liacouras, 2020a).

Pathophysiology

The pathology of HD relates to the absence of ganglion cells in the affected areas of the intestine, resulting in a loss of the rectosphincteric reflex and an abnormal microenvironment of the cells of the affected intestine. The term *congenital aganglionic megacolon* describes the primary defect, which is the absence of ganglion cells in the myenteric plexus of Auerbach and the submucosal plexus of Meissner (Fig. 22.2).

The absence of ganglion cells in the affected bowel results in a lack of enteric nervous system stimulation, which decreases the internal sphincter's ability to relax. Unopposed sympathetic stimulation of the intestine results in increased intestinal tone. In addition to the contraction of the abnormal bowel and the resulting lack of peristalsis, there is a loss of the rectosphincteric reflex. Normally, when a stool bolus enters the rectum, the internal sphincter relaxes and the stool is evacuated. In HD, the internal sphincter does not relax. In about 80% of the cases, the aganglionic segment includes only the rectum and some portion of the distal colon, called *short-segment disease* (Maqbool & Liacouras, 2020a). However, the entire colon or part of the small intestine may be involved; this is considered *long-segment HD*. Occasionally, skip segments or total intestinal aganglionosis may occur. Approximately 15% have long-segment disease, and 5% have total intestinal aganglionosis (Maqbool & Liacouras, 2020a).

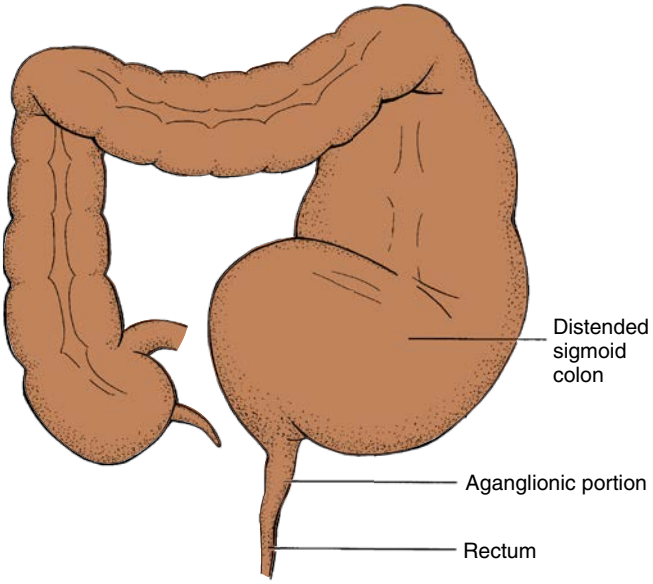

Fig. 22.2 Hirschsprung disease.

BOX 22.2 Clinical Manifestations of Hirschsprung Disease

Newborn Period
Failure to pass meconium within 24 to 48 hours after birth
Refusal to feed
Bilious vomiting
Abdominal distention

Infancy
Failure to thrive
Constipation
Abdominal distention
Episodes of diarrhea and vomiting
Signs of enterocolitis
- Explosive, watery diarrhea
- Fever
- Appears significantly ill

Childhood
Constipation
Ribbonlike, foul-smelling stools
Abdominal distention
Visible peristalsis
Easily palpable fecal mass
Undernourished, anemic appearance

Clinical Manifestations

Most children with HD are diagnosed in the first few months of life. Clinical manifestations vary according to the age when symptoms are recognized and the presence of complications, such as enterocolitis (Box 22.2). A neonate usually is seen with a distended abdomen, feeding intolerance with bilious vomiting, and a delay in the passage of meconium. Typically, 99% of term infants pass meconium in the first 48 hours of life, whereas few infants with HD do so (Maqbool & Liacouras, 2020a).

Diagnostic Evaluation

In the neonate the diagnosis is suspected on the basis of clinical signs of intestinal obstruction or failure to pass meconium. In infants and children the history is an important part of diagnosis and typically includes a chronic pattern of constipation. On examination the rectum is empty of feces, the internal sphincter is tight, and leakage of liquid stool and accumulated gas may occur if the aganglionic segment is short. A contrast enema often demonstrates the transition zone between the dilated proximal colon (megacolon) and the aganglionic distal segment. However, this typical megacolon and narrow distal segment may not develop until age 2 months or later.

To confirm the diagnosis, rectal biopsy is performed either surgically to obtain a full-thickness biopsy specimen or by suction biopsy for histologic evidence of the absence of ganglion cells. A noninvasive procedure that may be used is anorectal manometry, in which a catheter with a balloon attached is inserted into the rectum. The test records the reflex pressure response of the internal anal sphincter to distention of the balloon. A normal response is relaxation of the internal sphincter, followed by a contraction of the external sphincter. In HD the external sphincter contracts normally but the internal sphincter fails to relax.

Therapeutic Management

The majority of children with HD require surgery rather than medical therapy. One of three operative procedures is performed: a Soave pull-through, the Swenson procedure, and the Duhamel procedure (Maqbool & Liacouras, 2020a). Once the child is stabilized with fluid and electrolyte replacement and colonic cleansing with enemas, if needed, surgery is performed, usually with a high rate of success. Surgical management consists primarily of the removal of the aganglionic portion of the bowel to relieve obstruction, restore normal motility, and preserve the function of the external anal sphincter. The transanal Soave endorectal pull-through procedure consists of pulling the end of the normal bowel through the muscular sleeve of the rectum, from which the aganglionic mucosa has been removed. With earlier diagnosis the proximal bowel may not be extremely distended, thus allowing for a primary pull-through or one-stage procedure and eliminating the need for a temporary colostomy. Simpler operations, such as an anorectal myomectomy, may be indicated in very short-segment disease.

After the pull-through procedure, the majority of children achieve fecal continence. However, some children may experience anal stricture, recurrent enterocolitis, prolapse, or perianal abscess, and incontinence may occur and require further therapy, including dilations or bowel retraining therapy (Maqbool & Liacouras, 2020a).

Nursing Care Management

The nursing concerns depend on the child's age and the type of treatment. If the disorder is diagnosed during the neonatal period, the main objectives are to help the parents adjust to a congenital defect in their child, foster infant-parent bonding, prepare the parents for the medical-surgical intervention, and prepare the parents to assume the care of the child after surgery.

The child's preoperative care depends on the age and clinical condition. A child who is malnourished may not be able to withstand surgery until his or her physical status improves. Often this involves symptomatic treatment with enemas and a low-fiber, high-calorie, high-protein diet. Physical preoperative preparation includes the same measures that are common to any surgery. (See Chapter 20, Surgical Procedures.) In the newborn, whose bowel is presumed sterile, no additional preparation is necessary. However, in other children, preparation for the pull-through procedure involves emptying the bowel with repeated saline enemas and decreasing bacterial flora with oral or systemic antibiotics and colonic irrigations using antibiotic solution. Enterocolitis is the most serious complication of HD. Emergent preoperative care includes frequent monitoring of vital signs and blood pressure for signs of shock; monitoring fluid and electrolyte replacements, as well as plasma or other blood derivatives; and observing for symptoms of bowel perforation, such as fever, increasing abdominal distention, vomiting, increased tenderness, irritability, dyspnea, and cyanosis.

Because progressive distention of the abdomen is a serious sign, the nurse measures abdominal circumference with a paper tape measure, usually at the level of the umbilicus or at the widest part of the abdomen. The point of measurement is marked with a pen to ensure reliability of subsequent measurements. Abdominal measurement can be obtained with the vital sign measurements and is recorded in serial order so that any change is obvious. To reduce stress to the acutely ill child when frequent measurements of abdominal circumference are needed, the tape measure can be left in place beneath the child rather than removed each time.

Postoperative care is the same as that for any child or infant with abdominal surgery. (See Chapter 20, Surgical Procedures.) The nurse involves the parents in the care of the child, allowing them to help with feedings and observe for signs of wound infection or irregular passage of stool. After surgery, parents need instruction concerning the development of complications such as enterocolitis, fecal incontinence, and obstruction. Some children will require daily anal dilations in the postoperative period to avoid anastomotic strictures; parents are often taught to perform the procedure in the home and will need encouragement and detailed instructions to perform these dilations. Although less common, a diverting colostomy may be performed in some children with HD. Parents are taught how to care for the colostomy and how to provide meticulous skin care to prevent skin breakdown; the assistance of a wound and skin care specialist is essential for optimal follow-up and consistent skin care.

Parents may need to bring the child with an ostomy to an outpatient clinic for support, encouragement, and additional instructions on skin and ostomy care after the child is discharged. In general, the prognosis for the infant or child with HD is positive, and most live a normal life. In a few cases, problems with fecal incontinence may persist. A long-term study of children with HD for 1 to 19 years reported satisfying bowel control among 53% of the sample, soiling with 13%, constipation among 6%, and abdominal distention with 26% (Muller, Rossignol, Montalva, et al., 2016).

GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux (GER) is defined as the transfer of gastric contents into the esophagus. This phenomenon is physiologic, occurring throughout the day, most frequently after meals and at night; therefore it is important to differentiate GER from **gastroesophageal reflux disease (GERD)**. GERD represents symptoms or tissue damage that results from GER. The peak incidence of GER occurs at 4 months of age, and GER generally resolves spontaneously in most infants by 1 year of age (Mousa & Hassan, 2017). GER becomes a disease when complications such as failure to thrive, respiratory problems, or dysphagia develop.

Certain conditions predispose children to a high prevalence of GERD, including neurologic impairment, chronic respiratory disorders, esophageal atresia, and obesity (Mousa & Hassan, 2017). Family clustering has also been identified; therefore a genetic predisposition to GERD is also likely (Khan & Matta, 2020a). Sandifer syndrome is an uncommon condition, usually occurring in young children, that is characterized by repetitive stretching and arching of the head and neck that

BOX 22.3 Clinical Manifestations and Complications of Gastroesophageal Reflux

Symptoms in Infants

Spitting up, regurgitation, recurrent vomiting (may be forceful)
Excessive crying, irritability, arching of the back, stiffening
Poor weight gain
Respiratory problems (e.g., cough, wheeze, stridor, gagging, choking with feedings)
Feeding refusal

Symptoms in Children

Heartburn
Abdominal pain
Chronic cough, hoarse voice
Dysphagia
Asthma
Recurrent vomiting

Complications

Esophagitis
Esophageal stricture
Laryngitis
Recurrent pneumonia
Anemia
Barrett esophagus

Adapted from Lightdale, J. R., Gremse, D. A., & Section on Gastroenterology, Hepatology, and Nutrition. (2013). Gastroesophageal reflux: Management guidance for the pediatrician. *Pediatrics, 131*(5), e1684–e1695.

can be mistaken for a seizure. This maneuver likely represents a physiologic neuromuscular response attempting to prevent acid refluxate from reaching the upper portion of the esophagus (Khan & Matta, 2020a).

Infants who are prone to develop GER include premature infants and infants with bronchopulmonary dysplasia. Children who have had tracheoesophageal or esophageal atresia repairs, neurologic disorders, scoliosis, asthma, cystic fibrosis, or cerebral palsy are also prone to develop GER.

Pathophysiology

Although the pathogenesis of GER is multifactorial, its primary causative mechanism likely involves inappropriate transient relaxation of the lower esophageal sphincter (LES). Factors that increase abdominal pressure (e.g., coughing and sneezing, scoliosis, overeating) may contribute to GER. Esophageal symptoms are caused by inflammation from the acid in the gastric refluxate, whereas reactive airway disease may result from stimulation of airway reflexes by the acid refluxate.

Clinical Manifestations

During infancy the most common clinical manifestation of GER is passive regurgitation. Regurgitation generally resolves spontaneously in most infants by 12 months of age and in almost all infants by 24 months of age (Khan & Matta, 2020a). Clinical manifestations of GER are listed in Box 22.3. GER is one of the causes of apparent life-threatening events and has also been associated with chronic respiratory disorders, including reactive airway disease, recurrent stridor, chronic cough, and recurrent pneumonia in infants. Esophagitis can also cause discomfort in the chest area, which may be manifested as unusual irritability or poor intake of nutrients. Poor weight gain and poor growth may occur in a child with an insufficient intake of nutrients or with a large amount of regurgitation.

In preschool children, GER may occur with intermittent vomiting. Older children tend to initially come to the physician with a more adult-like pattern of heartburn, regurgitation, and reswallowing. GERD may cause severe inflammation, chronic blood loss with anemia and hematemesis, hypoproteinemia, or melena. If the inflammation goes untreated, scarring and strictures may form. Barrett mucosa, another potential finding in the presence of chronic inflammation, is characterized by changes in the distal esophageal mucosa with metaplastic, potentially malignant epithelium.

GER is common in children with asthma, but recurrent pneumonia caused by GER is uncommon except in children with neurologic impairments. Hoarseness has also been associated with GER in children.

Diagnostic Evaluation

The history and physical examination are usually sufficiently reliable to establish the diagnosis of GER. Standardized questionnaires, such as the Infant Gastroesophageal Reflux Questionnaire, are commonly used to assist with the diagnosis (Khan & Matta, 2020a). An upper GI series is helpful in evaluating the presence of anatomic abnormalities (e.g., pyloric stenosis, malrotation, annular pancreas, hiatal hernia, esophageal stricture). The 24-hour intraesophageal pH monitoring study was the gold standard in the diagnosis of GER; however, this test is a poor detector of weakly acidic (pH 4 to 7) reflux, which is prevalent in infants and children (Mousa & Hassan, 2017). Endoscopy with biopsy may be helpful to assess the presence and severity of esophagitis, strictures, and Barrett esophagus and to exclude other disorders such as Crohn disease. Scintigraphy detects radioactive substances in the esophagus after a feeding of the compound and assesses gastric emptying. It can differentiate between aspiration of gastric contents from reflux and aspiration from poor oropharyngeal muscle coordination.

Therapeutic Management

Therapeutic management of GER depends on its severity. No therapy is needed for the infant who is thriving and has no respiratory complications. Avoidance of certain foods that exacerbate acid reflux (e.g., caffeine, citrus, tomatoes, alcohol, peppermint, spicy or fried foods) can improve mild GER symptoms. Lifestyle modifications in children (e.g., weight control if indicated; small, more frequent meals) and feeding maneuvers in infants (e.g., thickened feedings; upright positioning) can help as well.

Feedings thickened with 1 teaspoon to 1 tablespoon of rice cereal per ounce of formula may be recommended. This may benefit infants who are underweight as a result of GERD; however, the additional calories are not beneficial among infants who are overweight. These infants may benefit from prethickened formulas that are now commercially available. Constant NG feedings may be necessary for the infant with severe reflux and failure to thrive until surgery can be performed. Elevating the head of the bed and weight loss, if applicable, can reduce GER symptoms. Prone positioning of infants also decreases episodes of GER; however, due to the risk of sudden infant death syndrome, all infants should sleep in the supine position (Khan & Matta, 2020a). The American Academy of Pediatrics continues to recommend supine positioning for sleep (see Chapter 8).

Pharmacologic therapy may be used to treat infants and children with GERD. Both histamine (H_2)–receptor antagonists (ranitidine [Zantac] or famotidine [Pepcid]) and proton pump inhibitors (PPIs; esomeprazole [Nexium], lansoprazole [Prevacid], omeprazole [Prilosec], pantoprazole [Protonix], and rabeprazole [Aciphex]) reduce gastric hydrochloric acid secretion and may stimulate some increase in the lower esophageal sphincter tone. Use of metoclopramide for GERD in infants and children is no longer recommended

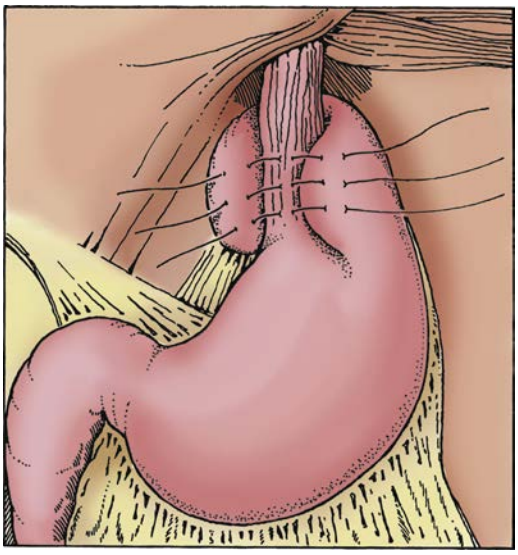

Fig. 22.3 Nissen fundoplication sutures passing through esophageal musculature. (Redrawn from Campbell, A., & Ferrara, B. [1993]. Toupet partial fundoplication. *AORN Journal, 57,* 671–679.)

due to the common incidence of side effects without significant benefit (Cohen, Bueno de Mesquita, & Mimouni, 2015).

Surgical management of GER is reserved for children with severe complications such as recurrent aspiration pneumonia, apnea, severe esophagitis, or failure to thrive and for children who have failed to respond to medical therapy. The **fundoplication** (Fig. 22.3) is a common surgical procedure for the treatment of GERD in children who have failed medical therapy or have life-threatening complications of GERD (Mousa & Hassan, 2017). This surgery involves passage of the gastric fundus behind the esophagus to encircle (i.e., wrap) the distal esophagus. Complications after fundoplication include a wrap that is too tight, causing dysphagia, small bowel obstruction, or gas-bloat; or a wrap that is too loose, causing continuation of symptoms (Khan & Matta, 2020a).

Prognosis

The majority of infants with GER have a mild problem that generally improves by 12 to 18 months of age and requires only conservative lifestyle changes or medical therapy. If GER is severe and remains unsuccessfully treated, multiple complications can occur. Esophageal strictures caused by persistent esophagitis with scarring are one of the most significant complications. Recurrent respiratory distress with aspiration pneumonia, another serious complication, is an indication for surgery. Failure to thrive caused by GER can often be managed with medical therapy and nutritional support. (See Quality Patient Outcomes box.)

QUALITY PATIENT OUTCOMES: Gastroesophageal Reflux

- Adequate weight gain
- Limited spitting up or vomiting
- Good sleep habits
- No recurrent pneumonias

Nursing Care Management

Nursing care is directed at identifying children with symptoms suggestive of GER; educating parents on home care, including feeding, positioning, and medications when indicated; and caring for the child undergoing surgical intervention. For the majority of infants, parental reassurance of the benign nature of the condition and its relationship to physiologic maturity is the most important intervention. To help parents cope with the inconvenience of dealing with a child who spits up or regurgitates frequently, simple tips such as using bibs and protective clothes during feeding and prone positioning when holding the infant after feeding are beneficial.

It is important to educate and reassure parents about positioning. In the past, recommendations encouraged upright positioning during sleeping for both infants and older children. The supine position for sleeping continues to be the recommended infant sleeping position. Parents should not place infants on their sides as an alternative to fully supine sleeping, and avoidance of soft bedding and soft objects in the bed is important. Rescheduling of the family's routine may be required to accommodate more frequent feeding times. If parents use thickened formula, they should also enlarge the nipple opening for easier sucking. Usually breastfeeding may continue, and the mother may provide more frequent feeding times or express the milk for thickening with rice cereal. Parents should avoid feeding the child spicy foods or any foods that they find aggravate symptoms in general and should avoid caffeine, chocolate, tobacco smoke, and alcohol when breastfeeding. Other practical advice includes advising the parents to avoid vigorous play after feedings and to avoid feeding just before bedtime.

When regurgitation is severe and growth is a problem, continuous NG tube feedings may decrease the amount of emesis and provide constant buffering of gastric acid. Special preparation of caregivers is required when this type of nutritional therapy is indicated.

The nurse can support the family by providing information about all aspects of treatment. Parents often require specific information about the medications given for GER. PPIs are most effective when administered 30 minutes before breakfast so that the peak plasma concentrations occur with mealtimes. If they are given twice a day, the second best time for administration is 30 minutes before the evening meal. Parents need to be reassured because it takes several days of administration to achieve a steady state of acid suppression. They may not see the results that they expect right away. A number of formulations available in PPIs allow for more efficient administration. Some preparations are available in dissolvable pills. There are powder and granule preparations as well. Many pharmacies will compound the medication in a liquid form for administration.

Postoperative nursing care after the Nissen fundoplication is similar to that for other types of abdominal surgery (see Chapter 20, Surgical Procedures). Gastric decompression by an NG tube or gastrostomy must be maintained to avoid distention in the immediate postoperative period. Usually the NG tube should not be replaced by the nurse if it is accidentally removed because of the risk of injury to the operative site. When postoperative ileus resolves, the NG tube is removed or the gastrostomy tube is elevated in preparation for feeding. If bolus feedings are initiated through the gastrostomy, the tube may need to remain vented for several days or longer to avoid gastric distention from swallowed air. Edema surrounding the surgical site and a tight gastric wrap may prohibit the infant from expelling air through the esophagus. Some infants benefit from clamping of the tube for increasingly longer intervals until they are able to tolerate continuous clamping between feedings. During this time, if the infant displays increasing irritability and evidence of cramping, some relief may be provided by venting the tube.

Preparation for Home Care

If medical management is prescribed or surgery is performed, nursing responsibilities include educating caregivers about administering drugs at home, special feeding regimens or formula preparation, gastrostomy care, and postoperative care (see Chapter 20). After surgery, reflux is

completely controlled in most cases, with these children attaining normal health and growth. If a gastrostomy tube is inserted during surgery, it may be removed after several months unless nutritional supplementation is needed. In severe cases of bloating or dumping syndrome, continuous tube feedings may be better tolerated. Caregivers should be aware of potential postoperative problems, such as difficulty vomiting, bloating symptoms, or discomfort with large solid-food meals, and seek guidance from their health care provider as needed.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is classified as a functional GI disorder. IBS occurs more frequently in adolescents than in children, 22% to 35% versus 6% to 14%, respectively (Giannetti, Maglione, Sciorio, et al., 2017). Children with IBS often have alternating diarrhea and constipation, flatulence, bloating or a feeling of abdominal distention, lower abdominal pain, a feeling of urgency when needing to defecate, and a feeling of incomplete evacuation of the bowel. Abdominal pain should be present for at least 4 days per month over the last 2 months, plus there should be a change in either frequency or appearance of stool (Chopra, Patel, Basude, et al., 2017). IBS has been identified as a cause of recurrent abdominal pain in 68% of children (Giannetti et al., 2017).

The cause of IBS is not clear, but it is believed to involve a combination of genetic and environmental factors. Strong predictors for the development of IBS in a child include having a mother, father, or twin with IBS (Kridler & Kamat, 2016). In addition, children with IBS have been noted to be less confident in their ability to deal with daily stress and have higher prevalence of anxiety, depression, introverted personalities, and difficulty sleeping (Kridler & Kamat, 2016). The intestinal microbiome is the focus of IBS research to evaluate whether inflammation may trigger nerves in the gut to cause IBS symptoms (Chopra et al., 2017; Kridler & Kamat, 2016).

Children with IBS are evaluated to rule out organic causes for their symptoms, such as IBD, lactose intolerance, and parasitic infections. A comprehensive history is obtained, including features and triggers of the symptoms, as well as associated symptoms such as headaches, recent infections, diet history, family history, and social history. Typically there are no abnormal physical findings on examination. Many children with symptoms appear active and healthy and have normal growth.

Therapeutic Management

There is no cure for IBS, so management involves controlling the child's symptoms. The long-range goal of treatment is development of regular bowel habits and relief of symptoms. Management depends on whether IBS is constipation or diarrhea predominant. Constipation-predominant IBS is managed by increasing fiber with diet changes and supplements, whereas diarrhea-predominant IBS is managed with diet changes, PPIs, and loperamide (Chopra et al., 2017; Kridler & Kamat, 2016). A recent Cochrane systematic review found evidence suggesting that probiotics are effective in relieving recurrent abdominal pain (Newlove-Delgado, Martin, Abbott, et al., 2017).

Psychosocial interventions, including cognitive-behavioral therapy and hypnotherapy, can decrease abdominal pain in children (Abbott, Martin, Newlove-Delgado, et al., 2017; Chopra et al., 2017). Cognitive-behavioral therapy provides stress management and coping skills that may lessen IBS symptoms.

Nursing Care Management

The primary nursing goal is family support and education. The disorder is stressful to children and parents. The nurse can help by providing support and reassurance that, although the symptoms are difficult to deal with, the disorder is not generally a threat to the child's health.

INFLAMMATORY CONDITIONS

ACUTE APPENDICITIS

Appendicitis, inflammation of the **vermiform appendix** (blind sac at the end of the cecum), is the most common cause of emergency abdominal surgery in childhood. In the United States 100,000 cases are diagnosed each year (Aiken, 2020a). The peak incidence of appendicitis is between 12 and 18 years, with boys affected slightly more often than girls (Aiken, 2020a). Classically, the first symptom of appendicitis is periumbilical pain, followed by nausea, right lower quadrant pain, and, later, vomiting with fever (Rentea, Peter, & Snyder, 2017). Perforation occurs in up to 82% of children under 5 years of age, likely due to an inability to verbalize their symptoms (Aiken, 2020a). Perforation of the appendix can occur within approximately 48 hours of the initial complaint of pain (Aiken, 2020a). Complications from appendiceal perforation include major abscess, phlegmon, enterocutaneous fistula, peritonitis, and partial bowel obstruction. A **phlegmon** is an acute suppurative inflammation of subcutaneous connective tissue that spreads.

Etiology

The cause of appendicitis is obstruction of the lumen of the appendix, usually by hardened fecal material (fecalith). Swollen lymphoid tissue, frequently occurring after a viral infection, can also obstruct the appendix. Another rare cause of obstruction is a parasite such as *Enterobius vermicularis,* or pinworms, which can obstruct the appendiceal lumen.

Pathophysiology

With acute obstruction, the outflow of mucus secretions is blocked and pressure builds within the lumen, resulting in compression of blood vessels. The resulting ischemia is followed by ulceration of the epithelial lining and bacterial invasion. Subsequent necrosis causes perforation or rupture with fecal and bacterial contamination of the peritoneal cavity. The resulting inflammation spreads rapidly throughout the abdomen (**peritonitis**), especially in young children, who are unable to localize infection. Progressive peritoneal inflammation results in functional intestinal obstruction of the small bowel (**ileus**) because intense GI reflexes severely inhibit bowel motility. Because the peritoneum represents a major portion of total body surface, the loss of ECF to the peritoneal cavity leads to electrolyte imbalance and hypovolemic shock.

Clinical Manifestations

The first symptom of appendicitis is usually colicky, cramping, abdominal pain located around the umbilicus (Box 22.4). **Referred pain** is the term used for this vague periumbilical localization. The midgut shares the same T10 dermatome, so pain is often perceived to be coming from this area. Generally, this pain progresses and becomes constant. The most important physical finding is focal abdominal tenderness. As the inflammation progresses to involve the serosa of the appendix and the peritoneum of the abdominal wall, the pain may shift to the right lower quadrant. The **McBurney point**, located two-thirds the distance along a line between the umbilicus and the anterosuperior iliac spine, is the most common point of tenderness. Localized peritoneal signs may occur with gentle percussion or maneuvers such as heel strike or shaking the bed. Other helpful findings are Rovsing sign, tenderness in the right lower quadrant that occurs during palpation or percussion of other abdominal quadrants; obturator sign, pain with flexion and internal rotation of the right hip; psoas sign, pain on the left side with right hip extension; and Dunphy sign, pain with coughing (Rentea et al., 2017). Rebound tenderness—pain on deep palpation

BOX 22.4 Clinical Manifestations of Appendicitis

- Right lower quadrant abdominal pain
- Fever
- Rigid abdomen
- Decreased or absent bowel sounds
- Vomiting (typically follows onset of pain)
- Constipation or diarrhea
- Anorexia
- Tachycardia
- Rapid, shallow breathing
- Pallor
- Lethargy
- Irritability
- Stooped posture

with sudden release—may be present, but it is not a finding specific to appendicitis (Aiken, 2020a). Nausea, vomiting, and anorexia typically occur after the pain starts. Diarrhea, as well as other common signs of childhood illness such as upper respiratory tract congestion, poor feeding, lethargy, or irritability, may accompany appendicitis.

The child may not be able to walk well and may complain of pain in the right hip caused by inflammation in the psoas or iliopsoas muscles. Low-grade fever (38°C [100.4°F]) may occur with the initial presentation; however, the absence of fever does not exclude appendicitis. Because of the great variability in the presentation and location of appendicitis, any child with focal tenderness, regardless of the location, should be considered to potentially have acute appendicitis (see Community Focus box).

COMMUNITY FOCUS

Acute Appendicitis

Abdominal pain is a common complaint among school-age children, but in some cases it may indicate acute appendicitis. School nurses and nurse practitioners in school-based clinics should become familiar with the "typical" pattern of symptoms in acute appendicitis and how to assess and evaluate an acute abdomen. School nurses also need to impress on teachers and coaches the importance of early referral to the health suite for further assessment. Early referral to the health suite and an alert school nurse or nurse practitioner may make the difference between an uncomplicated appendectomy and a delayed diagnosis of a perforated appendix with peritonitis.

NURSING ALERT

Signs of peritonitis in addition to fever usually include sudden relief from pain after perforation; subsequent increase in pain, which is usually diffuse and accompanied by rigid guarding of the abdomen; progressive abdominal distention; tachycardia; rapid, shallow breathing as the child refrains from using abdominal muscles; pallor; chills; irritability; and restlessness.

Diagnostic Evaluation

Diagnosis is not always straightforward. Fever, vomiting, abdominal pain, and an elevated white blood cell count are associated with appendicitis but are also seen in IBD, pelvic inflammatory disease, gastroenteritis, urinary tract infection, right lower lobe pneumonia, mesenteric adenitis, Meckel diverticulum, and intussusception. Prolonged symptoms and delayed diagnosis often occur in younger children, in whom the risk of perforation is greatest because of their inability to verbalize their complaints.

The diagnosis is based primarily on the history and physical examination (see Box 22.4). Pain, the cardinal feature, is initially generalized (usually periumbilical). However, it usually descends to the lower right quadrant. The most intense site of pain may be at the McBurney point. Rebound tenderness is not a reliable sign and is extremely painful to the child. Referred pain, elicited by light percussion around the perimeter of the abdomen, indicates peritoneal irritation. Movement, such as riding over bumps in an automobile or gurney, aggravates the pain. In addition to pain, significant clinical manifestations include fever, a change in behavior, anorexia, and vomiting.

Laboratory studies usually include a CBC; urinalysis (to rule out a urinary tract infection); and, in adolescent females, serum human chorionic gonadotropin (to rule out an ectopic pregnancy). A white blood cell count greater than 10,000/mm^3 and an elevated C-reactive protein (CRP) are common but not necessarily specific for appendicitis. An elevated percentage of bands (often referred to as "a left shift") may indicate an inflammatory process. CRP is an acute-phase reactant that rises within 12 hours of the onset of infection. A CRP level greater than 10 mg/mL is a sign of infection.

Ultrasound is the imaging technique of choice in diagnosing appendicitis, although a computed tomography (CT) scan may be used. Ultrasound is considered positive in the presence of enlarged appendiceal diameter; appendiceal wall thickening; and periappendiceal inflammatory changes, including fat streaks, phlegmon, fluid collection, and extraluminal gas (Aiken, 2020a). The accuracy of imaging for diagnosing appendicitis is 95% (Rentea et al., 2017).

Therapeutic Management

The treatment for appendicitis before perforation is surgical removal of the appendix (appendectomy). Usually antibiotics are administered preoperatively. IV fluids and electrolytes are often required before surgery, especially if the child is dehydrated as a result of the marked anorexia characteristic of appendicitis.

The operation is usually performed through a right lower quadrant incision (open appendectomy). Laparoscopic surgery is commonly used to treat nonperforated acute appendicitis in pediatric patients. Three cannulas are inserted in the abdomen: one in the umbilicus, one in the left lower abdominal quadrant, and one in the suprapubic area. A small telescope is inserted through the left lower quadrant cannula, and an endoscopic stapler is inserted through the umbilical cannula. The appendix is ligated with the stapler and removed through the umbilical cannula. Advantages of laparoscopic appendectomy include reduced time in surgery and under anesthesia and reduced risk of postoperative wound infection (Aiken, 2020a).

Ruptured Appendix

Management of the child diagnosed with peritonitis caused by a ruptured appendix often begins preoperatively with IV administration of fluid and electrolytes, systemic antibiotics, and NG suction. Postoperative management includes IV fluids, continued administration of antibiotics, and NG suction for abdominal decompression until intestinal activity returns. Sometimes surgeons close the wound after irrigation of the peritoneal cavity. Other times they leave the wound open (delayed closure) to prevent wound infection.

The treatment of a localized perforation with an appendiceal abscess is controversial. Some surgeons prefer to treat these children with antibiotics and IV fluids and allow the abscess to drain spontaneously. An elective appendectomy is then performed 2 to 3 months later.

Prognosis

Complications are uncommon after a simple appendectomy, and recovery is usually rapid and complete. The mortality rate from perforating appendicitis has improved from nearly certain death a century ago to less than 1% at the present time (Rentea et al., 2017). Complications, however, including wound infection and intra-abdominal abscess, are not uncommon. Early recognition of the illness is important to prevent complications.

! NURSING ALERT

In any instance in which severe abdominal pain is observed, the nurse must be aware of the danger of administering laxatives or enemas. Such measures stimulate bowel motility and increase the risk of perforation.

Nursing Care Management

Because successful treatment of appendicitis is based on prompt recognition of the disorder, an important nursing objective is to assist in establishing a diagnosis. Because abdominal pain is a common childhood complaint, the nurse needs to make some preliminary assessment of the severity of the pain (see Chapter 5). One of the most reliable estimates is the degree of change in behavior. A child who stays home from school and voluntarily lies down or refuses to play is much more likely to have considerable pain than a child who is absent from school but plays contentedly at home. Younger, nonverbal children will assume a rigid, side-lying position with the knees flexed and have decreased range of motion of the right hip.

For nurses involved in primary ambulatory care, the responsibility of recognizing a possible case of appendicitis and prompt medical or surgical referral is particularly important. The importance of a detailed history and thorough abdominal examination cannot be overemphasized. Palpating the abdomen should be delayed until all other assessments have been made. Instruct the child to point with one finger to the site of the abdominal pain. Rebound tenderness may be present but is not always a sufficiently reliable test in children. Light palpation will satisfactorily elicit pain without causing excessive trauma (see Atraumatic Care box). Ask the child with mild pain to lift the heels and drop them to the floor two or three times, to hop on one foot, or to "puff out" or "pull in" the abdomen to check for tenderness without more painful probing. Chapter 4 discusses other techniques for assessment of the abdomen.

ATRAUMATIC CARE

Palpating the Abdomen for Abdominal Pain

Because children associate the stethoscope with listening, use the bell piece for initial palpation of the abdomen for tenderness. Children usually endure pressure from the stethoscope that they would not tolerate from a probing hand. Follow with manual palpation, using a gentle touch without lifting the hand from the abdomen while observing the child's face for signs of discomfort, such as a grimace and watchful eyes on the examination of the abdomen.

Physical preparation of the child with appendicitis is similar to that for any child undergoing surgery (see Chapter 20, Surgical Procedures). In situations in which medical treatment is required to correct problems associated with peritonitis, the nurse must anticipate procedures and set up equipment as quickly as possible to avoid any delay in preparing the child for surgery. Psychologic preparation of the child and parents is similar to that used in other emergency situations (see Chapter 20).

Postoperative care for the nonperforated appendix is the same as for most abdominal operations. Care of the child with a ruptured appendix and peritonitis is more complex. The child may need to remain in the hospital for several days or may be discharged with home care services to provide IV antibiotics and dressing changes.

Postoperatively the child is maintained on IV fluids and antibiotics and is allowed nothing by mouth (NPO). The child also remains on low, intermittent gastric decompression until there is evidence of return of intestinal motility. Listening for bowel sounds and observing for other signs of bowel activity (such as passage of stool) are part of the routine assessment.

A drain may be placed in the wound during surgery, and frequent dressing changes with meticulous skin care are essential to prevent excoriation of the surgery area. If the wound is left open, moist dressings (usually saline-soaked gauze) and wound irrigations with antibacterial solution are used to provide an optimum healing environment.

Pain management is an essential part of the child's care. Not only is the incision painful, but the repeated dressing changes and irrigations also cause considerable distress. Because pain is continuous during the first few postoperative days, analgesics are given regularly to control pain. Procedures are performed when the analgesics are at peak effect. (See Chapter 5.)

Psychosocial care after surgery is also important. Sudden, acute illnesses cause unique stress because there is little time for preparation or planning. Parents and older children need an opportunity to express their feelings and concerns regarding the events surrounding the illness and hospitalization. The nurse can provide important education and psychosocial support to promote adequate coping, with alleviation of anxiety for both the child and the family (see Next-Generation NCLEX® Examination-Style Unfolding Case Study box).

MECKEL DIVERTICULUM

Meckel diverticulum is a remnant of the fetal omphalomesenteric duct, which connects the yolk sac with the primitive midgut during fetal life (Maqbool & Liacouras, 2020d). Normally the structure is obliterated between the fifth and seventh week of gestation, when the placenta replaces the yolk sac as the source of nutrition for the fetus. Failure of obliteration may result in an omphalomesenteric fistula (a fibrous band connecting the small intestine to the umbilicus), umbilical cyst, vitelline duct remnant, mesodiverticular bands, and Meckel diverticula (Bagade & Khanna, 2015).

Meckel diverticulum is a true diverticulum because it arises from the antimesenteric border of the small intestine and includes all layers of the intestinal wall. Meckel diverticulum is often referred to by the "rule of 2s" because it occurs in 2% of the population, has a 2:1 male-to-female ratio, is located within 2 feet of the ileocecal valve, is commonly 2 cm in diameter and 2 inches in length, contains 2 types of ectopic tissue (pancreatic and gastric), and is more common before age 2 years (Maqbool & Liacouras, 2020d).

Pathophysiology

Bleeding, obstruction, or inflammation causes the symptomatic complications of Meckel diverticulum (Lin, Huang, Bao, et al., 2017). Bleeding, which is the most common problem in children, is caused by peptic ulceration or perforation because of the unbuffered acidic secretion. Several mechanisms may cause obstruction, such as intussusception or entanglement of the small intestine.

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

The Child With Appendicitis

Day 1, 11:00 am

1. A 10-year-old girl has a 2-day history of generalized periumbilical pain and anorexia. Today she developed a fever and vomiting, so her parents took her to the clinic. On review of the history, physical examination, and laboratory results, the nurse notes the findings below. Select findings that require follow-up by the nurse. **Select all that apply.**
   - A. Weight 70lb (32kg)
   - B. Hemoglobin = 13.8 g/dL
   - C. Platelets = 252,000/mm^3
   - D. C-reactive Protein (CRP) of 40 mg/dL
   - E. Pain intensifies with any activity or deep breathing
   - F. Oral temperature of 102° F (38.9° C)
   - G. Pulse of 80 beats/min and blood pressure is 108/74 mm/Hg
   - H. Abdominal pain midway between the anterior superior iliac crest and umbilicus
   - I. White blood cell (WBC) count of 21,000/mm^3, 79% bands, 14% lymphocytes, 6% eosinophils
2. Based on the case presented in the question above, **choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.** Based on the child's assessment data, the nurse determines that the laboratory findings reflect the probable presence of ____1____. The ____2____ is elevated and her periumbilical pain, along with other symptoms is most likely due to _____3_____.

Options for 1	Options for 2	Options for 3
Anemia	Blood pressure of 108/74	Ruptured kidney
Pain	Pulse of 80	Acute abdomen
Bleeding	CRP	Influenza
Infection	Hemoglobin	Urinary Tract Infection
Heart failure	Platelets	Vomiting
Cancer	Serum sodium	Anxiety

Day 1, 11:30 am

Unfolding Case Continues: A 10-year-old girl who has a 2-day history of generalized periumbilical pain and anorexia. Today she developed a fever and vomiting, so her parents took her to her pediatrician. On review of the history, physical examination, and laboratory results, the nurse notes the following:

- Oral temperature of 102° F (38.9° C)
- Pulse of 80 beats/min and blood pressure is 108/74 mm/Hg
- Abdominal pain midway between the anterior superior iliac crest and umbilicus
- Pain intensifies with any activity or deep breathing
- White blood cell (WBC) count of 21,000/mm^3, 79% bands, 14% lymphocytes, 6% eosinophils
- C-reactive Protein (CRP) of 18 mg/dL
- Hemoglobin = 13.8 g/dL
- Platelets = 252,000/mm^3
- Weight 70lb (32kg)

3. The pediatrician examines the child and highly suspects appendicitis. A CT scan of the abdomen has been prescribed and the child is placed on NPO status. When planning care for this child, which **priority** symptoms would the nurse consider most immediate at this time? **Select all that apply.**
   - A. Pain
   - B. Anemia
   - C. Infection
   - D. Vomiting
   - E. Weight loss
   - F. Dehydration
   - G. Constipation
   - H. Hyperthermia
   - I. Rupture of the appendix

Unfolding Case Continues: A 10-year-old girl who has a 2-day history of generalized periumbilical pain and anorexia. Today she developed a fever and vomiting, so her parents took her to her pediatrician. On review of the history, physical examination, and laboratory results, the nurse notes the following:

- Oral temperature of 102° F (38.9° C)
- Pulse of 80 beats/min and blood pressure is 108/74 mm/Hg
- Abdominal pain midway between the anterior superior iliac crest and umbilicus
- Pain intensifies with any activity or deep breathing
- White blood cell (WBC) count of 21,000/mm^3, 79% bands, 14% lymphocytes, 6% eosinophils
- C-reactive Protein (CRP) of 18 mg/dL
- Hemoglobin = 13.8 g/dL
- Platelets = 252,000/mm^3
- Weight 70lb (32kg)

Day 1, 12:00 noon

Results of the CT scan demonstrate a ruptured appendix. The child is being prepared for surgery. The nurse performing the assessment finds her temperature is 102° F (38.9° C). The child reports that the pain had initially resolved but now reports increasing pain (rated 9 out of 10 on a 1 to 10 pain intensity scale) and nausea.

Day 1, 2:00 pm

The child undergoes surgery for an appendectomy. She is transferred to the pediatric unit from the recovery room and the nurse plans care.

4. Indicate which nursing action listed in the far-left column is appropriate for the potential postoperative complication following appendectomy listed in the middle column**. Indicate the nursing action number in the far-right column. Note that ONLY one nursing action can be used for each potential postoperative complication and that NOT all nursing actions will be used.**

Nursing Action	Potential Postoperative Complication	Nursing Action for Postoperative Complication
1. Administer pain medications	Inflammation at the wound site	
2. Initiate IV fluids and assess intake and output (I&O)	Electrolyte imbalance	
3. Assess temperature and report elevation	Fluid deficit	
4. Administer antiemetics	Pain	
5. Administer IV sodium heparin	Nausea and vomiting	
6. Draw blood as scheduled and evaluate results	Infection	
7. Report changes in vital signs, behavior and level of consciousness	Fever	
8. Administer IV antibiotics		
9. Administer a blood transfusion		
10. Observe wound site		

Continued

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—cont'd

Day 3, 9:00 am Unfolding Case Continues

5. The child is recovering well following surgery. The nurse performing the assessment finds her oral temperature is 98.6° F (37° C). The child reports that the pain is a 1 out of 10 on a 10 point pain intensity scale). She has no nausea or vomiting. **For each nursing action, use an X to indicate whether it was Effective (helped to meet expected quality patient outcomes), Ineffective (did not help to meet expected quality patient outcomes), or Unrelated (not related to the quality patient outcomes).**

Nursing Action	Effective	Ineffective	Unrelated
Observe no signs of infection.			
Pain is controlled.			
Referral is made to a physical therapist.			
No complaints of nausea or vomiting and a regular diet is tolerated.			
No complaints of headaches.			
Temperature remains in the normal range			
Child spending all of the time in bed.			

Day 5, 10:00 am Unfolding Case Continues

6. The child has recovered and is ready for discharge and the nurse is providing essential education to the parents and child for care at home. **Use an X for the health teaching statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
"Take your child's temperature if she feels warm and call the surgeon if she has a fever over 101° F"			
"Give ibuprofen every 6 hours for the next 5 days."			
"Sit beside her all day and watch her favorite movies."			
"Inspect the surgical incision every day for increased redness, heat, or drainage; if present call the surgeon immediately."			
Ask the parents, "What are your concerns regarding your daughter's care at home?"			
"Apply a topical antibiotic to the surgical wound for the next week."			

Clinical Manifestations

Signs and symptoms are based on the specific pathologic process, such as inflammation, bleeding, or intestinal obstruction (Box 22.5). The most common clinical presentation is rectal bleeding caused by ulceration at the junction of the ectopic gastric mucosa and normal ileal mucosa. The bleeding is usually painless and may be dramatic and occur as bright red or currant jelly–like stools, or it may occur intermittently and appear as tarry stools. The bleeding may be significant enough to cause hypotension. Volvulus and intussusception are common obstructive mechanisms in children with Meckel diverticulum, and these children present with symptoms of abdominal pain, distention, nausea, and vomiting (Maqbool & Liacouras, 2020d).

Diagnostic Evaluation

Diagnosis is usually based on the history, physical examination, and radiographic studies. Meckel diverticulum is often a diagnostic challenge. A technetium-99m pertechnetate scan (Meckel scan) is the most effective diagnostic testing, especially for a bleeding diverticulum, with sensitivity ranging from 80% to 90% and a specificity of 95% (Lin et al., 2017). Laboratory studies such as a CBC and a basic metabolic panel are usually part of the general workup to rule out any bleeding disorder and to evaluate for dehydration.

Therapeutic Management

The standard treatment for symptomatic Meckel diverticulum is surgical removal. In instances in which severe hemorrhage increases the

BOX 22.5 Clinical Manifestations of Meckel Diverticulum

Abdominal Pain
Similar to appendicitis
May be vague and recurrent

Bloody Stools[a]
Painless
Bright or dark red with mucus (currant jelly–like stool)
In infants, bleeding sometimes accompanied by pain

Occasional
Severe anemia
Shock

[a]Often a presenting sign.

surgical risk, medical intervention to correct hypovolemic shock (e.g., blood replacement, IV fluids, oxygen) may be necessary. Antibiotics may be used preoperatively to control infection. If intestinal obstruction has occurred, appropriate preoperative measures are used to correct fluid and electrolyte imbalances and prevent abdominal distention.

Prognosis

If symptomatic Meckel diverticulum is diagnosed and treated early, full recovery is likely. Because of the potential for surgical complications, resection of asymptomatic Meckel diverticulum remains controversial.

Nursing Care Management

Nursing objectives are the same as for any child undergoing surgery (see Chapter 20, Surgical Procedures). When intestinal bleeding is present, specific preoperative considerations include frequent monitoring of vital signs and blood pressure, keeping the child on bed rest, and recording the approximate amount of blood lost in stools.

Postoperatively the child requires IV fluids and an NG tube for decompression and evacuation of gastric secretions. Because the onset of illness is usually rapid, psychologic support is important, as in other acute conditions, such as appendicitis. It is important to remember that massive rectal bleeding is usually traumatic to both the child and the parents and may significantly affect their emotional reaction to hospitalization and surgery.

INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) should not be confused with IBS. *IBD* is a term used to refer to three major forms of chronic intestinal inflammation: Crohn disease (CD), ulcerative colitis (UC), and inflammatory bowel disease unspecified (IBDU). CD and UC have similar epidemiologic, immunologic, and clinical features, but they are distinct disorders. The diagnosis of IBDU is used for patients with colonic disease, but whose features are not specific to UC or CD; it is very rare (Conrad & Rosh, 2017).

Approximately 70,000 children in the United States have IBD (Rosen, Dhawan, & Saeed, 2017). Over the past 30 years the incidence of CD has risen, whereas the incidence of UC in children has remained stable (Stein & Baldassano, 2020). Both CD and UC tend to be more aggressive if the onset occurs in childhood (Conrad & Rosh, 2017). Exacerbations and remissions without complete resolution of symptoms are also characteristics of IBD.

Etiology

Despite decades of research, the etiology of IBD is not completely understood, and there is no known cure. There is evidence to indicate a multifactorial etiology. Genetic, environmental, and microbial factors are associated with IBD, and research focuses on genetic associations and theories of defective immunoregulation of the inflammatory response to bacteria or viruses in the GI tract (Rosen et al., 2017). Genome-wide studies have confirmed at least 150 genes that increase the risk for IBD in individuals (Rosen et al., 2017). Furthermore, children who immigrate from developing countries to Western countries show an incidence of IBD similar to that of Western populations, confirming an environmental factor with the disease (Rosen et al., 2017). Finally, most individuals have 10 trillion bacteria and fungi in their intestinal microbiome, but children and adults with IBD have small diversity of intestinal bacterial species with an overrepresentation and underrepresentation of some species (Rosen et al., 2017).

Pathophysiology

The inflammation found with UC is limited to the colon and rectum, with the distal colon and rectum the most severely affected. Inflammation affects the mucosa and submucosa and involves continuous segments along the length of the bowel with varying degrees of ulceration, bleeding, and edema. Thickening of the bowel wall and fibrosis are unusual, but long-standing disease can result in shortening of the colon and strictures. Toxic megacolon is the most dangerous form of severe colitis.

The chronic inflammatory process of CD involves any part of the GI tract from the mouth to the anus but most often affects the terminal ileum. The disease involves all layers of the bowel wall (transmural) in a discontinuous fashion, meaning that between areas of intact mucosa there are areas of affected mucosa (skip lesions). The inflammation may result in ulcerations; fibrosis; adhesions; stiffening of the bowel wall; stricture formation; and fistulas to other loops of bowel, bladder, vagina, or skin.

Clinical Signs and Symptoms

Children with UC may experience mild, moderate, or severe symptoms, depending on the extent of mucosal inflammation and systemic symptoms. UC often manifests with the insidious onset of diarrhea, possibly with hematochezia, and usually without fever or weight loss. The course of the disease may remain mild with intermittent exacerbations. Some children and adolescents are seen with grossly bloody diarrhea, cramps, urgency with defecation, mild anemia, fever, anorexia, weight loss, and moderate signs of systemic illness. Severe UC is characterized by frequent bloody stools, abdominal pain, significant anemia, fever, and weight loss. Extraintestinal manifestations are not common in UC. Enlarged lymph nodes (lymphadenopathy), arthritis, and the skin lesions of erythema nodosum may be present.

Common presenting manifestations of CD include diarrhea, abdominal pain with cramps, fever, and weight loss. Extraintestinal manifestations, including aphthous ulcers, peripheral arthritis, erythema nodosum, digital clubbing, renal stones, and gallstones, are more common with CD than UC (Stein & Baldassano, 2020). Growth failure and delayed sexual maturation are often present for several years before overt GI symptoms are present (Conrad & Rosh, 2017). Both malabsorption and anorexia are factors that contribute to the growth problems that are prevalent in CD. Children with CD may have perianal disease, including tags, fissures, fistulas, or abscesses (Rosen et al., 2017). The effects of UC and CD are listed in Table 22.7, which provides a comparison of UC and CD.

Diagnostic Evaluation

The diagnosis of UC and CD comes from the history, physical examination, laboratory evaluation, and other diagnostic procedures.

TABLE 22.7 Comparison of Inflammatory Bowel Diseases

Characteristics	Ulcerative Colitis	Crohn Disease
Rectal bleeding	Common	Uncommon
Diarrhea	Often severe	Moderate to severe
Pain	Less frequent	Common
Anorexia	Mild or moderate	May be severe
Weight loss	Moderate	May be severe
Growth retardation	Usually mild	May be severe
Anal and perianal lesions	Rare	Common
Fistulas and strictures	Rare	Common
Rashes	Mild	Mild
Joint pain	Mild to moderate	Mild to moderate

Laboratory tests include a CBC to evaluate anemia and an erythrocyte sedimentation rate (ESR) or CRP to assess the systemic reaction to the inflammatory process. The ESR or CRP may be elevated, indicating a systemic response to an inflammatory process. Levels of total protein, albumin, iron, zinc, magnesium, vitamin B_{12}, and fat-soluble vitamins may be low in children with CD. Stools are examined for blood, leukocytes, and infectious organisms. A serologic panel is often used in combination with clinical findings to diagnose IBD and to differentiate between CD and UC.

In patients with CD, an upper GI series with small bowel follow-through assists in assessing the existence, location, and extent of disease. Upper endoscopy and colonoscopy with biopsies are an integral part of diagnosing IBD (Rosen et al., 2017). Endoscopy allows direct visualization of the surface of the GI tract so that the extent of inflammation and narrowing can be evaluated. CT and ultrasound also may be used to identify bowel wall inflammation, intra-abdominal abscesses, and fistulas. Colonoscopy can confirm the diagnosis and evaluate the extent of the disease. Discrete ulcers are commonly seen in patients with CD, whereas microulcers and diffuse abnormalities and inflammation are seen in patients with UC (Stein & Baldassano, 2020). CD lesions may pierce the walls of the small intestine and colon, creating tracts called *fistulas* between the intestine and adjacent structures such as the bladder, anus, vagina, or skin.

Therapeutic Management

The natural history of the disease continues to be unpredictable and characterized by recurrent flare-ups that can severely impair patients' physical and social functioning (Stein & Baldassano, 2020). The goals of therapy are to control the inflammatory process to reduce or eliminate the symptoms, obtain long-term remission, promote normal growth and development, and allow as normal a lifestyle as possible. Treatment is individualized and managed according to the type and the severity of the disease, its location, and the response to therapy. CD is more disabling, has more serious complications, and is often less amenable to medical and surgical treatment than is UC. Because UC is confined to the colon, a colectomy may cure UC.

Medical Treatment

The goal of any treatment regimen is first to induce remission of acute symptoms and then to maintain remission over time. 5-Aminosalicylates (5-ASAs) are effective in the induction and maintenance of remission in mild to moderate UC. Mesalamine, olsalazine, and balsalazide are preferred over sulfasalazine because of reduced side effects (e.g., headache, nausea, vomiting, neutropenia, oligospermia). Suppository and enema preparations of mesalamine are used to treat left-sided colitis. These drugs decrease inflammation by inhibiting prostaglandin synthesis. 5-ASAs can be used to induce remission in mild CD.

Corticosteroids, such as prednisone and prednisolone, are indicated in induction therapy in children with moderate to severe UC and CD. These drugs inhibit the production of adhesion molecules, cytokines, and leukotrienes. Although these drugs reduce the acute symptoms of IBD, they are not commonly used for maintenance therapy because of their long-term side effects, including growth suppression (adrenal suppression), weight gain, and decreased bone density (Rosen et al., 2017). High doses of IV corticosteroids may be administered in acute episodes and tapered according to clinical response. Budesonide, a synthetic corticosteroid, is designed for controlled release in the ileum and is indicated for ileal and right-sided colitis; budesonide has fewer side effects than prednisone and prednisolone but is also less effective (Rosen et al., 2017).

Immunomodulators, such as azathioprine and its metabolite 6-mercaptopurine (6-MP), are used to induce and maintain remission in children with IBD who are steroid resistant or steroid dependent and to treat chronic draining fistulas. They block the synthesis of purine, thus inhibiting the ability of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) to hinder lymphocyte function, especially that of T cells. Side effects include infection, pancreatitis, hepatitis, bone marrow toxicity, arthralgia, and malignancy. Methotrexate is also useful in inducing and maintaining remission in patients with CD who are unresponsive to standard therapies. Cyclosporine and tacrolimus have both been effective in inducing remission in severe steroid-dependent UC. 6-MP or azathioprine is then used to maintain remission. Patients on immunomodulating medications require regular monitoring of their CBC and differential to assess for changes that reflect suppression of the immune system because many of the side effects can be prevented or managed by dose reduction or discontinuation of medication.

Antibiotics, such as metronidazole and ciprofloxacin, may be used as an adjunctive therapy to treat complications such as perianal disease or small bowel bacterial overgrowth in CD. Side effects of these drugs are peripheral neuropathy, nausea, and a metallic taste.

Biologic therapies act to regulate inflammatory and antiinflammatory cytokines. The use of anti–tumor necrosis factor-alpha (anti-TNF-α) agents such as infliximab and adalimumab decrease active inflammation, are effective in healing the intestinal mucosal lining and perianal fistulas, and have even improved linear growth in children (Rosen et al., 2017; Stein & Baldassano, 2020). These agents are now being used as front-line therapy in children with CD who have severe deep mucosal ulcerations, perianal fistulas, or growth failure (Rosen et al., 2017).

Nutritional Support

Nutritional support is important in the treatment of IBD. Growth failure is a common serious complication, especially in CD. Growth failure is characterized by weight loss, alteration in body composition, retarded height, and delayed sexual maturation. Malnutrition causes the growth failure, and its etiology is multifactorial. Malnutrition occurs as a result of inadequate dietary intake, excessive GI losses, malabsorption, drug-nutrient interaction, and increased nutritional requirements. Inadequate dietary intake occurs with anorexia and episodes of increased disease activity. Excessive loss of nutrients (e.g., protein, blood, electrolytes, and minerals) occurs secondary to intestinal inflammation and diarrhea. Carbohydrate, lactose, fat, vitamin, and mineral malabsorption, as well as vitamin B_{12} and folic acid deficiencies, occur with disease episodes and with drug administration and when the terminal ileum is resected. Finally, nutritional requirements are increased with inflammation, fever, fistulas, and periods of rapid growth (e.g., adolescence).

The goals of nutritional support include correction of nutrient deficits and replacement of ongoing losses, provision of adequate energy and protein for healing, and provision of adequate nutrients to promote normal growth. Nutritional support includes both enteral and parenteral nutrition. A well-balanced, high-protein, high-calorie diet is recommended for children whose symptoms do not prohibit an adequate oral intake. There is little evidence that avoiding specific foods influences the severity of the disease. Supplementation with multivitamins, iron, and folic acid is recommended.

Special enteral formulas, given either by mouth or continuous NG infusion (often at night), may be required. Elemental formulas are completely absorbed in the small intestine with almost no residue. A diet consisting only of elemental formula not only improves nutritional status but also induces disease remission, either without steroids or with a diminished dosage of steroids required. An elemental diet is a safe and potentially effective primary therapy for patients with CD. Unfortunately, remission is not sustained when NG feedings are discontinued unless maintenance medications are added to the treatment regimen.

Total parenteral nutrition (TPN) has also improved nutritional status in patients with IBD. Short-term remissions have been achieved after TPN, although complete bowel rest has not reduced inflammation or added to the benefits of improved nutrition by TPN. Nutritional support is less likely to induce a remission in UC than in CD. However, improvement of nutritional status is important in preventing deterioration of the patient's health status and in preparing the patient for surgery.

Surgical Treatment

Surgery is indicated for UC when medical and nutritional therapies fail to prevent complications. Surgical options include a **subtotal colectomy** and **ileostomy** that leaves a rectal stump as a blind pouch. A reservoir pouch is created in the configuration of a J or an S to help improve continence postoperatively. An ileoanal pull-through preserves the normal pathway for defecation. Pouchitis, an inflammation of the surgically created pouch, is the most common late complication of this procedure. In many cases, UC can be cured with a total colectomy.

Surgery may be required in children with CD when complications cannot be controlled by medical and nutritional therapy. Segmental intestinal resections are performed for small bowel obstructions, strictures, or fistulas. Diversion of the fecal stream, such as a colostomy, allows the colon to be less active and causes the disease to become dormant, but on reconnection of the colon, disease often reoccurs (Stein & Baldassano, 2020).

Prognosis

IBD is a chronic disease. Relatively long periods of quiescent disease may follow exacerbations. The outcome is influenced by the regions and severity of involvement, as well as by appropriate therapeutic management. Malnutrition, growth failure, and bleeding are serious complications. The overall prognosis for UC is good.

The development of colorectal cancer (CRC) is a long-term complication of IBD. Because the risk for CRC occurs 8 to 10 years after diagnosis, surveillance colonoscopy with multiple biopsies should begin approximately 7 to 10 years after diagnosis of UC or CD (Rosen et al., 2017). In CD, surgical removal of the affected colon does not prevent cancer from developing elsewhere in the GI tract.

Nursing Care Management

The nursing considerations in the management of IBD extend beyond the immediate period of hospitalization. These interventions involve continued guidance of families in terms of (1) managing diet; (2) coping with factors that increase stress and emotional lability; (3) adjusting to a disease of remissions and exacerbations; and (4) when indicated, preparing the child and parents for the possibility of diversionary bowel surgery. (See Quality Patient Outcomes box.)

QUALITY PATIENT OUTCOMES: Inflammatory Bowel Disease

- Remission without symptoms of abdominal pain, bloating, diarrhea, and rectal bleeding
- Optimum quality of life maintained by minimizing impairment of daily activities

Because nutritional support is an essential part of therapy, encouraging the anorexic child to consume sufficient quantities of food is often a challenge. Successful interventions include involving the child in meal planning; encouraging small, frequent meals or snacks rather than three large meals a day; serving meals around medication schedules when diarrhea, mouth pain, and intestinal spasm are controlled; and preparing high-protein, high-calorie foods such as eggnog, milkshakes, cream soups, puddings, or custard (if lactose is tolerated) (see Chapter 20, Feeding the Sick Child). Using bran or a high-fiber diet for active IBD is questionable. Bran, even in small amounts, has been shown to worsen the patient's condition. Occasionally the occurrence of aphthous stomatitis further complicates adherence to dietary management. Mouth care before eating and the selection of bland foods help relieve the discomfort of mouth sores.

When NG feedings or TPN is indicated, nurses play an important role in explaining the purpose and the expected outcomes of this therapy. The nurse should acknowledge the anxieties of the child and family members and give them adequate time to demonstrate the skills necessary to continue the therapy at home, if needed.

The importance of continued drug therapy despite remission of symptoms must be stressed to the child and family members. Failure to adhere to the pharmacologic regimen can result in exacerbation of the disease (see Chapter 20, Compliance). Unfortunately, exacerbation of IBD can occur even if the child and family are compliant with the treatment regimen; this is difficult for the child and family to cope with.

Emotional Support

The nurse should attend to the emotional components of the disease and assess any sources of stress. Frequently, the nurse can help children adjust to problems of growth retardation, delayed sexual maturation, dietary restrictions, feelings of being "different" or "sickly," inability to compete with peers, and necessary absence from school during exacerbations of the illness.

If a permanent colectomy-ileostomy is required, the nurse can teach the child and family how to care for the ileostomy. The nurse can also emphasize the positive aspects of the surgery, particularly accelerated growth and sexual development, permanent recovery, and the normality of life despite bowel diversion. Introducing the child and parents to other ostomy patients, especially those who are the same age, is effective in fostering eventual acceptance. Whenever possible, offer continent ostomies as options to the child, although they are not performed in all centers in the United States.

Because of the chronic and often lifelong nature of the disease, families benefit from the educational services provided by organizations such as the Crohn's and Colitis Foundation.[a] If diversionary bowel

[a]3733 Third Ave., Suite 510, New York, NY 10017; 888-694-8872; http://www.ccfa.org. In Canada: Crohn's and Colitis Canada, https://crohnsandcolitis.ca/.

surgery is indicated, United Ostomy Associations of America[b] and the Wound, Ostomy and Continence Nurses Society[c] are available to assist with ileostomy care and provide important psychologic support through their self-help groups. Adolescents often benefit by participating in peer-support groups, which are sponsored by the CCFA.

PEPTIC ULCER DISEASE

Peptic ulcer disease (PUD) is a chronic condition that affects the stomach or duodenum. Ulcers are described as gastric or duodenal and as primary or secondary. A **gastric ulcer** involves the mucosa of the stomach; a **duodenal ulcer** involves the pylorus or duodenum. Most **primary ulcers** are idiopathic or associated with *Helicobacter pylori* infection and tend to be chronic, occurring more frequently in the duodenum (Blanchard & Czinn, 2020). **Secondary ulcers** result from the stress of a severe underlying disease or injury (e.g., severe burns, sepsis, increased intracranial pressure, severe trauma, multisystem organ failure) and are more frequently gastric with an acute onset (Blanchard & Czinn, 2020).

Etiology

The exact cause of PUD is unknown, although infectious, genetic, and environmental factors are important. There is an increased familial incidence, likely due to *H. pylori*, which is known to cluster in families (Blanchard & Czinn, 2020). *H. pylori* is a microaerophilic, gram-negative, slow-growing, spiral-shaped, and flagellated bacterium known to colonize the gastric mucosa in about half of the population of the world (Blanchard & Czinn, 2020). *H. pylori* synthesizes the enzyme urease, which hydrolyzes urea to form ammonia and carbon dioxide. Ammonia then absorbs acid to form ammonium, thus raising the gastric pH. *H. pylori* may cause ulcers by weakening the gastric mucosal barrier and allowing acid to damage the mucosa. It is believed that it is acquired via the fecal-oral route, and this hypothesis is supported by finding viable *H. pylori* in feces.

In addition to ulcerogenic drugs, both alcohol and smoking contribute to ulcer formation. There is no conclusive evidence to implicate particular foods, such as caffeine-containing beverages or spicy foods, but polyunsaturated fats and fiber may play a role in ulcer formation. Psychologic factors may play a role in the development of PUD, and stressful life events, dependency, passiveness, and hostility have all been implicated as contributing factors.

Pathophysiology

Most likely, the pathology is due to an imbalance between the destructive (cytotoxic) factors and defensive (cytoprotective) factors in the GI tract. The toxic mechanisms include acid, pepsin, medications such as aspirin and nonsteroidal antiinflammatory drugs (NSAIDs), bile acids, and infection with *H. pylori.* The defensive factors include the mucus layer, local bicarbonate secretion, epithelial cell renewal, and mucosal blood flow. Prostaglandins play a role in mucosal defense because they stimulate both mucus and alkali secretion. The primary mechanism that prevents the development of peptic ulcer is the secretion of mucus by the epithelial and mucus glands throughout the stomach. The thick mucus layer acts to diffuse acid from the lumen to the gastric mucosal surface, thus protecting the gastric epithelium. The stomach and the duodenum produce bicarbonate, decreasing acidity on the epithelial cells and thereby minimizing the effects of the low pH. When abnormalities in the protective barrier exist, the mucosa is vulnerable to damage by acid and pepsin. Exogenous factors, such as aspirin and NSAIDs, cause gastric ulcers by inhibition of prostaglandin synthesis.

Zollinger-Ellison syndrome is rare but may occur in children who have multiple, large, or recurrent ulcers. This syndrome is characterized by hypersecretion of gastric acid, intractable ulcer disease, and intestinal malabsorption caused by a gastrin-secreting tumor of the pancreas.

BOX 22.6 Characteristics of Peptic Ulcers

Neonates
- Usually gastric and secondary ulcers
- Commonly a history of prematurity, respiratory distress, sepsis, hypoglycemia, or an intraventricular hemorrhage
- Perforation possibly leading to massive bleeding

Infants to 2-Year-Old Children
- Most likely to have a secondary ulcer located equally in the stomach or duodenum
- Primary ulcers less common and usually located in stomach
- Likely to be noticed in relation to illness, surgery, or trauma
- Hematemesis, melena, or perforation

2- to 6-Year-Old Children
- Primary or secondary ulcers
- Located equally in stomach and duodenum
- Perforation more likely in secondary ulcers
- Periumbilical pain, poor eating, vomiting, irritability, nighttime wakening, hematemesis, melena

Children Over 6 Years
- Usually primary and most often duodenal ulcers
- More typical of adult type
- Chance of recurrence greater
- Often associated with *Helicobacter pylori*
- Epigastric pain or vague abdominal pain
- Nighttime wakening, hematemesis, melena, and anemia possible

Clinical Manifestations

The clinical manifestations of PUD vary according to the child's age and the ulcer's location. Common clinical manifestations include chronic abdominal pain, especially when the stomach is empty, such as during the night or early morning; recurrent vomiting; hematemesis; melena; chronic anemia; and abdominal tenderness (Box 22.6).

Diagnostic Evaluation

Diagnosis is based on the history of symptoms, physical examination, and diagnostic testing. The focus is on symptoms such as epigastric abdominal pain, nocturnal pain, oral regurgitation, heartburn, weight loss, hematemesis, and melena. History should include questions relating to the use of potentially causative substances such as NSAIDs, corticosteroids, alcohol, and tobacco. Frequently a history of epigastric and periumbilical pain accompanies PUD. However, children often find it difficult to describe the location of their pain and frequently indicate the location by moving their hand in a circular movement all around the stomach area. Asking the child to take one finger and point to the area where it hurts the most often helps identify the location of the pain. Pain may also be elicited during the examination with palpation.

Laboratory studies may include a CBC to detect anemia, stool analysis for occult blood, liver function tests (LFTs), ESR, or CRP to evaluate IBD; amylase and lipase to evaluate pancreatitis; and gastric acid measurements to identify hypersecretion. Stool analysis is performed to rule out infection. Polyclonal and monoclonal stool antigen tests are an accurate, noninvasive method both for the initial diagnosis of *H. pylori* and for the confirmation of its eradication after treatment (Yang, 2016). A C13 urea breath test measures bacterial colonization in the gastric mucosa and can be used as an additional noninvasive test to determine the presence of antibodies to *H. pylori*.

An upper GI series is the most reliable way to detect and diagnose PUD in children (Blanchard & Czinn, 2020). Direct visualization of the gastric and duodenal mucosa helps identify specific lesions, and biopsy specimens can determine the presence of *H. pylori*.

Therapeutic Management

The major goals of therapy for children with PUD are to relieve discomfort, promote healing, prevent complications, and prevent recurrence. Management is primarily medical and consists of administration of medications to treat the infection and to reduce or neutralize gastric acid secretion. Antacids are beneficial medications to neutralize gastric acid. H_2-receptor antagonists (antisecretory drugs) act to suppress gastric acid production. These medications have few side effects. PPIs, such as omeprazole, lansoprazole, pantoprazole, and esomeprazole, act to inhibit the hydrogen ion pump in the parietal cells, thus blocking the production of acid. Although these drugs have not been well studied in children, they are used in clinical practice to treat ulcers, GER, esophagitis, and gastritis, and appear to be well tolerated with infrequent side effects (e.g., headache, diarrhea, nausea) (Blanchard & Czinn, 2020).

Mucosal protective agents, such as sucralfate and bismuth-containing preparations, may be prescribed for PUD. Sucralfate is an aluminum-containing agent that forms a barrier over ulcerated mucosa to protect against acid and pepsin. Bismuth compounds are sometimes prescribed for the relief of ulcers, but they are used less frequently than PPIs. Although these compounds inhibit the growth of microorganisms, the mechanism of their activity is poorly understood. In combination with antibiotics, bismuth is effective against *H. pylori*. Although concern has been expressed about the use of bismuth salts in children because of potential side effects, none of these side effects has been reported when these compounds have been used in the treatment of *H. pylori* infection. These agents are available in both pill and liquid forms. Because they block the absorption of other medications, they should be given separately from other medications.

Triple-drug therapy is the standard first-line treatment regimen for *H. pylori* and has demonstrated 90% efficacy in the eradication of *H. pylori* (Kalach, Bontems, & Cadranel, 2015). Examples of drug combinations used in triple therapy are (1) bismuth, clarithromycin, and metronidazole; (2) lansoprazole, amoxicillin, and clarithromycin; and (3) metronidazole, clarithromycin, and omeprazole. Common side effects of medications include diarrhea, nausea, and vomiting.

Children with an acute ulcer who have developed complications, such as massive hemorrhage, require emergency care. The administration of IV fluids, blood, or plasma depends on the amount of blood loss. Replacement with whole blood or packed cells may be necessary for significant loss.

Surgical intervention may be required for complications such as hemorrhage, perforation, or gastric outlet obstruction. Ligation of the source of bleeding or closure of a perforation is performed. A vagotomy and pyloroplasty may be indicated in children with bleeding ulcers despite aggressive medical treatment (Patel, Bommayya, Choudhry, et al., 2015).

Prognosis

The long-term prognosis for PUD is variable. Many ulcers are successfully treated with medical therapy; however, primary duodenal peptic ulcers often recur. Complications such as GI bleeding can occur and extend into adult life. The effect of maintenance drug therapy on long-term morbidity remains to be established with further studies.

Nursing Care Management

The primary nursing goal is to promote healing of the ulcer through compliance with the medication regimen. If an analgesic-antipyretic is needed, acetaminophen, not aspirin or NSAIDs, is used. Critically ill neonates, infants, and children in intensive care units should receive H_2 blockers to prevent stress ulcers.

DRUG ALERT

H_2 Blockers

Critically ill children receiving intravenous (IV) histamine (H_2) blockers should have their gastric pH values checked at frequent intervals.

For nonhospitalized children with chronic illnesses, consider the role that stress plays. In children, many ulcers occur secondary to other conditions, and the nurse should be aware of family and environmental conditions that may aggravate or precipitate ulcers. Children may benefit from psychologic counseling and from learning how to cope constructively with stress.

OBSTRUCTIVE DISORDERS

Obstruction in the GI tract occurs when the passage of nutrients and secretions is impeded by a constricted or occluded lumen or when there is impaired motility (**paralytic ileus**). Obstructions may be congenital or acquired. Congenital obstructions, such as esophageal or intestinal atresias, imperforate anus, and meconium ileus, usually appear in the neonatal period. Other obstructions of congenital etiology (e.g., malrotation, HD, pyloric stenosis, volvulus, incarcerated hernia, Meckel diverticulum) appear after the first few weeks of life. Intestinal obstruction from acquired causes such as intussusception and tumors may occur in infancy or childhood.

Acute intestinal obstruction is commonly characterized by abdominal pain, nausea, vomiting, abdominal distention, and a change in stooling patterns. Pain is caused by intermittent muscular contractions proximal to the obstruction as the bowel attempts to move luminal contents along the normal path. It may also be due to severe abdominal distention, which results from accumulation of gas and fluid above the level of the obstruction. As abdominal distention progresses, the abdomen may become extremely tender, rigid, and firm.

When abdominal contents continue to accumulate, nausea and vomiting occur. Vomiting of gastric contents is often the first sign of a high obstruction, such as obstruction of the pylorus, and vomiting of bile-stained material is a sign of obstruction of the small intestine. Persistent vomiting can lead to dehydration and electrolyte disturbances. Constipation and obstipation (prolonged absence of defecation) are early signs of low obstructions and later signs of higher obstructions. In acute conditions such as intussusception, the clinical manifestations are apparent within a few hours of the onset of the disorder. In other conditions such as hypertrophic pyloric stenosis, the signs and symptoms may have a more gradual onset. Bowel sounds

may initially be hyperactive, then diminish or cease. Respiratory distress may occur when the diaphragm is pushed up into the pleural cavity as a result of severe abdominal distention.

HYPERTROPHIC PYLORIC STENOSIS

Hypertrophic pyloric stenosis (HPS) occurs when the circumferential muscle of the pyloric sphincter becomes thickened, resulting in elongation and narrowing of the pyloric canal. This produces an outlet obstruction and compensatory dilation, hypertrophy, and hyperperistalsis of the stomach. This condition usually develops in the first few weeks of life, causing nonbilious vomiting, which occurs after a feeding; projectile vomiting may develop, and the infant is fussy and hungry after vomiting. If the condition is not diagnosed early, dehydration, metabolic alkalosis, and failure to thrive may occur. The precise etiology of HPS is not known. Boys are affected four to six times more frequently than girls (Maqbool & Liacouras, 2020b). It is more common in white infants and is seen less frequently in African American and Asian infants (Maqbool & Liacouras, 2020b).

Pathophysiology

The circular muscle of the pylorus thickens as a result of hypertrophy. This produces severe narrowing of the pyloric canal between the stomach and the duodenum. Consequently, the lumen at this point is partially obstructed. Over time, inflammation and edema further reduce the size of the opening, resulting in complete obstruction. The hypertrophied pylorus may be palpable as an olive-like mass in the upper abdomen (Fig. 22.4).

Pyloric stenosis is not a congenital disorder. It is believed that local innervation may be involved in the pathogenesis. In most cases, HPS is an isolated lesion; however, it may be associated with intestinal malrotation, esophageal and duodenal atresia, and anorectal anomalies.

Clinical Manifestations

Infants with HPS have nonbilious vomiting in the early stages (Box 22.7). Vomiting usually begins at 3 weeks of age but can start as early as 1 week and as late as 5 months. Vomiting usually occurs 30 to 60 minutes after feeding and becomes projectile as the obstruction progresses. Initially the infant is hungry and irritable, but prolonged vomiting may lead to dehydration, weight loss, and failure to thrive. Gastric peristalsis may be visible on examination, and the olive-shaped mass in the epigastrium just to the right of the umbilicus may be palpated (see Fig. 22.4A). Indirect (unconjugated) hyperbilirubinemia may be present in a small percentage of affected infants; this usually resolves with surgical correction and is reported to occur as a result of a decreased level of glucuronyl transferase (see also Chapter 8).

Diagnostic Evaluation

The diagnosis of HPS is often made after the history and physical examination. The olive-like mass is most easily palpated when the stomach is empty, the infant is quiet, and the abdominal muscles are relaxed. If the diagnosis is inconclusive from the history and physical examination, ultrasonography will demonstrate an elongated mass surrounding a long pyloric canal. If ultrasonography does not demonstrate a hypertrophied pylorus, upper GI radiography should be done to rule out other causes of vomiting.

If the condition is not diagnosed early, laboratory findings reflect the metabolic alterations created by moderate to severe depletion of both water and electrolytes from extensive and prolonged vomiting. There are decreased serum levels of both sodium and potassium, although these may be masked by the hemoconcentration from ECF depletion. Of greater diagnostic value are a decrease in serum chloride levels and increases in pH and bicarbonate (carbon dioxide content), indicative of metabolic alkalosis. The BUN will be elevated as evidence of dehydration. However, in those cases diagnosed early, laboratory findings may not be significant.

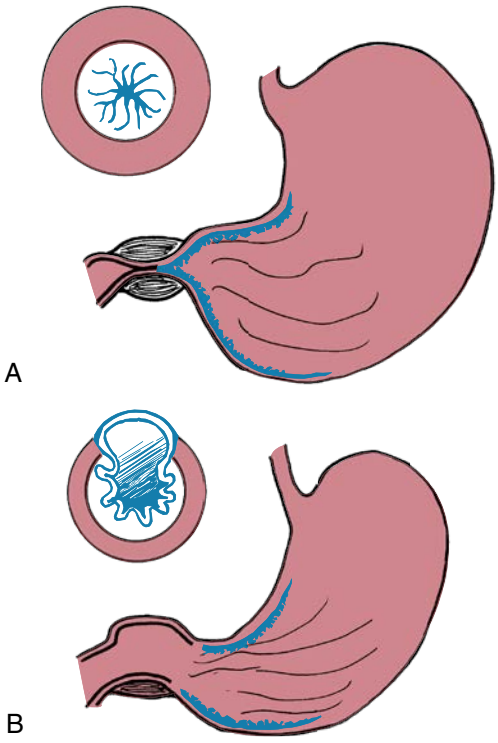

Fig. 22.4 Hypertrophic pyloric stenosis (HPS). **A,** Enlarged muscular area nearly obliterates the pyloric channel. **B,** Longitudinal surgical division of the muscle down to the submucosa establishes an adequate passageway.

BOX 22.7 Clinical Manifestations of Hypertrophic Pyloric Stenosis

Projectile vomiting
- May be ejected 3 to 4 feet from the child when in a side-lying position, 1 foot or more when in a back-lying position
- Usually occurs shortly after a feeding but may not occur for several hours
- May follow each feeding or appear intermittently
- Nonbilious vomitus that may be blood tinged

Infant hungry, avid nurser; eagerly accepts a second feeding after vomiting episode
No evidence of pain or discomfort except that of chronic hunger
Poor weight gain
Signs of dehydration
Distended upper abdomen
Readily palpable olive-shaped tumor in the epigastrium just to the right of the umbilicus
Visible gastric peristaltic waves that move from left to right across the epigastrium

Therapeutic Management

Surgical relief of the pyloric obstruction by pyloromyotomy is the standard therapy for this disorder. Preoperatively the infant must be rehydrated and metabolic alkalosis corrected with parenteral fluid and

electrolyte administration. Replacement fluid therapy usually delays surgery for 24 to 48 hours. The stomach is decompressed with an NG tube if the infant continues with vomiting. In infants with no evidence of fluid and electrolyte imbalance, surgery is performed without delay.

The surgical procedure is often performed by laparoscope and consists of a longitudinal incision through the circular muscle fibers of the pylorus down to, but not including, the submucosa (**pyloromyotomy**, or the Fredet-Ramstedt operation) (see Fig. 22.4B). The procedure has a high success rate. Laparoscopic surgery may result in a shorter surgical time, more rapid postoperative feeding, and shorter hospital stay (Maqbool & Liacouras, 2020b).

Feedings are usually begun 4 to 6 hours postoperatively, beginning with small, frequent feedings of water or electrolyte solution. If clear fluids are retained, formula is started in the same small increments about 24 hours after surgery. The amount and the interval between feedings are gradually increased until a full feeding schedule is reinstated, which usually takes about 48 hours.

Prognosis

The prognosis for infants and small children with HPS is excellent when the diagnosis is confirmed early, and the mortality rate is low (0% to 0.5%). A small percentage of children with HPS will have GER.

Nursing Care Management

Nursing care involves primarily observation for clinical features that help establish the diagnosis, careful regulation of fluid therapy, and reestablishment of normal feeding patterns. Nurses must be alert to signs of HPS in infants and refer them for medical evaluation. HPS should be considered a possibility in the very young infant who appears alert but fails to gain weight and has a history of vomiting after feedings. Assessment is based on observation of eating behaviors and evidence of other characteristic clinical manifestations, hydration, and nutritional status.

Preoperatively, the emphasis is on restoring hydration and electrolyte balance. The infant is kept NPO and given IV fluids with glucose and electrolytes based on serum electrolyte values and clinical appearance. Careful monitoring of the IV fluids and strict monitoring of intake and output are important. Record accurate description of any vomiting and the number and character of stools.

Observations include assessment of vital signs, particularly those that indicate fluid or electrolyte imbalances. These infants are especially prone to metabolic alkalosis from loss of hydrogen ions and depletion of potassium, sodium, and chloride, all of which are contained in gastric secretions. Assess the skin and mucous membranes for alterations in hydration status.

If stomach decompression and gastric lavage are part of preoperative management, the nurse is responsible for ensuring that the NG tube is patent and functioning properly and for measuring and recording the type and amount of drainage. Encourage parents to visit and become involved in the child's care. Most parents need support and reassurance that the condition is caused by a structural problem and is not a reflection of their parenting skills and capacities.

Postoperative vomiting is common, and most infants, even with successful surgery, exhibit some vomiting during the first 24 to 48 hours. IV fluids are administered until the infant is taking and retaining adequate amounts by mouth. Much of the same care that was instituted before surgery is continued postoperatively, including observation of vital signs, monitoring of IV fluids, and careful monitoring of intake and output. In addition, the infant is observed for responses to the stress of surgery and for evidence of pain. Appropriate analgesics should be given around the clock because pain is continuous. The surgical incision(s) is inspected for drainage or erythema, and any signs of infection are reported to the surgeon. A surgical adhesive may be used for incision closure, and parents are instructed regarding the care of the incision and any dressings before discharge.

Feedings are usually instituted within 12 to 24 hours postoperatively, beginning with clear liquids. They are offered in small quantities at frequent intervals. If the infant has been breastfed, breast milk expressed by the mother may be given by bottle when the infant is able to tolerate feedings, or the mother is instructed to limit nursing time and gradually increase the time to previous patterns. Observation and recording of feedings and the infant's responses to feedings are a vital part of postoperative care. Care of the operative site consists of observation for any drainage or signs of inflammation and care of the incision.

INTUSSUSCEPTION

Intussusception is the most common cause of intestinal obstruction in children between 3 months and 6 years old (Carroll, Kavanagh, Ni Leidhin, et al., 2017). Intussusception is more common in males than in females and is more common in children younger than 2 years old. Although specific intestinal lesions occur in a small percentage of the children, generally the cause is not known. Only 12.5% to 25% of intussusception cases have a pathologic lead point, such as a polyp, lymphoma, or Meckel diverticulum (Carroll et al., 2017). The idiopathic cases may be caused by hypertrophy of intestinal lymphoid tissue secondary to viral infection.

Pathophysiology

Intussusception occurs when a proximal segment of the bowel telescopes into a more distal segment, pulling the mesentery with it. The mesentery is compressed and angled, resulting in lymphatic and venous obstruction. As the edema from the obstruction increases, pressure within the area of intussusception increases. When the pressure equals the arterial pressure, arterial blood flow stops, resulting in ischemia and the pouring of mucus into the intestine. Venous engorgement also leads to leaking of blood and mucus into the intestinal lumen, forming the classic currant jelly–like stools. The most common site is the ileocecal valve (ileocolic), where the ileum invaginates into the cecum and then further into the colon (Fig. 22.5). Other forms include ileoileal (i.e., one part of the ileum invaginates into another section of the ileum) and colocolic (i.e., one part of the colon invaginates into another area of the colon) intussusceptions, usually in the area of the hepatic or splenic flexure or at some point along the transverse colon.

Clinical Manifestations

Intussusception usually manifests with the sudden onset of crampy abdominal pain, inconsolable crying, and a drawing up of the knees to the chest in an otherwise healthy child (Box 22.8). Between episodes the child appears normal. As the obstruction progresses, bilious vomiting may occur and lethargy increases. The classic triad of intussusception symptoms (abdominal pain, abdominal mass, bloody stools) is present in less than 30% of children (Maqbool & Liacouras, 2020d). A more chronic case, characterized by diarrhea, anorexia, weight loss, occasional vomiting, and periodic pain, may be presented. Because intussusception is potentially life threatening, be aware of such signs, and closely observe and refer these children for further medical evaluation. With atypical cases, lethargy may be the primary symptom. If the distal bowel remains distended, necrosis and perforation are possible.

Diagnostic Evaluation

Frequently, subjective findings lead to the diagnosis. However, definitive diagnosis is based on ultrasonography that reveals a characteristic heterogenous mass and a "bull's-eye." A rectal examination reveals mucus, blood, and occasionally a low intussusception itself.

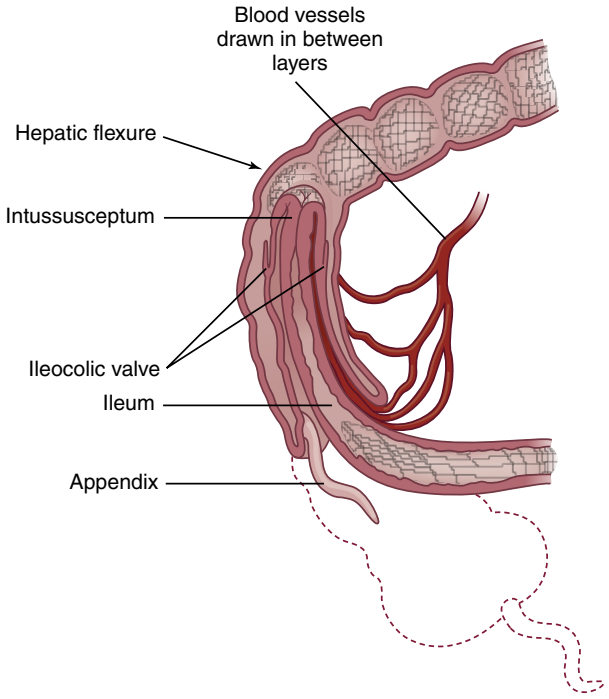

Fig. 22.5 Ileocecal valve (ileocolic) intussusception.

BOX 22.8 Clinical Manifestations of Intussusception

- Sudden acute abdominal pain
- Child screaming and drawing the knees onto the chest
- Child appearing normal and comfortable between episodes of pain
- Vomiting
- Lethargy
- Passage of red, currant jelly–like stools (stool mixed with blood and mucus)
- Tender, distended abdomen
- Palpable sausage-shaped mass in upper right quadrant
- Empty lower right quadrant (Dance sign)
- Eventual fever, prostration, and other signs of peritonitis

Therapeutic Management

Conservative treatment consists of radiologist-guided pneumoenema (gas enema) or ultrasound-guided hydrostatic enema, the advantage of the latter being that no ionizing radiation is needed (Maqbool & Liacouras, 2020e). Recurrence of intussusception after conservative treatment is rare; however, this procedure should not be attempted with prolonged intussusception, signs of shock, peritoneal irritation, or intestinal perforation (Maqbool & Liacouras, 2020e).

IV fluids, NG decompression, and antibiotic therapy may be used before hydrostatic reduction is attempted. If these procedures are not successful, the child may require surgical intervention. Surgery involves manually reducing the invagination and, when indicated, resecting any nonviable intestine.

Prognosis

Nonoperative reduction is successful in the majority of stable cases. Gas enema is slightly more successful with reduction compared to a hydrostatic enema (83% versus 70%, respectively) (Carroll et al., 2017). Surgery is required for patients in whom the reduction is unsuccessful or for patients who are unstable. With early diagnosis and treatment, serious complications and death are uncommon.

Nursing Care Management

The nurse can help establish a diagnosis by listening to the parents' description of the child's physical and behavioral symptoms. It is not unusual for parents to state that they thought something was seriously wrong before others shared their concerns. The description of the child's severe colicky abdominal pain combined with vomiting is a significant sign of intussusception.

As soon as a possible diagnosis of intussusception is made, the nurse prepares the parents for the immediate need for hospitalization, the nonsurgical technique of hydrostatic reduction, and the possibility of surgery. It is important to explain the basic defect of intussusception. The nurse can easily demonstrate this by creating a model of the defect. Use the example of a telescoping rod, or push the end of a finger on a rubber glove back into itself. Then demonstrate the principle of reduction by hydrostatic pressure by filling the glove with water, which pushes the "finger" into a fully extended position.

Physical care of the child does not differ from that for any child undergoing abdominal surgery. Even though nonsurgical intervention may be successful, the usual preoperative procedures, such as maintenance of NPO status, routine laboratory testing (CBC and urinalysis), signed parental consent, and preanesthetic sedation, are performed. Children with perforation will require IV fluids, systemic antibiotics, and bowel decompression before undergoing surgery. Fluid volume replacement and restoration of electrolytes may be required in such children before surgery. Before surgery the nurse monitors all stools.

! NURSING ALERT

Passage of a normal brown stool usually indicates that the intussusception has reduced itself. This is immediately reported to the practitioner, who may choose to alter the diagnostic and therapeutic care plan.

Postprocedural care includes observations of vital signs, blood pressure, intact sutures and dressing, and the return of bowel sounds. After spontaneous or hydrostatic reduction, the nurse observes for passage of water-soluble contrast material (if used) and stool patterns because the intussusception may recur. Children may be admitted to the hospital or monitored on an outpatient basis. A recurrence of intussusception is treated with the conservative reduction techniques described previously, but a laparotomy is considered for multiple recurrences.

MALROTATION AND VOLVULUS

Malrotation of the intestine is caused by the abnormal rotation of the intestine around the superior mesenteric artery during embryologic development. Malrotation may manifest in utero or at any age, but most patients (80%) present in the first month of life (Carroll et al., 2017). Infants may have intermittent bilious vomiting, recurrent abdominal pain, distention, or lower GI bleeding. Malrotation is the most serious type of intestinal obstruction because if the intestine undergoes complete volvulus (i.e., the intestine twisting around itself), compromise of the blood supply will result in intestinal necrosis, peritonitis, perforation, and death.

Diagnostic Evaluation

It is imperative that malrotation and volvulus be diagnosed promptly and surgical treatment instituted quickly. In addition to a history and

physical, a plain abdominal radiograph and lateral decubitus view are obtained; bowel distention will be present proximal to the distention on plain radiograph, and a lateral view will demonstrate air-fluid levels in the distended bowel. An upper GI series is the most accurate imaging study (Carroll et al., 2017).

Therapeutic Management

Surgery is indicated to remove the affected area. Because of the extensive nature of some lesions, short bowel syndrome (SBS) is a postoperative complication.

Nursing Care Management

Preoperatively the nursing care is the same as that provided to an infant or child with intestinal obstruction. IV fluids, NG decompression, and systemic antibiotics are implemented. In the rapidly deteriorating infant, fluid volume resuscitation and vasopressors may be required for preoperative stabilization. Postoperatively, the nursing care is similar to that provided to the infant or child who has undergone abdominal surgery.

MALABSORPTION SYNDROMES

Chronic diarrhea and malabsorption of nutrients characterize malabsorption syndromes. An important complication of malabsorption syndromes in children is failure to thrive. Most cases are classified according to the location of the supposed anatomic or biochemical defect. The term **celiac disease** is often used to describe a symptom complex with four characteristics: (1) steatorrhea (fatty, foul, frothy, bulky stools), (2) general malnutrition, (3) abdominal distention, and (4) secondary vitamin deficiencies.

Digestive defects are conditions in which the enzymes necessary for digestion are diminished or absent, such as (1) cystic fibrosis, in which pancreatic enzymes are absent; (2) biliary or liver disease, in which bile flow is affected; or (3) lactase deficiency, in which there is congenital or secondary lactose intolerance.

Absorptive defects are conditions in which the intestinal mucosal transport system is impaired. This may occur because of a primary defect (e.g., celiac disease) or secondary to inflammatory disease of the bowel that results in impaired absorption because bowel motility is accelerated (e.g., ulcerative colitis). Obstructive disorders (e.g., Hirschsprung disease) also cause secondary malabsorption from enterocolitis.

Anatomic defects, such as extensive resection of the bowel or SBS, affect digestion by decreasing the transit time of substances and affect absorption by severely compromising the absorptive surface.

CELIAC DISEASE (GLUTEN-SENSITIVE ENTEROPATHY)

Celiac disease, also known as *gluten-induced enteropathy, gluten-sensitive enteropathy,* and *celiac sprue,* is an autoimmune disorder triggered by the ingestion of gluten in genetically susceptible individuals (Fok, Holland, Gil-Zaragozano, et al., 2016). The disorder results in permanent intestinal intolerance to dietary gluten, a protein present in wheat, barley, and rye that causes damage to the villi in the small intestine. Children with unexplained iron deficiency anemia, recurrent aphthous stomatitis, dental enamel defects, type 1 diabetes, Down syndrome, selective immunoglobulin A deficiency, autoimmune thyroid disease, Turner syndrome, or Williams syndrome are more susceptible to being diagnosed with the disease (Paul, McVeigh, Gil-Zaragozano, et al., 2016). The disease is seen more frequently in Europe and the United States in approximately 1% of these populations, and it is rarely reported in Asians or African Americans (Troncone & Shamir, 2020).

Pathophysiology

Celiac disease is characterized by villous atrophy in the small intestine in response to the protein gluten. When individuals are unable to digest the gliadin component of gluten, an accumulation of a toxic substance that is damaging to the mucosal cells occurs. Damage to the mucosa of the small intestine leads to villous atrophy, hyperplasia of the crypts, and infiltration of the epithelial cells with lymphocytes. Villous atrophy leads to malabsorption due to the reduced absorptive surface area.

Genetic predisposition is an essential factor in the development of celiac disease. Membrane receptors involved in preferential antigen presentation to $CD4^+$ T cells play a crucial role in the immune response characteristic of celiac disease. Children with genetic susceptibilities, namely *HLA-DQ2* or *HLA-DQ8,* are more susceptible to being diagnosed with celiac disease (Lebwohl, Sanders, & Green, 2017).

Clinical Manifestations

Symptoms of celiac disease appear when solid foods such as beans and pasta are introduced in the child's diet between the ages of 1 and 5 years (Box 22.9). There is usually an interval of several months between the introduction of gluten in the diet and the onset of symptoms. Intestinal symptoms are common in children diagnosed within the first 2 years of life. Other symptoms include failure to thrive, chronic diarrhea, abdominal distention and pain, muscle wasting, aphthous ulcers, and fatigue.

Diagnostic Evaluation

Gluten should not be excluded from the diet until the diagnostic evaluation is complete so that proper identification can occur. The first step is a serologic blood test for tissue transglutaminase and antiendomysial antibodies in children 18 months of age or older (Troncone & Shamir,

BOX 22.9 Clinical Manifestations of Celiac Disease

Impaired Fat Absorption
Steatorrhea (excessively large, pale, oily, frothy stools)
Exceedingly foul-smelling stools

Impaired Nutrient Absorption
Malnutrition
Muscle wasting (especially prominent in legs and buttocks)
Anemia
Anorexia
Abdominal distention

Behavioral Changes
Irritability
Uncooperativeness
Apathy

Celiac Crisis[a]
Acute, severe episodes of profuse watery diarrhea and vomiting
May be precipitated by:
- Infections (especially gastrointestinal)
- Prolonged fluid and electrolyte depletion
- Emotional disturbance

[a]In very young children.

2020). Positive serologic markers should be followed by an upper GI endoscopy with biopsy. The diagnosis of celiac disease is based on a biopsy of the small intestine demonstrating the characteristic changes of mucosal inflammation, crypt hyperplasia, and villous atrophy (Troncone & Shamir, 2020).

Therapeutic Management

Treatment of celiac disease consists primarily of dietary management. Although a gluten-free diet is prescribed, it is actually low in gluten because it is impossible to remove every source of this protein. Because gluten is found primarily in wheat and rye, but also in smaller quantities in barley and oats, these four foods are eliminated. Corn, rice, and millet are substitute grain foods.

Children with untreated celiac disease may have lactose intolerance, especially if their mucosal lesions are extensive. Lactose intolerance usually improves as the mucosa heals with gluten withdrawal. Specific nutritional deficiencies, such as iron, folic acid, and fat-soluble vitamin deficiencies, are treated with appropriate supplements.

Prognosis

Celiac disease is regarded as a chronic disease; its severity varies greatly among children. The most severe symptoms usually occur in early childhood and again in adult life. Most children who comply with dietary management are healthy and remain free of symptoms and complications; however, children should be evaluated annually for nutritional deficiencies, impaired growth, delayed puberty, and reduced bone mineral density (Fok et al., 2016).

Nursing Care Management

The main nursing consideration is helping the child adhere to the dietary regimen. Considerable time is involved in explaining the disease process to the child and parents, the specific role of gluten in aggravating the disorder, and those foods that must be restricted. It is difficult to maintain a diet indefinitely when the child has no symptoms and temporary transgressions result in no difficulties. However, the majority of individuals who relax their diet will experience a relapse of their disease.

Although the chief source of gluten is cereal and baked goods, grains are frequently added to processed foods as thickeners or fillers. To compound the difficulty, gluten is added to many foods as hydrolyzed vegetable protein, which is derived from cereal grains. The nurse must advise parents of the necessity of reading all label ingredients carefully to avoid hidden sources of gluten.

Many of children's favorite foods contain gluten, including bread, cake, cookies, crackers, donuts, pies, spaghetti, pizza, prepared soups, hot dogs, luncheon meats, and some prepared hamburgers. Many of these products can be eliminated from the infant's or young child's diet fairly easily, but monitoring the diet of the school-age child or adolescent is more difficult. Luncheon preparation away from home is particularly difficult because bread, luncheon meats, and instant soups are not allowed. For families on restricted food budgets, the diet adds another financial burden because many inexpensive or convenient foods cannot be used.

In addition to restricting gluten, other dietary alterations may be necessary. For example, in some children who have more severe mucosal damage, the digestion of disaccharides is impaired, especially in relation to lactose. Therefore these children often need a temporarily lactose-free diet, which necessitates eliminating all milk products. In general, dietary management includes a diet high in calories and proteins with simple carbohydrates such as fruits and vegetables, but low in fats. Because the bowel is inflamed as a result of the pathologic processes in absorption, the child must avoid high-fiber foods such as nuts, raisins, raw vegetables, and raw fruits with skin until inflammation has subsided.

It is important to stress long-range complications and to remind parents of the child's physical status before dietary treatment and the dramatic improvement after treatment. The nurse can be instrumental in allowing the child to express concerns and frustration while focusing on ways in which the child can still feel normal. Encourage the child and parents to find new recipes using suitable ingredients, such as Mexican or Chinese dishes that use corn or rice. Consult a registered dietitian to provide children and their families with detailed dietary instructions and education.

Several resources are available to assist children and parents in all aspects of coping with celiac disease. The National Celiac Association[d] provides support and guidance to families and supplies educational materials concerning a gluten-free diet, food sources, recipes, and travel information.

SHORT BOWEL SYNDROME

Short bowel syndrome (SBS) is a malabsorptive disorder that occurs as a result of decreased mucosal surface area, usually because of extensive resection of the small intestine. Malabsorption may be exacerbated by other factors, such as bacterial overgrowth and dysmotility. The most common congenital causes of SBS in children are multiple atresias, and gastroschisis; other causes resulting in bowel resection include necrotizing volvulus, meconium peritonitis, Crohn disease, and trauma (Avitzur & Shamir, 2020).

The definition of SBS includes two important findings: (1) decreased intestinal surface area for absorption of fluid, electrolytes, and nutrients; and (2) a need for parenteral nutrition (PN) (Martin, Ladd, Werts, et al., 2017). The prognosis for infants with SBS has improved dramatically, but the mortality rate within 5 years after diagnosis remains at 27% to 37% (Martin et al., 2017).

Therapeutic Management

The goals of therapy for infants and children with SBS include (1) preserving as much length of bowel as possible during surgery; (2) maintaining optimum nutritional status, growth, and development while intestinal adaptation occurs; (3) stimulating intestinal adaptation with enteral feeding; and (4) minimizing complications related to the disease process and therapy (Avitzur & Shamir, 2020).

Nutritional Support

Nutritional support is the long-term focus of care for children with SBS. The initial phase of therapy includes PN as the primary source of nutrition. The second phase is the introduction of enteral feeding, which usually begins as soon as possible after surgery. Elemental formulas containing glucose, sucrose and glucose polymers, hydrolyzed proteins, and medium-chain triglycerides facilitate absorption. Usually these formulas are given by continuous infusion through an NG or gastrostomy tube. As the enteral feedings are advanced, the PN solution is decreased in terms of calories, amount of fluid, and total hours of infusion per day. If enteral feedings are tolerated, oral feedings should be attempted to minimize oral aversion and preserve oral skills (Avitzur & Shamir, 2020).

[d]20 Pickering Street, Needham, MA 02492; 1-888-4CELIAC or 617-262-5422; http://www.nationalceliac.org. In Canada: Canadian Celiac Association, 1450 Meyerside Drive, Suite 503, Mississauga, Ontario L5T 2N5; 1-800-363-7296; http://www.celiac.ca.

The final phase of nutritional support occurs when growth and development are sustained. When PN is discontinued, there is a risk of nutritional deficiency secondary to malabsorption of fat-soluble vitamins (A, D, E, and K) and trace minerals (iron, selenium, zinc). Serum vitamin and mineral levels should be monitored closely and supplemented enterally, if needed. Pharmacologic agents have been used to reduce secretory losses. H_2 blockers, PPIs, and octreotide inhibit gastric or pancreatic secretion. Cholestyramine is often prescribed to improve diarrhea that is associated with bile salt malabsorption.

Numerous complications are associated with SBS and long-term PN. Infectious, metabolic, and technical complications can occur. Sepsis can occur after improper care of the catheter. The GI tract can also be a source of microbial seeding of the catheter. Bowel atrophy may foster increased intestinal permeability of bacteria. A lack of adequate sites for central lines may become a significant problem for the child in need of long-term PN. Hepatic dysfunction and cholestasis may also occur (Cohran, Prozialeck, & Cole, 2017).

Bacterial overgrowth is likely to occur when the ileocecal valve is absent or when stasis exists as a result of a partial obstruction or a dilated segment of bowel with poor motility. Alternating cycles of broad-spectrum antibiotics are used to reduce bacterial overgrowth. This treatment may also decrease the risk of bacterial translocation and subsequent central venous catheter infections. A high-fat and low-carbohydrate diet may be helpful in reducing bacterial overgrowth (Avitzur & Shamir, 2020). Other complications of bacterial overgrowth and malabsorption include metabolic acidosis and gastric hypersecretion.

Many surgical interventions, including intestinal valves, tapering enteroplasty or stricturoplasty, intestinal lengthening, and interposed segments, have been used to slow intestinal transit, reduce bacterial overgrowth, or increase mucosal surface area. Intestinal transplantation has been performed successfully in children. Children with a permanent dependence on PN or severe complications of long-term PN are candidates for transplantation.

Prognosis

The prognosis for infants with SBS has improved with advances in PN and with the understanding of the importance of intraluminal nutrition. Improved supportive care for the management of therapy-related problems and the development of more specific immunosuppressive medications for transplantation have all contributed to improved management. The prognosis depends in part on the length of the residual small intestine. An intact ileocecal valve also improves the prognosis. Infants and children with SBS die from PN-related problems, such as fulminant sepsis or severe PN cholestasis.

Nursing Care Management

The most important components of nursing care are administration and monitoring of nutritional therapy. During PN therapy, care must be taken to minimize the risk of complications related to the central venous access device (i.e., catheter infections, occlusions, dislodgment, or accidental removal). Care of the enteral feeding tubes and monitoring of enteral feeding tolerance are also important nursing responsibilities.

When hospitalization is prolonged, the child's developmental and emotional needs must be met. This often requires special planning to promote normal family adjustment and adaptation of the hospital routines. Family members require psychosocial support and education to cope successfully with SBS.

Many infants with SBS have an intestinal ostomy performed at the time of the initial bowel resection. Routine ostomy care is another important nursing responsibility. Because infants and children with SBS have chronic diarrhea, perineal skin irritation is often a problem after ostomy closure. Frequent diaper changes, gentle perineal cleansing, and protective skin ointments help prevent skin breakdown (see Chapter 31, Diaper Dermatitis).

Home Care

When long-term PN is required, preparation of the family for home care of the child is a major nursing responsibility. Preparation for home nutritional support begins as early as possible to prevent lengthy hospitalizations with subsequent problems such as developmental delays and family stresses. Many infants and children can be successfully cared for at home with enteral and parenteral nutrition if the family is thoroughly prepared and provided with adequate support services. Most families benefit from home nursing care to assist with and supervise therapy. Careful follow-up care by a multidisciplinary nutritional support service is essential. Most home health agencies now provide portable enteral and parenteral equipment, which enables the child and family to maintain a more normal and active lifestyle. The nurse plays an active and important role in the success of a home nutrition program. Home infusion companies provide portable equipment, which enables the child and family to maintain a more normal lifestyle.

HEPATIC DISORDERS

The liver is a vital organ whose functions can be divided into several groups: (1) vascular functions of storing and filtering blood; (2) secretory function of producing bile; (3) metabolism of carbohydrate, protein, and fat; (4) synthesis of blood-clotting components and storage of iron and vitamins (A, D, B_{12}, and K); and (5) detoxification and excretion of certain drugs and metabolic substances. Many disorders, including biliary atresia, hepatitis, and cirrhosis, can cause liver dysfunction in children.

ACUTE HEPATITIS

Hepatitis is an acute or chronic inflammation of the liver that can result from infectious or noninfectious reasons. Viruses such as hepatitis viruses, Epstein-Barr virus (EBV), and cytomegalovirus (CMV) are common causes of many types of hepatitis. Other causes of hepatitis are nonviral (e.g., abscess, amebiasis), autoimmune, metabolic, drug induced, anatomic (e.g., choledochal duct cyst and biliary atresia), hemodynamic (e.g., shock, congestive heart failure), and idiopathic (e.g., sclerosing cholangitis and Reye syndrome). Determining the cause of acute or chronic hepatitis is important in determining the treatment and prognosis for the child. Epidemiologic features and serologic testing are used to differentiate the causes. Table 22.8 compares the features of hepatitis A, B, and C viruses.

Hepatitis A Virus

Hepatitis A virus (HAV) incidence in the United States has declined since the introduction of a vaccine in 1995. There were approximately 1390 new cases in the United States in 2015 (Centers for Disease Control and Prevention, 2017). The virus is spread directly or indirectly by the fecal-oral route by ingestion of contaminated foods, direct exposure to infected fecal material, or close contact with an infected person. The virus is particularly prevalent in developing countries with poor living conditions, inadequate sanitation, crowding, and poor

TABLE 22.8 Comparison of Hepatitis Types A, B, and C

Characteristics	Type A	Type B	Type C
Incubation period	15-50 days, average 28 days	45-160 days, average 120 days	2-24 weeks, average 7-9 weeks
Period of communicability	Believed to be latter half of incubation period to first week after onset of clinical illness	Variable Virus in blood or other body fluids during late incubation period and acute stage of disease; may persist in carrier state for years to lifetime	Begins before onset of symptoms May persist in carrier state for years
Mode of transmission	Principal route—fecal-oral Rarely—parenteral	Principal route—parenteral Less frequent route—oral, sexual, any body fluid Perinatal transfer—transplacental blood (last trimester), at delivery, or during breastfeeding, especially if mother has cracked nipples	Principal route—parenteral Nonparenteral spread possible
Clinical features			
• Onset	Usually rapid, acute	More insidious	Usually insidious
• Fever	Common and early	Less frequent	Less frequent
• Anorexia	Common	Mild to moderate	Mild to moderate
• Nausea and vomiting	Common	Sometimes present	Mild to moderate
• Rash	Rare	Common	Sometimes present
• Arthralgia	Rare	Common	Rare
• Pruritus	Rare	Sometimes present	Sometimes present
• Jaundice	Present (many cases anicteric)	Present	Present
Immunity	Present after one attack; no crossover to type B or C	Present after one attack; no crossover to type A or C	Present after one attack; no crossover to type A or B
Carrier state	No	Yes	Yes
Chronic infection	No	Yes	Yes
Prophylaxis			
• Immune globulin (IG)	Passive immunity Successful, especially in early incubation period and preexposure prophylaxis	Passive immunity Inconsistent benefits; probably of no use	Not currently recommended by Centers for Disease Control and Prevention
• HAV vaccine	Two inactivated vaccines administered to all children ages 12-23 months old: Havrix and Vaqta; given in a 2-dose schedule (6 months between doses)		
• HBV immune globulin (HBIG)	No benefit	Postexposure protection possible if given immediately after definite exposure	No benefit
• HBV vaccine		Provides active immunity Universal vaccination recommended for all newborns	
Mortality rate	0.1%-0.2%	0.5%-2.0% in uncomplicated cases; may be higher in complicated cases	1%-2% in uncomplicated cases; may be higher in complicated cases

HAV, Hepatitis A virus; *HBV,* hepatitis B virus.

personal hygiene practices. The spread of HAV has been associated with improper food handling and high-risk areas such as households with infected persons, residential centers for the disabled, and day-care centers. The average incubation period is about 21 days (Jensen & Balistreri, 2020). Fecal shedding of the virus can occur for 2 weeks before and for 1 week after the onset of jaundice. During this time, although the individual is asymptomatic, the virus is most likely to be transmitted. Infants with HAV infection are likely to be asymptomatic (anicteric hepatitis). Children often have diarrhea, and their symptoms are frequently attributed to gastroenteritis. Younger children rarely develop jaundice; however, 70% of older children and adults infected with HAV develop clinical signs with icteric hepatitis that typically lasts 7 to 14 days (Jensen & Balistreri, 2020). The prognosis of HAV infection is usually good, and complications are rare.

Hepatitis B Virus

Although the incidence of hepatitis B virus (HBV) is declining after the introduction of a universal immunization program,

approximately 1.25 million people in the United States are infected with HBV, with 400 million HBV cases worldwide (Jensen & Balistreri, 2020). HBV can be an acute or chronic infection, ranging from an asymptomatic, limited infection to fatal, fulminant (rapid and severe) hepatitis (Jensen & Balistreri, 2020). There are no environmental or animal reservoirs for HBV. Humans are the main source of infections. HBV may be transmitted parenterally, percutaneously, or transmucosally. Hepatitis B surface antigen (HBsAg) has been found in all body fluids, including feces, bile, breast milk, sweat, tears, vaginal secretions, and urine, but only blood, semen, and saliva have been found to contain infectious HBV particles. HBV infection from human bites has been documented, but transmission from feces has not. HBV has been acquired after blood transfusion, but the likelihood of this has been reduced through blood product–screening procedures. Adults whose occupations are associated with considerable exposure to blood or blood products, such as health care workers, are at an increased risk of contracting HBV.

Most HBV infections in children are acquired perinatally. Transmission from mother to infant during the perinatal period (i.e., blood exposure during delivery) results in chronic infection in up to 90% of infants if the mother is positive for HBsAg and HBeAg (Jensen & Balistreri, 2020). HBsAg has been inconsistently detected in breast milk, but no increased risk of transmission has been found, and breastfeeding is currently recommended after infant immunization (Jensen & Balistreri, 2020). Infants and children who are not infected during the perinatal period remain at high risk for acquiring person-to-person transmission from their mother.

HBV infection occurs in children and adolescents in the following specific high-risk groups: (1) individuals with hemophilia or other disorders who have received multiple transfusions, (2) children and adolescents involved in IV drug abuse, (3) institutionalized children, (4) preschool children in endemic areas, and (5) individuals engaged in sexual activity with an infected partner. The incubation period for HBV infection ranges from 45 to 160 days, with an average of 120 days (Jensen & Balistreri, 2020). HBV infection can cause a carrier state and lead to chronic hepatitis with eventual cirrhosis or hepatocellular carcinoma in adulthood.

Hepatitis C Virus

Hepatitis C virus (HCV) is the most common cause of chronic liver disease, with an estimated 4 million people in the United States and 170 million people worldwide infected (Jensen & Balistreri, 2020). HCV is transmitted parenterally through exposure to blood and blood products from HCV-infected persons, whereas perinatal transmission is the most common mode of transmission among children (Jensen & Balistreri, 2020). Recent improvements in donor screening and inactivation procedures for blood products, such as the factor concentrates used for hemophilia patients, have significantly reduced the risk of transmission through blood products. Currently the most common cause of HCV infection is illegal drug use with exposure to blood or blood products from an HCV-infected individual, and sexual transmission is the second most common cause of HCV infection (Jensen & Balistreri, 2020).

The clinical course is variable. The incubation period for HCV ranges from 2 to 24 weeks, with an average of 7 to 9 weeks (Jensen & Balistreri, 2020). The natural history of the disease in children is not well defined. Some children may be asymptomatic, but HCV can become a chronic condition and can cause cirrhosis and hepatocellular carcinoma. About 85% of individuals infected with HCV develop chronic disease (Jensen & Balistreri, 2020).

Hepatitis D Virus

Hepatitis D virus (HDV) rarely occurs in children and must occur in individuals already infected with HBV (Jensen & Balistreri, 2020). HDV is a defective RNA virus that requires the helper function of HBV. The incubation period is 2 to 8 weeks, but with coinfection of HBV the incubation period is similar to an HBV infection (Jensen & Balistreri, 2020). HDV infection occurs through blood and sexual contact, and commonly occurs among drug abusers, individuals with hemophilia, and persons immigrating from endemic areas.

Hepatitis E Virus

Hepatitis E virus (HEV) was formerly known as non-A, non-B hepatitis. Transmission may occur through the fecal-oral route or from contaminated water. The incubation period ranges from 15 to 60 days, with an average of 40 days (Jensen & Balistreri, 2020). This illness is uncommon in children, does not cause chronic liver disease, is not a chronic condition, and has no carrier state. However, it can be a devastating disease among pregnant women, with an unusually high fatality rate.

Pathophysiology

Pathologic changes occur primarily in the parenchymal cells of the liver and result in variable degrees of swelling; infiltration of liver cells by mononuclear cells; and subsequent degeneration, necrosis, and fibrosis. Structural changes within the hepatocyte account for altered liver functions, such as impaired bile excretion, elevated transaminase levels, and decreased albumin synthesis. The disorder may be self-limiting, with regeneration of liver cells without scarring, leading to a complete recovery. However, some forms of hepatitis do not result in complete return of liver function. These include fulminant hepatitis, which is characterized by a severe, acute course with massive destruction of the liver tissue causing liver failure and high mortality risk within 1 to 2 weeks, and subacute or chronic active hepatitis, which is characterized by progressive liver destruction, uncertain regeneration, scarring, and potential cirrhosis.

The progression of liver disease is characterized pathologically by four stages: (1) stage one is characterized by mononuclear inflammatory cells surrounding small bile ducts, (2) in stage two there is proliferation of small bile ductules, (3) stage three is characterized by fibrosis or scarring, and (4) stage four is cirrhosis.

Clinical Manifestations

The clinical manifestations and course of uncomplicated acute viral hepatitis are similar for most of the hepatitis viruses. Usually the prodromal, or anicteric, phase (absence of jaundice) lasts 5 to 7 days. Anorexia, malaise, lethargy, and easy fatigability are the most common symptoms. Fever may be present, especially in adolescents. Nausea, vomiting, and epigastric or right upper quadrant abdominal pain or tenderness may occur. Arthralgia and skin rashes may occur and are more likely in children with hepatitis B than those with hepatitis A. The transaminases, rather than the bilirubin, are often elevated in acute hepatitis, and hepatomegaly may be present. Some mild cases of acute viral hepatitis do not cause symptoms or can be mistaken for influenza.

In young children most of the prodromal symptoms disappear with the onset of jaundice, or the icteric phase. However, many children with acute viral hepatitis never develop jaundice. If jaundice occurs, it is often accompanied by dark urine and pale stools. Pruritus may accompany jaundice and can be bothersome for children.

Children with chronic active hepatitis may be asymptomatic but more commonly have nonspecific symptoms of malaise, fatigue, lethargy, weight loss, or vague abdominal pain. Hepatomegaly may be present, and the transaminases are often very high, with mild to severe hyperbilirubinemia.

Fulminant hepatitis is due primarily to HBV or HCV. Many children with fulminant hepatitis develop characteristic clinical symptoms and rapidly develop manifestations of liver failure, including encephalopathy, coagulation defects, ascites, deepening jaundice, and an increasing white blood cell count. Changes in mental status or personality indicate impending liver failure. Although children with acute hepatitis may have hepatomegaly, a rapid decrease in the size of the liver (indicating loss of tissue due to necrosis) is a serious sign of fulminant hepatitis. Complications of fulminant hepatitis include GI bleeding, sepsis, renal failure, and disseminated coagulopathy.

Diagnostic Evaluation

Diagnosis is based on the history, physical examination, and serologic markers for hepatitis A, B, and C. No LFT is specific for hepatitis, but serum aspartate aminotransferase (AST) and serum alanine aminotransferase (ALT) levels are markedly elevated. Serum bilirubin levels peak 5 to 10 days after clinical jaundice appears. Histologic evidence from liver biopsy may be required to establish the diagnosis and to assess the severity of the liver disease. Serologic markers indicate the antibodies or antigens formed in response to the specific virus and confirm the diagnosis. Serum immunologic tests are not available to detect HAV antigen, but there are two HAV antibody tests: anti-HAV immunoglobulin G (IgG) and immunoglobulin M (IgM). Anti-HAV antibodies are present at the onset of the disease and persist for life. A positive anti-HAV antibody test can indicate acute infection, immunity from past infection, passive antibody acquisition (e.g., from transfusion, serum immunoglobulin infusion), or immunization. To diagnose an acute or recent HAV infection, a positive anti-HAV IgM test that is present with the onset of the disease and that persists for only 2 or 3 days is required.

Diagnosis of hepatitis B is confirmed by the detection of various hepatitis virus antigens and the antibodies that are produced in response to the infection. These antibodies and antigens and their significance include the following:

HBsAg—Hepatitis B surface antigen (found on the surface of the virus), indicating ongoing infection or carrier state

Anti-HBs—Antibody to surface antigen HbsAg, indicating resolving or past infection

HBcAg—Hepatitis B core antigen (found on the inner core of the virus), detected only in the liver

Anti-HBc—Antibody to core antigen HbcAg, indicating ongoing or past infection

HBeAg—Hepatitis B antigen (another component of the HBV core), indicating active infection

Anti-HBe—Antibody to HbeAg, indicating resolving or past infection

IgM anti-HBc—IgM antibody to core antigen

Tests are available for detection of all the HBV antigens and antibodies except HBcAg. HBsAg is detectable during acute infection. Presence of HBsAg indicates that the individual has been infected with the hepatitis virus. If the infection is self-limiting, HBsAg disappears in most patients before serum anti-HBs can be detected (called the *window phase of infection*). IgM anti-HBc is highly specific in establishing the diagnosis of acute infection, as well as during the window phase in older children and adults. However, IgM anti-HBc usually is not present in perinatal HBV infection. Clinical improvement is usually associated with a decrease in or disappearance of these antigens, followed by the appearance of their antibodies. For example, anti-HBc of the IgM class often occurs early in the disease, followed by a rise in anti-HBc of the IgG class. Because the antibodies persist indefinitely, they are used to identify the carrier state (i.e., individuals with HBV who have no clinical disease but are able to transmit the organism). Persons with chronic HBV infection have circulating HBsAg and anti-HBc, and on rare occasions anti-HBsAg is present. Both anti-HBs and anti-HBc are detected in persons with resolved infection, but anti-HBs alone is present in individuals who have been immunized with the HBV vaccine.

HCV-RNA is the earliest serologic marker for HCV. HCV-RNA can be detected during the incubation period before symptoms of HCV disease are expressed. A positive HCV-RNA result indicates active infection, and persistence of HCV-RNA indicates chronic infection. A negative test correlates with resolution of the disease. HCV-RNA is also used to determine patient response to antiviral therapy for HCV.

The history of all patients should include questions to seek evidence of (1) contact with a person known to have hepatitis, especially a family member; (2) unsafe sanitation practices, such as contaminated drinking water; (3) ingestion of certain foods, such as clams or oysters (especially from polluted water); (4) multiple blood transfusions; (5) ingestion of hepatotoxic drugs, such as salicylates, sulfonamides, antineoplastic agents, acetaminophen, and anticonvulsants; and (6) parenteral administration of illicit drugs or sexual contact with a person who uses these drugs.

Therapeutic Management

The goals of management include early detection, support and monitoring of the disease, recognition of chronic liver disease, and prevention of spread of the disease. Special high-protein, high-carbohydrate, low-fat diets are generally not of value. The use of corticosteroids alone or with immunosuppressive drugs is not advocated in the treatment of chronic viral hepatitis. However, steroids have been used to treat chronic autoimmune hepatitis. Hospitalization is required in the event of coagulopathy or fulminant hepatitis.

Therapy for hepatitis depends on the severity of inflammation and the cause of the disorder. HAV is treated primarily with supportive care. The US Food and Drug Administration approved several medications for treatment of children with HBV and HCV. Human interferon-alpha is being used successfully in the treatment of chronic hepatitis B and C in children. Lamivudine is used for the treatment of HBV. It is well tolerated with no significant side effects and is approved for children older than 2 years of age (Jensen & Balistreri, 2020). Combined therapy with lamivudine and interferon-alpha does not improve response rates (Jensen & Balistreri, 2020). Adefovir is used to treat HBV in children older than 12 years of age. Entecavir and tenofovir have recently been approved for HBV treatment in adolescents ages 16 years or older (Jensen & Balistreri, 2020). Peginterferon alfa-2b has not been approved for use in children in the United States but has been used to treat HBV in people in other countries (Jensen & Balistreri, 2020).

Prevention

Proper hand washing and Standard Precautions prevent the spread of viral hepatitis. Prophylactic use of standard immune globulin is effective in preventing hepatitis A in situations of preexposure (such as anticipated travel to areas where HAV is prevalent) or within 2 weeks of exposure.

Hepatitis B immune globulin (HBIG) is effective in preventing HBV infection after one-time exposures such as accidental needle punctures or other contact of contaminated material with mucous membranes and should be given to newborns whose mothers are HbsAg positive. HBIG is prepared from plasma that contains high titers of antibodies against HBV. HBIG should be given within 72 hours of exposure.

Vaccines have been developed to prevent HAV and HBV infection (see Table 22.8). HBV vaccination is recommended for all newborns and for children who did not receive the vaccination as a newborn. (See Chapter 6, Immunizations.) Because HDV cannot be transmitted in the absence of HBV infection, it is possible to prevent HDV infection by preventing HBV infection. Routine serologic testing for anti-HCV of children older than 12 months of age who were born to women previously identified as being infected with HCV is also recommended (Jensen & Balistreri, 2020).

Prognosis

The prognosis for children with hepatitis is variable and depends on the type of virus and the child's age and immunocompetency. Hepatitis A and E are usually mild, brief illnesses with no carrier state. Hepatitis B can cause a wide spectrum of acute and chronic illness. Infants are more likely than older children to develop chronic hepatitis. Hepatocellular carcinoma during adulthood is a potentially fatal complication of chronic HBV infection. Hepatitis C frequently becomes chronic, and cirrhosis may develop in these children.

Nursing Care Management

Nursing objectives depend largely on the severity of the hepatitis, the medical treatment, and factors influencing the control and transmission of the disease. Because children with mild viral hepatitis are frequently cared for at home, it is often the nurse's responsibility to explain any medical therapies and infection control measures. When further assistance is needed for parents to comply with instructions, a public health nursing referral is necessary.

Encourage a well-balanced diet and a schedule of rest and activity adjusted to the child's condition. Because the child with HAV is not infectious within 1 week after the onset of jaundice, the child may feel well enough to resume school shortly thereafter. Caution parents about administering any medication to the child because normal doses of many drugs may become dangerous because of the liver's inability to detoxify and excrete them.

Standard Precautions are followed when children are hospitalized. However, these children are not usually isolated in a separate room unless they are fecally incontinent or their toys and other personal items are likely to become contaminated with feces. Discourage children from sharing their toys.

Hand washing is the single most effective measure in prevention and control of hepatitis in any setting. Parents and children need an explanation of the usual ways in which hepatitis is spread (fecal-oral route and parenteral route). Parents should also be aware of the recommendation for universal vaccination against HBV for newborns and adolescents (see Chapter 6).

In young people with HBV infection who have a known or suspected history of illicit drug use, the nurse has the responsibility of helping them realize the associated dangers of drug abuse, stressing the parenteral mode of transmission of hepatitis, and encouraging them to seek counseling through a drug program.

BILIARY ATRESIA

Biliary atresia (BA), or extrahepatic biliary atresia (EHBA), is a progressive inflammatory process that causes both intrahepatic and extrahepatic bile duct fibrosis, resulting in eventual ductal obstruction. The incidence of BA is approximately 1 in 10,000 to 15,000 live births (Hassan & Balistreri, 2020). Associated malformations include polysplenia and malrotation of the intestine. BA, if untreated, usually leads to cirrhosis, liver failure, and death.

Pathophysiology

The exact cause of BA is unknown, although immune- or infection-mediated mechanisms may be responsible for the progressive process that results in complete obliteration of the bile ducts. BA is not seen in the fetus or stillborn or newborn infant. This suggests that BA is acquired late in gestation or in the perinatal period and is manifested a few weeks after birth.

Congenital infections have been implicated as a cause of hepatocellular damage leading to BA, yet no specific agent is identified in every case. Immune-mediated bile duct injury from viral exposure and immaturity of the neonatal immune system may play a role in the destruction of bile ducts and development of EHBA. Other potential causes include an early first trimester insult to the developing bile ducts or a postnatal viral insult (Hassan & Balistreri, 2020). Early in the course of the disease, the intrahepatic ducts are patent from the interlobular ductules to the porta hepatis. The size of these structures is variable and is correlated with the infant's age and with bile excretion after surgical treatment. These structures are present in most affected infants under 2 months of age but gradually disappear over the next few months and by 4 months are completely replaced by fibrous tissue.

The degree of involvement of the extrahepatic biliary ducts is also variable. The majority of cases of BA (85%) have a complete obliteration of the extrahepatic biliary tree at or above the porta hepatis (Hassan & Balistreri, 2020). But some infants have a patent proximal portion of the extrahepatic duct or patency of the gallbladder, cystic duct, and common bile duct. Microscopic examination of the liver tissue reveals cholestasis with absent or diminished bile duct proliferation and fibrosis.

Clinical Manifestations

Many infants with BA are full term and appear healthy at birth. If **jaundice** persists beyond 2 weeks of age, especially if the direct (conjugated) serum bilirubin is elevated, the nurse should suspect BA. The urine may be dark, and the stools often become progressively acholic or gray, indicating absence of bile pigment. Hepatomegaly is present early in the course of the disease, and the liver is firm on palpation.

Diagnostic Evaluation

Early diagnosis is critical to the child with EHBA; the outcome in children surgically treated before 2 months of age is much better than in patients with delayed treatment. The diagnosis of BA is suspected on the basis of the history, physical findings, and laboratory studies. Laboratory tests include a CBC, bilirubin levels, and liver function studies. Additional laboratory analyses, including alpha-1 antitrypsin level, TORCH titers and other intrauterine infections (see Chapter 9), hepatitis serology, and urine cytomegalovirus, may be indicated to rule out other conditions that cause cholestasis and jaundice. An abdominal ultrasound is usually performed to identify potential causes of extrahepatic obstruction, such as a choledochal cyst. The patency of the extrahepatic biliary system is demonstrated by a nuclear scintiscan using technetium-99m iminodiacetic acid (^{99m}Tc IDA or HIDA; **HIDA scan**). If there is no evidence of radioactive material excreted into the duodenum, BA is the most probable diagnosis. Because the nuclear scan may take up to 5 days for the results, a percutaneous liver biopsy is probably the most useful method of diagnosing BA (Govindarajan, 2016). The definitive diagnosis of BA is further established during an

exploratory laparotomy and an intraoperative cholangiogram that demonstrates complete obstruction at some level of the biliary tree.

Therapeutic Management

Medical management of BA is primarily supportive. It includes nutritional support with infant formulas that contain medium-chain triglycerides and essential fatty acids. Supplementation with fat-soluble vitamins (A, D, E, and K); a multivitamin; and minerals, including iron, zinc, and selenium, is usually required. Aggressive nutritional support in the form of continuous gastrostomy feedings or TPN may be indicated for moderate to severe growth failure; the enteral solution should be low in sodium. Phenobarbital may be prescribed after hepatic portoenterostomy to stimulate bile flow, and ursodeoxycholic acid may be used to decrease cholestasis and the intense pruritus from jaundice. In cases of advanced liver dysfunction, management is the same as in infants with cirrhosis.

The primary surgical treatment of BA is hepatic portoenterostomy (**Kasai procedure**), in which a segment of intestine is anastomosed to the resected porta hepatis to attempt bile drainage. A Roux-en-Y jejunal limb is then anastomosed to the porta hepatis (a Y-shaped anastomosis performed to provide bile drainage without reflux). Complications after portoenterostomy include ascending cholangitis, cirrhosis, portal hypertension, and GI bleeding. Prophylactic antibiotics are given after the Kasai procedure to minimize the risk of ascending cholangitis. After the Kasai procedure approximately one-third of infants become jaundice free and regain normal liver function. Another one-third of infants demonstrate liver damage; however, they may be supported by medical and nutritional interventions. A final third require liver transplantation. Liver transplantation is required for children who cannot regain bile flow and for those with end-stage liver disease or severe portal hypertension. Complications after liver transplantation include obstruction and bile leaks at the biliary anastomosis, portal hypertension, hemorrhage, infection, and rejection. Immunosuppressive drugs are required after transplantation.

Prognosis

Untreated BA results in progressive cirrhosis and death in most children by 3 years of age (Govindarajan, 2016). The Kasai procedure improves the prognosis but is not a cure. There is only 20% survival in patients 20 years after the Kasai procedure and only 10% survival in patients 30 years after the procedure (Govindarajan, 2016).

Biliary drainage can often be achieved if the surgery is performed before the intrahepatic bile ducts are destroyed; the success rate is much higher, up to 90%, if surgery is performed in an infant younger than 2 months of age (Hassan & Balistreri, 2020). Long-term survival rates of 64% to 92% have been noted in children after portoenterostomy (Govindarajan, 2016). However, even with successful bile drainage, many children ultimately develop liver failure and require liver transplantation.

The advances in surgical techniques for liver transplantation and the development of immunosuppressive and antifungal drugs have significantly improved the success of transplantation. Surgical techniques and immunosuppression have contributed to survival rates of 83% to 91% in children who underwent transplant (Yanagi, Matsuura, Hayashida, et al., 2017). The major obstacle remains the shortage of suitable infant donors.

Liver disease progresses in infants with delayed diagnosis or in children in whom surgery has failed to provide adequate bile drainage. Cirrhosis and splenomegaly occur with hypoalbuminemia, ascites, and coagulopathy. Malabsorption of fat and fat-soluble vitamins and malnutrition result in severe growth failure. Retained bile salts and cholesterol further contribute to **pruritus** (itching) and xanthomas, often requiring the administration of **ursodeoxycholic acid**. The severity of pruritus intensifies as the jaundice progresses as the result of disease advancement.

Nursing Care Management

There are many important nursing interventions for the child with BA. The nurse should educate family members on all aspects of the treatment plan and the rationale for therapy. Immediately after a hepatic portoenterostomy, nursing care is similar to that after any major abdominal surgery. If an interrupted jejunal conduit has been performed, the family needs to learn how to care for the two stomas and how to refeed the bile after feedings. Teaching includes the proper administration of medications. Administration of nutritional therapy, including special formulas, vitamin and mineral supplements, gastrostomy feedings, or parenteral nutrition, is an essential nursing responsibility. Growth failure in such infants is common, and increased metabolic needs combined with ascites, pruritus, and nutritional anorexia constitute a challenge for care. The nurse teaches caregivers how to monitor and administer nutritional therapy in the home. Pruritus may be a significant problem that is addressed by drug therapy or comfort measures such as baths in colloidal oatmeal compounds and trimming of fingernails. The risk of complications of BA, such as cholangitis, portal hypertension, GI bleeding, and ascites, should be explained to the caregivers.

These children and their families require special psychosocial support. The uncertain prognosis, discomfort, and waiting for transplantation can produce considerable stress (see Cirrhosis, next). In addition, extended hospitalizations, as well as pharmacologic and nutritional therapy, can impose significant financial burdens on the family, as with any chronic condition. The expertise of a multidisciplinary health care team, including surgeons, gastroenterologists, pediatricians, nurses, nutritionists, pharmacists, child life specialists, and social workers, is often necessary. Parent support groups can be beneficial as well. The Children's Liver Association for Support Services (C.L.A.S.S.)[e] and the American Liver Foundation[f] provide educational materials, programs, and support systems for parents of children with liver disease.

CIRRHOSIS

Cirrhosis occurs as an end stage of many chronic liver diseases, including BA and chronic hepatitis. Infectious, autoimmune, toxic injury, and chronic diseases such as hemophilia and cystic fibrosis can cause severe liver damage. A cirrhotic liver is irreversibly damaged.

Pathophysiology

Cirrhosis occurs as a result of hepatocyte injury with necrosis, fibrosis, regeneration, and eventual degeneration. The diminished parenchymal cell mass causes regeneration of tissue with nodular areas of proliferating hepatocytes that stretch the surrounding connective tissue. Hepatocytes respond to injury with deposition of collagen that forms fibrous connective tissue. This scar tissue and nodular areas of regeneration impair the intrahepatic blood flow. Ongoing necrosis and self-perpetuation of this pathologic process are the result of cirrhosis.

Failure of hepatocellular function and portal hypertension occur and often lead to complications, including ascites, severe cholestasis, encephalopathy (hepatic coma), and GI bleeding.

[e]P.O. Box 186, Monaca, PA 15061; (724) 581-5527; http://www.class-kids.org.

[f]39 Broadway, Suite 2700, New York, NY 10006; 212-668-1000; http://www.liverfoundation.org.

Clinical Manifestations

Clinical manifestations of cirrhosis include jaundice, poor growth, anorexia, muscle weakness, and lethargy. Ascites, edema, GI bleeding, anemia, and abdominal pain may be present in children with impaired intrahepatic blood flow. Pulmonary function may be impaired because of pressure against the diaphragm due to hepatosplenomegaly and ascites. Dyspnea and cyanosis may occur, especially on exertion. Intrapulmonary arteriovenous shunts may develop, which can also cause hypoxemia. Spider angiomas and prominent blood vessels on the upper torso are often present.

Diagnostic Evaluation

The diagnosis of cirrhosis is based on (1) the history, especially in regard to prior liver disease, such as hepatitis; (2) physical examination, particularly hepatosplenomegaly; (3) laboratory evaluation, especially LFTs, such as bilirubin and transaminases, ammonia, albumin, cholesterol, and prothrombin time; and (4) liver biopsy for characteristic changes. Doppler ultrasonography of the liver and spleen is useful to confirm ascites, to evaluate the blood flow through the liver and spleen, and to determine the patency and size of the portal vein if liver transplantation is considered.

NURSING ALERT

The most common complication from percutaneous liver biopsy is internal bleeding. Vital signs and laboratory values, especially hematocrit, should be monitored for evidence of hemorrhage and shock.

Therapeutic Management

Unfortunately, there is no successful treatment to arrest the progression of cirrhosis. The goals of management include monitoring liver function and managing specific complications such as esophageal varices and malnutrition. Assessment of the child's degree of liver dysfunction is important so that the child can be evaluated for transplantation at the appropriate time.

Liver transplantation has improved the prognosis substantially for many children with cirrhosis. Pediatric liver transplantation is one of the most successful solid organ transplants with a 1-year survival rate of 83% to 91%, depending on the age at transplant (Yanagi et al., 2017). The policy governing the allocation of livers for transplantation by the United Network for Organ Sharing allows pediatric patients younger than 12 years of age, those with acute fulminant liver failure, or those with chronic liver disease to be placed at the top of the network's transplantation lists (United Network for Organ Sharing, 2017). Although this change has benefited many pediatric patients, the shortage of available donors for children continues to dictate transplantation decisions, and many children continue to die while waiting for a suitable donor.

Nutritional support is an important therapy for children with cirrhosis and malnutrition. Supplements of fat-soluble vitamins are often required, and mineral supplements may be indicated. In some instances aggressive nutritional support in the form of enteral feeding or PN may be necessary.

Esophageal and gastric varices can be a life-threatening complication of portal hypertension. Acute hemorrhage is managed with IV fluids; blood products; vitamin K, if needed to correct coagulopathy; vasopressin or somatostatin; and gastric lavage. If acute hemorrhage persists, the most common secondary approach is endoscopic sclerotherapy or endoscopic banding ligation (Choudhary, Puri, Saigal, et al., 2016). Balloon tamponade with a Sengstaken-Blakemore tube may be indicated for the unstable patient with acute hemorrhage (Choudhary et al., 2016). Ascites is managed by sodium and fluid restrictions and diuretics. Severe ascites with respiratory compromise is managed with albumin infusions or by paracentesis.

Although the full mechanism of hepatic encephalopathy is unknown, failure of the damaged liver to remove endogenous toxins, such as ammonia, plays a role. Treatment is directed at limiting the ammonia formation and absorption that occur in the bowel, especially with the drugs neomycin and lactulose. Because ammonia is formed in the bowel by the action of bacteria on ingested protein, neomycin reduces the number of intestinal bacteria so that less ammonia is produced. The fermentation of lactulose by colonic bacteria produces short-chain fatty acids, which lower the colonic pH, thereby inhibiting bacterial metabolism. This decreases the formation of ammonia from bacterial metabolism of protein.

Prognosis

The success of liver transplantation has revolutionized the approach to liver cirrhosis. Liver failure and cirrhosis are indications for transplantation. Careful monitoring of the child's condition and quality of life is necessary to evaluate the need for and timing of transplantation.

Nursing Care Management

Several factors influence nursing care of the child with cirrhosis, including the cause of the cirrhosis, the severity of complications, and the prognosis. The prognosis is often poor unless successful liver transplantation occurs. Therefore nursing care of this child is similar to that for any child with a life-threatening illness (see Chapter 19). Hospitalization is required when complications such as hemorrhage, severe malnutrition, or hepatic failure occur. Nursing assessments are directed at monitoring the child's condition, and interventions are aimed at treatment of specific complications. If liver transplantation is an option, the family needs support and assistance to cope (see Family-Centered Care box).

FAMILY-CENTERED CARE

End-Stage Liver Disease

In many cases the child with liver disease and the family must cope with an uncertain progression of the disease. The only hope for long-term survival may be liver transplantation. Transplantation can be successful, but the waiting period may be long because there are many more children in need of organs than there are donors. The procedure is expensive and is performed only at designated medical centers, which are often far from the family's home. The nurse should recognize the unique stresses of coping with end-stage liver disease and waiting for transplantation and should offer support and assistance to the family in coping with these stressors. The assistance of social workers and support from other parents can also be beneficial.

STRUCTURAL DEFECTS

Congenital defects of the GI tract can involve any portion from the mouth to the anus. Most are apparent at birth or shortly thereafter and are anomalies in which normal growth ceased at a crucial stage of embryonic development, leaving the structure in an embryonic form or only partially completed. The result may be atresia, malposition, nonclosure, or any number of variations.

Atresia is absence of a normal opening or normally patent lumen. Atresia at any point along the length of the GI tract creates an obstruction to the normal progress of nutrients and secretions. The most common anomalies requiring surgical intervention are atresias of the

esophagus, intestine, and anus. The congenital defects considered in this chapter include abnormalities of the lip, palate, trachea, esophagus, and anus.

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

Congenital esophageal atresia (EA) and tracheoesophageal fistula (TEF) are rare malformations that represent a failure of the esophagus to develop as a continuous passage and a failure of the trachea and esophagus to separate into distinct structures. These defects may occur as separate entities or in combination, and without early diagnosis and treatment they pose a serious threat to the infant's well-being.

The incidence of EA is estimated to be approximately 1 in 3000 neonates (Wu, Kuang, Lv, et al., 2017). There appears to be a slightly higher incidence in males, and the birth weight of most affected infants is significantly lower than average, with an unusually high incidence of preterm birth in infants with EA and a subsequent increase in mortality. A history of maternal polyhydramnios is common.

Approximately 50% of the cases of EA or TEF are a component of VATER or VACTERL association, acronyms used to describe associated anomalies (VATER for *V*ertebral defects, imperforate *A*nus, *T*racheo*e*sophageal fistula, and *R*adial and *R*enal dysplasia; and VACTERL for *V*ertebral, *A*nal, *C*ardiac, *T*racheal, *E*sophageal, *R*enal, and *L*imb) (Khan & Matta, 2020b). Cardiac anomalies may also occur with EA or TEF; therefore all patients should undergo a workup for associated anomalies.

Pathophysiology

The esophagus develops from the first segment of the embryonic gut. During the fourth and fifth weeks of gestation, the foregut normally lengthens and separates longitudinally. Each longitudinal portion fuses to form two parallel channels (the esophagus and the trachea) that are joined only at the larynx. Anomalies involving the trachea and esophagus are caused by defective separation, incomplete fusion of the tracheal folds after this separation, or altered cellular growth during embryonic development.

The most commonly encountered form of EA and TEF (80% to 90% of cases) is one in which the proximal esophageal segment terminates in a blind pouch and the distal segment is connected to the trachea or primary bronchus by a short fistula at or near the tracheal bifurcation (Fig. 22.6C). The second most common type (7% to 8%) consists of a blind pouch at each end, widely separated and with no communication to the trachea (Fig. 22.6A). An H-type EA refers to an otherwise normal trachea and esophagus connected by a fistula (4% to 5%) (Fig. 22.6E). Extremely rare anomalies involve a fistula from the trachea to the upper esophageal segment (0.8%) (Fig. 22.6B) or to both the upper and lower segments (0.7% to 6%) (Fig. 22.6D).

Clinical Manifestations

The presence of EA is suspected in a newborn with frothy saliva in the mouth and nose, drooling, choking, and coughing. Respiratory distress may be mild or significant, depending on the type of defect and the infant's gestational age. If fed, the infant may swallow normally but suddenly cough and gag, with return of fluid through the nose and mouth. The infant may become cyanotic and apneic because of aspiration of breast milk or saliva.

In the infant who has EA with a distal TEF (type C), the stomach becomes distended with air, and thoracic and abdominal compressions (especially during crying) cause the gastric contents to be regurgitated through the fistula and into the trachea, producing a chemical pneumonitis. When the upper segment of the esophagus opens directly into the trachea (types B and D), the infant is in danger of aspirating any swallowed material. Cyanosis or choking during feeding may be the only symptom of type H fistula (see Fig. 22.6E). The child with this type of EA may not manifest symptoms until later in life when he or she shows signs of chronic respiratory problems, recurrent pneumonia, and signs of GER (Khan & Matta, 2020b).

Diagnostic Evaluation

Although the diagnosis is established on the basis of clinical signs and symptoms, the exact type of anomaly is determined by radiographic studies. A radiopaque catheter is inserted into the hypopharynx and advanced until it encounters an obstruction. Chest radiographs are taken to ascertain esophageal patency or the presence and level of a blind pouch. Films that show air in the stomach indicate a connection between the trachea and the distal esophagus in types C, D, and E. Complete absence of air in the stomach is seen in types A and B. Occasionally, fistulas are not patent, which makes their presence more difficult to diagnose. A careful bronchoscopic examination may be performed in an attempt to visualize the fistula.

The presence of **polyhydramnios** (accumulation of 2000 ml of amniotic fluid) prenatally is a clue to the possibility of EA in the unborn infant, especially with defect type A, B, or C. With these types of EA or TEF, amniotic fluid normally swallowed by the fetus is unable to reach the GI tract to be absorbed and excreted by the kidneys. The result is an abnormal accumulation of amniotic fluid, or polyhydramnios.

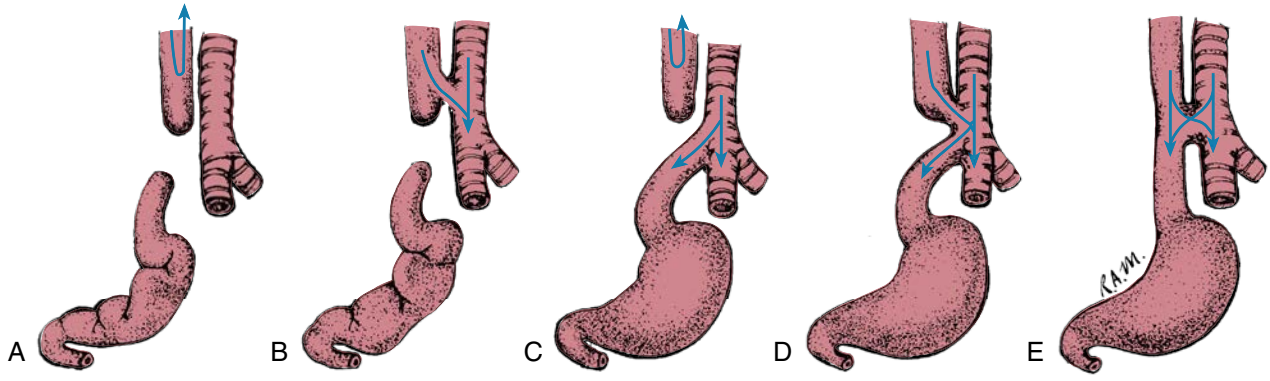

Fig. 22.6 A to E, Five most common types of esophageal atresia and tracheoesophageal fistula. (See text for discussion.)

Therapeutic Management

The treatment of EA and TEF includes maintenance of a patent airway, prevention of pneumonia, gastric or blind pouch decompression, supportive therapy, and surgical repair of the anomaly.

When EA with a TEF is suspected, the infant is immediately deprived of oral intake, IV fluids are initiated, and the infant is positioned to facilitate drainage of secretions and decrease the likelihood of aspiration. Accumulated secretions are suctioned frequently from the mouth and pharynx. A double-lumen catheter should be placed into the upper esophageal pouch and attached to intermittent or continuous low suction. The infant's head is kept upright to facilitate removal of fluid collected in the pouch and to prevent aspiration of gastric contents. Broad-spectrum antibiotic therapy is often instituted if there is a concern about aspiration of gastric contents.

Most malformations can be corrected surgically in one operation or in two or more staged procedures. The success depends on early diagnosis before complications occur and on the presence and severity of associated anomalies and illness factors, including preterm birth. With measures instituted to prevent aspiration pneumonia and to ensure adequate hydration and nutrition, surgery may be postponed to allow for more effective treatment of pneumonia and physiologic stabilization so that the infant can better withstand the complex surgery. The delay also offers an opportunity for further evaluation and assessment to rule out any associated anomalies and to optimize respiratory support.

Thoracoscopic repair of EA or TEF is being used successfully, thus negating the need for a thoracotomy and minimizing associated postoperative complications and morbidities (Khan & Matta, 2020b). The surgery consists of a thoracotomy with division and ligation of the TEF and an end-to-end or end-to-side anastomosis of the esophagus. A chest tube may be inserted to drain intrapleural air and fluid. For infants who are not stable enough to undergo definitive repair or those with a lengthy gap (>3 to 4 cm) between the proximal and distal esophagus, a staged operation is preferred that involves gastrostomy, ligation of the TEF, and constant drainage of the esophageal pouch (Khan & Matta, 2020b). A delayed esophageal anastomosis is usually attempted after several weeks to months.

A primary anastomosis may be impossible because of insufficient length of the two segments of esophagus. This occurs if the distance between the two segments is 3 to 4 cm (1.2 to 1.6 inches) (approximately three vertebral bodies) or greater; this is often referred to as *long-gap EA* (Khan & Matta, 2020b). In these cases an esophageal replacement procedure using a part of the colon or gastric tube interposition may be necessary to bridge the missing esophageal segment. Further surgical techniques may be performed later to facilitate esophageal lengthening.

Tracheomalacia may occur as a result of weakness in the tracheal wall that exists when a dilated proximal pouch compresses the trachea early in fetal life. It may also occur as a result of inadequate intratracheal pressure causing abnormal tracheal development. Clinical signs of tracheomalacia include barking cough, stridor, wheezing, recurrent respiratory tract infections, cyanosis, and sometimes apnea.

Prognosis

The survival rate is nearly 100% in otherwise healthy children. Most deaths are the result of extreme prematurity or other lethal associated anomalies.

Potential complications after the surgical repair of EA and TEF depend on the type of defect and surgical correction. Complications of repair include an anastomotic leak, strictures caused by tension or ischemia, esophageal motility disorders causing dysphagia, respiratory compromise, scoliosis, chest wall deformity, and GER. Anastomotic esophageal strictures may cause dysphagia, choking, and respiratory distress. The strictures are often treated with routine esophageal dilation. Feeding difficulties are often present for months or years after surgery, and the infant must be monitored closely to ensure adequate weight gain, growth, and development. In some cases laparoscopic fundoplication may be required. At times the infant must be fed via gastrostomy or jejunostomy to provide adequate caloric intake.

Nursing Care Management

Nursing responsibility for detection of this serious malformation begins immediately after birth. For the infant with the classic signs and symptoms of EA (see Nursing Alert) the major concern is the establishment of a patent airway and prevention of further respiratory compromise. Cyanosis is usually a result of laryngeal spasm caused by overflow of saliva into the larynx from the proximal esophageal pouch or aspiration; it normally resolves after removal of the secretions from the oropharynx by suctioning. The passage of a small-gauge orogastric (OG) feeding tube via the mouth into the stomach during the initial nursing physical assessment is helpful to determine the presence of EA or other obstructive defects.

! NURSING ALERT

Any infant who has an excessive amount of frothy saliva in the mouth or difficulty with secretions and unexplained episodes of apnea, cyanosis, or oxygen desaturation should be suspected of having an esophageal atresia (EA) or tracheoesophageal fistula (TEF) and referred immediately for medical evaluation.

Preoperative Care

The nurse carefully suctions the mouth and nasopharynx and places the infant in an optimum position to facilitate drainage and avoid aspiration. The most desirable position for a newborn who is suspected of having the typical EA with a TEF (e.g., type C) is supine (or sometimes prone) with the head elevated on an inclined plane of at least 30 degrees. This positioning minimizes the reflux of gastric secretions at the distal esophagus into the trachea and bronchi, especially when intra-abdominal pressure is elevated.

It is imperative to immediately remove any secretions that can be aspirated. Until surgery the blind pouch is kept empty by intermittent or continuous suction through an indwelling double-lumen catheter passed orally or nasally to the end of the pouch. In some cases a percutaneous gastrostomy tube is inserted and left open so that any air entering the stomach through the fistula can escape, thus minimizing the danger of gastric contents being regurgitated into the trachea. The gastrostomy tube is emptied by gravity drainage. Feedings through the gastrostomy tube and irrigations with fluid are contraindicated before surgery in the infant with a distal TEF.

Nursing interventions include respiratory assessment, airway management, thermoregulation, fluid and electrolyte management, and parenteral nutritional support.

Often the infant must be transferred to a hospital with a specialized care unit and pediatric surgical team. The nurse advises the parents of the infant's condition and provides them with necessary support and information.

Postoperative Care

Postoperative care for these infants is the same as for any high-risk newborn. Adequate thermoregulation is provided, the double-lumen NG catheter is attached to low-suction or gravity drainage, parenteral nutrition is provided, and the gastrostomy tube (if applicable)

is returned to gravity drainage until feedings are tolerated. If a thoracotomy is performed and a chest tube is inserted, attention to the appropriate function of the closed drainage system is imperative. Pain management in the postoperative period is important even if only a thoracoscopic approach is used. In the first 24 to 36 hours the nurse should provide pain management for the neonate just as for an adult undergoing a similar procedure (see Chapter 5, Pain in Neonates). Tracheal suction should only be done using a premeasured catheter and with extreme caution to avoid injury to the suture line.

If tolerated, gastrostomy feedings may be initiated and continued until the esophageal anastomosis is healed. Before oral feedings are initiated and the chest tube (if applicable) is removed, a contrast study or esophagram will verify the integrity of the esophageal anastomosis.

The nurse must carefully observe the initial attempt at oral feeding to make certain the infant is able to swallow without choking. Oral feedings are begun with sterile water, followed by frequent small feedings of breast milk or formula. Until the infant is able to take a sufficient amount by mouth, oral intake may need to be supplemented by bolus or continuous gastrostomy feedings. Ordinarily infants are not discharged until they can take oral fluids well. The gastrostomy tube may be removed before discharge or maintained for supplemental feedings at home.

Special Problems

Upper respiratory tract complications are a threat to life in both the preoperative and the postoperative periods. In addition to pneumonia, the infants are in constant danger of respiratory distress resulting from atelectasis, pneumothorax, and laryngeal edema. Any persistent respiratory difficulty after removal of secretions must be reported to the surgeon immediately. The infant should be monitored for anastomotic leaks and signs of infection such as purulent chest tube drainage, an increased white blood cell count, and temperature instability.

For the infant who requires esophageal replacement, nonnutritive sucking should be provided with a pacifier. Infants who are on NPO status for an extended period and have not received oral stimulation frequently have difficulty eating by mouth after corrective surgery and may develop oral hypersensitivity and feeding aversion. They require patient, firm guidance in learning the techniques of taking food into the mouth and swallowing after repair. A referral to a multidisciplinary feeding behavior team may be necessary.

One of the difficulties in TEF is the immediate transfer of the sick infant to the intensive care unit and sometimes lengthy hospitalization. Parent-infant bonding is facilitated by encouraging parents to visit the infant, participate in his or her care when appropriate, and express their feelings regarding the infant's condition. The nurse in the intensive care unit should assume responsibility for ensuring that the parents are fully informed of the infant's progress.

Family Support, Discharge Planning, and Home Care

Some infants with EA or TEF may require periodic esophageal dilations on an outpatient basis. Discharge education should include instructions about feeding techniques in the child with a repaired esophagus, including a semiupright feeding position, small feedings, and observation for adequacy of swallowing (e.g., regurgitation, cyanosis, choking). Tracheomalacia is often a complication; parents are educated about the signs and symptoms of this condition, which include a barking cough, stridor, wheezing, recurrent respiratory tract infections, cyanosis, and sometimes apnea. GER may also occur when feedings resume and may contribute to reactive airway disease with wheezing and labored respirations as the prominent clinical manifestations. Problems with thriving and gaining weight may occur in the first 5 years of life in the child with EA or TEF, especially if the infant is born preterm. The nurse should be alert to the achievement of developmental milestones that indicate a need for early intervention and multidisciplinary referral.

Fig. 22.7 Newborn with umbilical hernia. (From Zitelli, B. J., & Davis, H. W. [2007]. *Atlas of pediatric physical diagnosis* [5th ed.]. St. Louis, MO: Mosby.)

Preparing parents for discharge of their infant involves teaching the techniques that will be continued at home. The parents learn signs of respiratory difficulty and of esophageal stricture (e.g., poor feeding, choking, dysphagia, drooling, regurgitating undigested food) and GER.

Parents must be aware of feeding restrictions. Remind parents that it is particularly important to guard against the infant swallowing foreign objects. They should cut solid food into small pieces, teach the child to chew thoroughly, give frequent sips of liquid to help swallow food, and avoid foods such as whole hot dogs or large pieces of meat that may become lodged in the esophagus. (See Chapter 10.)

Discharge planning should include attainment of needed equipment and home nursing services to assist with ongoing assessment of the child and continuity of care.

HERNIAS

A **hernia** is a protrusion of a portion of an organ or organs through an abnormal opening. The danger of herniation arises when the protrusion is constricted, impairing circulation, or when the protrusion interferes with the function or development of other structures. The herniations discussed in this section are those that protrude through the diaphragm, the abdominal wall, or the inguinal canal.

Umbilical Hernia

The **umbilical hernia** is a common hernia observed in infants. It occurs when fusion of the umbilical ring is incomplete at the point where the umbilical vessels exit the abdominal wall. It affects low-birth-weight and preterm infants more often than full-term infants. An umbilical hernia usually is an isolated defect, but it may be associated with other congenital anomalies, such as Down syndrome (trisomy 21) and trisomies 13 and 18. The size of the defect is variable, and the protrusion is more prominent when the infant is crying (Fig. 22.7). **Incarceration**, in which the hernia is constricted and cannot be reduced manually, is rare. Hernias usually resolve spontaneously by 3 to 5 years of age. If the hernia persists beyond this age, it is usually surgically corrected on an elective basis.

Nursing Care Management

The appearance of an umbilical hernia may be disconcerting to parents. Therefore they need reassurance that the defect usually is not harmful. Taping or strapping the abdomen to flatten the protrusion does not aid in resolution and can produce skin irritation.

Nursing care of the child with an umbilical hernia repair is essentially the same as that for other minor GI surgery. The procedure may be performed on an outpatient basis. Observe the child for complications related to a hematoma or infection. The child may resume a normal diet and activity postoperatively; however, strenuous activity or play is restricted for 2 to 3 weeks.

Inguinal Hernia

Inguinal hernias account for approximately 80% of all childhood hernias and occur more frequently in boys than in girls (approximately 6:1). An incidence of 0.8% to 5% is reported in term newborns and of up to 30% is reported in low-birth-weight and preterm infants (Abdulhai, Glenn, & Ponsky, 2017).

Pathophysiology

Inguinal hernia comes from persistence of all or part of the processus vaginalis, the tube of peritoneum that precedes the testicle through the inguinal canal into the scrotum (in boys) or the round ligament into the labia (in girls), during the eighth month of gestation. After descent of the testicle, the proximal portion of the processus vaginalis normally atrophies and closes, whereas the distal portion forms the tunica vaginalis, which envelops the testicle in the scrotum. When the upper portion fails to atrophy, the abdominal fluid or an abdominal structure (e.g., bowel, ovary, fallopian tubes) can be forced into it, creating a palpable bulge or mass. The persistent sac may end at any point along the inguinal canal; it may stop at the inguinal ring or extend all the way into the scrotum or labia.

Clinical Manifestations

This common defect is usually asymptomatic unless the abdominal contents are forced into the patent sac. Most often it appears as a painless inguinal swelling that varies in size. It disappears during periods of rest or is reducible by gentle compression. It appears when the infant cries or strains or when the older child strains, coughs, or stands for a long time. The defect can be palpated as a thickening of the cord in the groin, and the silk glove sign can be elicited by rubbing together the sides of the empty hernial sac.

Sometimes the herniated loop of intestine becomes partially obstructed, producing variable symptoms that may include irritability, tenderness, anorexia, abdominal distention, and difficulty defecating. Occasionally the loop of bowel becomes **incarcerated** (irreducible) or strangulated (loss of blood supply), with symptoms of complete intestinal obstruction that, left untreated, will progress to strangulation and necrotic bowel. Incarceration occurs more often in infants younger than 12 months of age. The incidence of incarceration is reported to be 3% to 16% but as high as 30% in premature infants (Abdulhai et al., 2017).

Therapeutic Management

The treatment for hernias is prompt, elective surgical repair in the healthy child as soon as the defect is diagnosed. However, an incarcerated hernia requires emergent surgical care. Because there was believed to be a significant incidence of bilateral involvement, many surgeons advocated exploration of both sides; however, this practice has gained disfavor due to complications occurring with open exploration (Aiken, 2020b). Laparoscopic exploration of the contralateral side may be performed without risk of injury to the vas deferens (Aiken, 2020b).

Nursing Care Management

Prompt recognition of an inguinal hernia is imperative. The hernia may first be noticed when the infant is crying or straining to stool (Valsalva maneuver). Nursing care of the infant or child with an inguinal hernia involves preoperative preparation of the infant and appropriate explanation to the parents of the child's expected postoperative status. Most hernia repairs can be managed on an outpatient basis. The preterm infant usually has hernia repair several days before discharge. The former preterm infant diagnosed after discharge is admitted on the day of surgery and, after repair, is observed for 12 to 24 hours for apnea and bradycardia.

Postoperatively the incision is kept clean and dry, and the infant's pain is managed appropriately. In infants and small children who are not yet toilet trained, the wound may be covered with an occlusive dressing or left without a dressing. Changing diapers as soon as they become damp helps reduce the chance of irritation or infection of the incision.

No restrictions are placed on activity for the infant or toddler, but older children are cautioned against lifting, pushing, wrestling or fighting, bicycle riding, and participation in sporting events for about 3 weeks.

If surgery is postponed, parents need to learn the signs of incarcerated hernia, simple measures to reduce it (e.g., a warm bath, avoidance of upright positioning, and comfort measures to reduce crying), and where to call for assistance if relief is not obtained in a reasonably short time.

Femoral Hernia

Femoral hernias are rare in children, with a reported incidence of less than 1% (Abdulhai et al., 2017). The incidence is higher in girls than in boys. The hernia may manifest as a recurrent hernia after inguinal hernia repair. Initial symptoms are swelling in the groin area associated with severe abdominal pain and cramping. Treatment and management are the same as for inguinal hernia. Incarceration and strangulation are frequent complications.

ANORECTAL MALFORMATIONS

Anorectal malformations (ARMs) are among the more common congenital malformations caused by abnormal development, with an incidence of approximately 1 in 3000 births (Shanti, 2020). These malformations may range from simple imperforate anus to other associated complex anomalies of genitourinary (GU) and pelvic organs, which may require extensive treatment for fecal, urinary, and sexual function. Anorectal malformations may occur in isolation or as a part of the VACTERL association (see earlier in the chapter). These anomalies are classified according to the newborn's gender and abnormal anatomic features, including GU defects (Box 22.10). More than half of all ARMs are associated with other anomalies.

Rectal atresia and stenosis occur when the anal opening appears normal, there is a midline intergluteal groove, and usually no fistula exists between the rectum and urinary tract. **Rectal atresia** is a complete obstruction (inability to pass stool) and requires immediate surgical intervention. **Rectal stenosis** may not become apparent until later in infancy when the infant has a history of difficult stooling, abdominal distention, and ribbonlike stools. A **persistent cloaca** is a complex ARM in which the rectum, vagina, and urethra drain into a common channel opening into the perineum (Fig. 22.8A).

Imperforate anus includes several forms of malformation without an obvious opening (Fig. 22.8). Frequently a fistula (an abnormal communication) leads from the distal rectum to the perineum or GU system (see Fig. 22.8B and C). The fistula may be evidenced when meconium is evacuated through the vaginal opening, the perineum

below the vagina, the male urethra, or the perineum under the scrotum. The presence of meconium on the perineum does not indicate anal patency. A fistula may not be apparent at birth, but as peristalsis increases, meconium is forced through the fistula into the urethra or onto the newborn's perineum.

Pathophysiology

During embryonic development the cloaca becomes the common channel for the developing urinary, genital, and rectal systems. The cloaca is divided at the sixth week of gestation into an anterior urogenital sinus and a posterior intestinal channel by the urorectal septum. After the lateral folds join the urorectal septum, separation of the urinary and rectal segments takes place. Further differentiation results in the anterior GU system and the posterior anorectal channel. An interruption of this development leads to incomplete migration of the rectum to its normal perineal position.

Diagnostic Evaluation

The diagnosis of an ARM is based on the physical finding of an absent anal opening. Other symptoms may include abdominal distention, vomiting, absence of meconium passage, or presence of meconium in the urine. Additional physical findings with an ARM are a flat perineum and the absence of a midline intergluteal groove. The appearance of the perineum alone does not accurately predict the extent of the defect and associated anomalies. GU and spinal-vertebral anomalies associated with ARMs should be considered when an anomaly is noted. EA with or without TEF, cardiac defects, and spinal or vertebral anomalies may occur in association with ARMs, and the infant should be carefully evaluated for the presence of these and other anomalies. Although rare, some ARMs may not be diagnosed until later in infancy or early childhood.

A perineal fistula (see Box 22.10) may be diagnosed by clinical observation. The presence of a prominent anal dimple and a band of skin tissue commonly known as a bucket handle is indicative of a perineal fistula. Abdominal and pelvic ultrasonography is performed to further evaluate the infant's anatomic malformation. An IV pyelogram and a voiding cystourethrogram are performed to evaluate associated anomalies involving the urinary tract. Other diagnostic examinations that may be performed include pelvic magnetic resonance imaging, radiography, ultrasound, and fluoroscopic examination of pelvic anatomic contents and lower spinal anatomy.

BOX 22.10 Classification of Anorectal Malformations

Male Defects
Perineal fistula
Rectourethral bulbar fistula
Rectourethral prostatic fistula
Rectovesicular (bladder neck) fistula
Imperforate anus without fistula
Rectal atresia

Female Defects
Perineal fistula
Rectovestibular fistula
Imperforate anus without fistula
Rectal atresia and stenosis
Cloaca

From Gangopadhyay, A. N., & Pandey, V. (2015). Anorectal malformations. *Journal of Indian Association of Pediatric Surgeons, 20*(1), 10–15.

Therapeutic Management

The primary management of ARMs is surgical. Once the defect is identified, take steps to rule out associated life-threatening defects, which need immediate surgical intervention. Provided no immediate life-threatening problems exist, the newborn is stabilized and kept NPO for further evaluation. IV fluids are provided to maintain glucose and fluid and electrolyte balance. Current recommendation is that surgery be delayed at least 24 hours to properly evaluate for the presence of a fistula and possibly other anomalies (Shanti, 2020).

The surgical treatment of ARMs varies according to the defect but usually involves one, or possibly a combination of several, of the following procedures: anoplasty, colostomy, **posterior sagittal anorectoplasty (PSARP)** or other pull-through with colostomy, and colostomy (take-down) closure. The Nursing Care Management discussion below outlines some aspects of preoperative and postoperative care.

A primary laparoscopic repair (without colostomy) of some ARMs is being used successfully for the treatment of ARMs. This minimizes surgical risks, associated morbidity, and postoperative pain management with no significant risk for rectal prolapse, anal stenosis, or anorectal manometry (Han, Xia, Guo, et al., 2017).

Prognosis

The long-term prognosis depends on such factors as the type of defect, anatomy of the sacrum and vertebrae, quality of muscles, and success of the surgery.

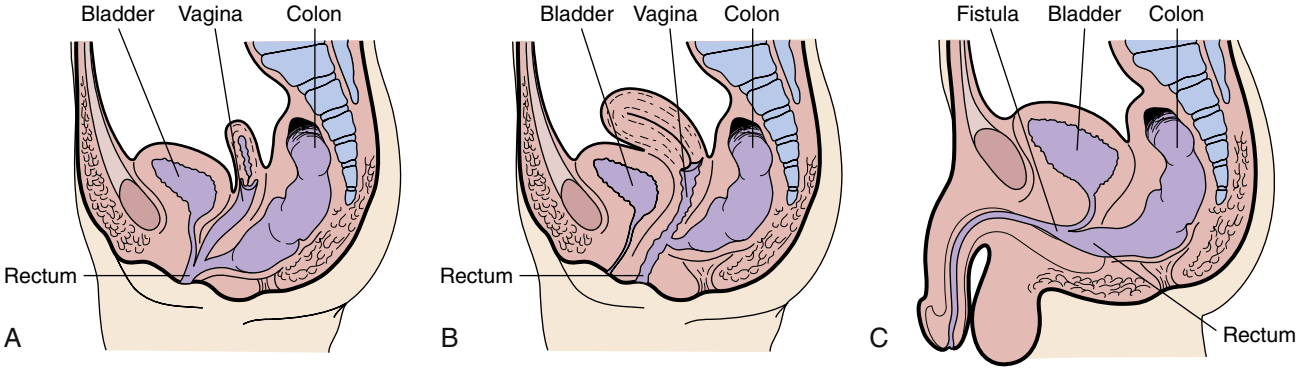

Fig. 22.8 Anorectal malformations. **A,** Typical cloaca (female). **B,** Low rectovaginal fistula (female). **C,** Rectourethral bulbar fistula (male).

The presence of a flat or "rocker" bottom and no midline groove usually carries a poor prognosis for bowel continence because of associated neurologic, muscular, and anatomic problems. When the internal anal sphincter is absent, incontinence is a common long-term problem. These children may achieve socially acceptable continence over time with the aid of a bowel management program. Other potential complications after surgical treatment of anorectal anomalies include strictures, recurrent rectourinary fistula, mucosal prolapse, and constipation. Long-term outcomes in adults with surgically treated ARM are reported to be positive, depending on the type and severity of the defect as well as associated anomalies (Gangopadhyay & Pandey, 2015). Constipation, fecal soiling, and fecal incontinence are problems that such children and adults must cope with on a regular basis, but the functional outcome is reported to be excellent (Gangopadhyay & Pandey, 2015).

Nursing Care Management

The first nursing responsibility is assisting in identification of ARMs. A newborn who does not pass stool within 24 hours after birth or has meconium that appears at a location other than the anal opening requires further assessment. Preoperative care includes diagnostic evaluation, GI decompression, bowel preparation, and IV fluids.

For the newborn with a perineal fistula, an **anoplasty** is performed, which involves moving the fistula opening to the center of the sphincter and enlarging the rectal opening. Postoperative nursing care after anoplasty is primarily directed toward healing the surgical site without other complications. A program of anal dilations is usually initiated when the child returns for the 2-week checkup. Feedings are started soon after surgical repair, and breastfeeding is encouraged because it causes less constipation.

In neonates with anomalies such as **cloaca** (female), rectourethral prostatic fistula (male), and vestibular fistula (female), a descending colostomy is performed to allow fecal elimination and avoid fecal contamination of the distal imperforate section and subsequent urinary tract infection in infants with urorectal fistulas. With a colostomy, postoperative nursing care is directed toward maintaining appropriate skin care at the stoma sites (both distal and proximal), managing postoperative pain, and administering IV fluids and antibiotics. Postoperative NG decompression may be required with laparotomy, and nursing care focuses on maintenance of appropriate drainage (see Chapter 20 for colostomy care).

The PSARP is a common surgical procedure for the repair of ARMs in infants approximately 1 to 2 months after the initial colostomy. Preoperative PSARP care often involves irrigation of the distal stoma to prevent fecal contamination of the operative site. During this time parents must be given accurate yet simple information regarding the infant's appearance postoperatively and expectations as to their level of involvement in the child's care.

In the PSARP procedure the repair is made via a posterior midline sacral approach to dissect the different muscle groups involved without damaging strategic innervation of pelvic structures so that optimum postoperative bowel continence is achieved. A laparotomy may be required if the rectum is unidentifiable by the posterior approach. Additional management after successful repair involves a program of anal dilations, colostomy closure, and a bowel management program.

Parents are instructed in perineal and wound care or care of the colostomy as needed. Anal dilations may be necessary for some infants. Parents should observe stooling patterns and observe for signs of anal stricture or complications. Information on dietary modifications and administration of medications is included in counseling. Nurses have a vital role in helping families of a child with ARMs provide optimum care so bowel management is successful and quality of life enhanced for the child and family.

Family Support, Discharge Planning, and Home Care

Long-term follow-up care is essential for children with complex malformations. When a colostomy is performed, parents need reassurance regarding the child's appearance and their ability to care for the child at home. With much patience and reassurance, parents learn how to provide optimum care of the skin and the appliance, while maintaining an appropriate bond with the child.

After the definitive pull-through procedure, toilet training may be delayed. Complete continence is seldom achieved at the usual age of 2 to 3 years. Bowel habit training, bowel management irrigation programs, diet modification, and administration of stool softeners or fiber help children improve bowel function and social continence. Some children never achieve bowel continence and must rely on daily bowel irrigations. Support and reassurance during the slow progression to normal, socially acceptable function are essential.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A 16-month-old has a history of diarrhea for 3 days with poor oral intake. He received intravenous fluids, has tolerated some oral fluids in the emergency department, and is being discharged home. **For each home care instruction, use an X to indicate whether it was Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Home Care Instruction	Indicated	Contraindicated	Non-Essential
Keep on clear liquids and toast for 24 hours		X	
Offer a regular diet as child's appetite warrants	X		
Sterilize the infant's eating utensils before each meal			X
Give a BRAT diet (bananas, rice, applesauce, and toast) for 24 hours, then a soft diet as tolerated		X	
Find out what the infant's favorite food is			X
Give chicken or beef broth for 24 hours, then resume a soft diet		X	

2. A 3-year-old has a history of chronic diarrhea, lack of weight gain, and abdominal distension. He has a positive serological blood test and small intestine biopsy confirming Celiac Disease. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**

Because children with celiac disease must limit their intake of products containing_____1_____ in many food items, one being_____2_____, they are at most risk for_____3_____ as well as a number of other deficiencies.

Options for 1	Options for 2	Options for 3
Sugar	Yogurt	Iron-deficiency anemia
Meat	Corn on the cob	Bleeding
Gluten	Lettuce and tomato salad	Asthma
Salt	Toast	Hepatitis
Milk	Baked chicken	Pyloric stenosis
Eggs	Carrot sticks	Hoarseness and difficulty swallowing

3. A preterm infant who had surgery for necrotizing enterocolitis is now 6 months old and has short bowel syndrome. He is unable to absorb most nutrients taken by mouth and is totally dependent on parenteral nutrition, which he receives via a central venous catheter. The clinic nurse following the care for this infant is aware that he should be closely observed for the development of which complications? **Select all that apply.**

A. Cholestasis
B. Constipation
C. Failure to thrive
D. Chronic diarrhea
E. Intestinal stricture
F. Intestinal failure
G. Hepatic dysfunction
H. Gastroesophageal reflux

4. A 3 month old infant who has not receive her immunizations is seen in the clinic following concerns that there was a Hepatitis outbreak in the day care where the infant was enrolled. The day care notified the mother that other children who were not immunized were also enrolled and that she should take her infant to the clinic. **Choose the most likely options for the information missing from the statements below by selecting from the list of options provided.**

The nurse recognizes that the principle mode of transmission for_____1_____ is by the_____2_____ route. The_____3_____, an inactivated vaccine, is approved for children 12-23 months of age and given in_____4_____ doses.

Options for 1	Options for 2	Options for 3	Options for 4
Hepatitis A	parenteral	HAV	Four
Hepatitis C	fecal-oral	HCV	Two
Hepatitis B	contaminated water	polio vaccine	Three
Hepatitis D	perinatal	HBV	One

CONCEPTS

- Perfusion
- Hemodynamics

CARDIOVASCULAR DYSFUNCTION

Cardiovascular disorders in children are divided into two major groups: congenital heart disease and acquired heart disorders. **Congenital heart disease (CHD)** includes primarily anatomic abnormalities present at birth that result in abnormal cardiac function. The clinical consequences of congenital heart defects fall into two broad categories: heart failure (HF) and hypoxemia. **Acquired cardiac disorders** are disease processes or abnormalities that occur after birth and can be seen in the normal heart or in the presence of congenital heart defects. They result from various factors, including infection, autoimmune responses, environmental factors, and familial tendencies. The pathophysiology review found in Fig. 23.1 describes the flow of blood through the heart.

HISTORY AND PHYSICAL EXAMINATION

Taking an accurate health history is an important first step in assessing an infant or child for possible heart disease. Parents may have specific concerns, such as an infant with poor feeding or fast breathing, or a 7-year-old who can no longer keep up with friends on the soccer field. Others may not realize that their child has a medical problem because their baby has always been pale and fussy.

Asking details about the mother's health history, pregnancy, and birth history is important in assessing infants. Mothers with chronic health conditions, such as diabetes or lupus, are more likely to have infants with heart disease. Some medications, such as phenytoin (Dilantin), are teratogenic to fetuses. Maternal alcohol use or illicit drug use increases the risk of congenital heart defects. Exposures to infections, such as rubella, early in pregnancy may result in congenital anomalies. Infants with low birth weight resulting from intrauterine growth restriction are more likely to have congenital anomalies. High-birth-weight infants have an increased incidence of heart disease.

A detailed family history is also important. There is an increased incidence of congenital cardiac defects if either parent or a sibling has a heart defect. Some diseases, such as Marfan syndrome, and some cardiomyopathies are hereditary. A family history of frequent fetal loss, sudden infant death, and sudden death in adults may indicate heart disease. Congenital heart defects are seen in many syndromes such as Down and Turner syndromes.

The physical assessment of suspected cardiac disease begins with observation of general appearance and then proceeds with more specific observations. The following lists are supplementary to the general assessment techniques described for physical examination of the chest and heart in Chapter 4.

Inspection

Nutritional state: Failure to thrive or poor weight gain is associated with heart disease.
Color: Cyanosis is a common feature of CHD, and pallor is associated with poor perfusion.
Chest deformities: An enlarged heart sometimes distorts the chest configuration.
Unusual pulsations: Visible pulsations of the neck veins are seen in some patients.
Respiratory excursion: This refers to the ease or difficulty of respiration (e.g., tachypnea, dyspnea, expiratory grunt).
Clubbing of fingers: This is associated with cyanosis.

Palpation and Percussion

Chest: These maneuvers help discern heart size and other characteristics (e.g., thrills) associated with heart disease.
Abdomen: Hepatomegaly or splenomegaly may be evident.
Peripheral pulses: Rate, regularity, and amplitude (strength) may reveal discrepancies.

Auscultation

Heart rate and rhythm: Listen for fast heart rates (tachycardia), slow heart rates (bradycardia), and irregular rhythms.
Character of heart sounds: Listen for distinct or muffled sounds, murmurs, and additional heart sounds.

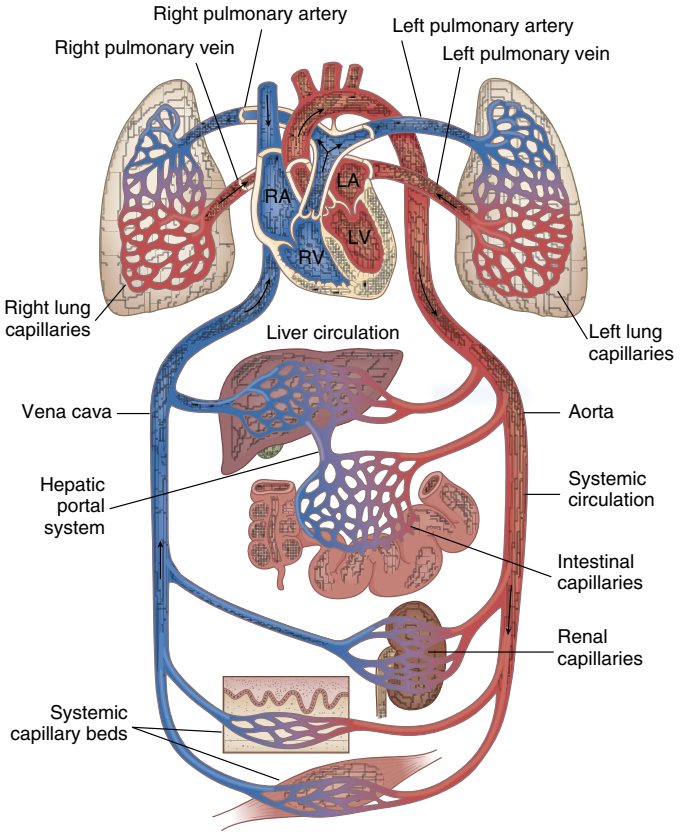

Fig. 23.1 Diagram showing serially connected pulmonary and systemic circulatory systems and how to trace the flow of blood. Right heart chambers propel unoxygenated blood through the pulmonary circulation, and the left side of the heart propels oxygenated blood through the systemic circulation. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (From McCance, K. L., & Huether, S. E. [2019]. *Pathophysiology: The biological basis for disease in adults and children* [8th ed.]. St. Louis, MO: Mosby.)

Diagnostic Evaluation

A variety of invasive and noninvasive tests may be used in the diagnosis of heart disease (Table 23.1). Some of the more common diagnostic tools that require nursing assessment and intervention are described in the following sections.

Electrocardiogram

Electrocardiography (ECG) measures the electrical activity of the heart; provides a graphic display; and supplies information on heart rate and rhythm, abnormal rhythms or conduction, ischemic changes, and other information. A standard ECG uses 12 leads to get different views of the heart. An ECG takes about 15 minutes to perform; infants and young children may be fussy with lead placement.

Bedside cardiac monitoring with a single lead of the ECG is commonly used in pediatrics, especially in the care of children with heart disease. An alarm can be set with parameters for individual patient requirements and will sound if the heart rate is above or below the set parameters. Gel foam electrodes are commonly used and placed on the right side of the chest (above the level of the heart) and on the left side of the chest, and a ground electrode is placed on the abdomen. Bedside monitors are an adjunct to patient care and should never be substituted for direct assessment and auscultation of heart sounds. The nurse should assess the patient, not the monitor.

TABLE 23.1 Procedures for Cardiac Diagnosis

Procedure	Description
Chest radiography (x-ray)	Provides information on heart size and pulmonary blood flow patterns
Electrocardiography (ECG)	Graphic measure of electrical activity of heart
Holter monitor	24-hour continuous ECG recording used to assess dysrhythmias
Echocardiography	Use of high-frequency sound waves obtained by a transducer to produce an image of cardiac structures
Transthoracic	Done with transducer on chest
M-mode	One-dimensional graphic view used to estimate ventricular size and function
Two-dimensional	Real-time, cross-sectional views of heart used to identify cardiac structures and cardiac anatomy
Doppler	Shows blood flow patterns and pressure gradients across structures
Fetal	Imaging fetal heart in utero
Transesophageal echocardiography (TEE)	Transducer placed in esophagus behind heart to obtain images of posterior heart structures or in patients with poor images from chest approach
Cardiac catheterization	Imaging study using radiopaque catheters placed in a peripheral blood vessel and advanced into heart to measure pressures and oxygen levels in heart chambers and visualize heart structures and blood flow patterns
Hemodynamics	Measurements of pressures and oxygen saturations in heart chambers
Angiography	Use of contrast material to illuminate heart structures and blood flow patterns
Biopsy	Use of special catheter to remove tiny samples of heart muscle for microscopic evaluation; used in assessing infection, inflammation, or muscle dysfunction disorders; also to evaluate for rejection after heart transplant
Electrophysiology study (EPS)	Special catheters with electrodes inserted to record electrical activity from within the heart; used to diagnose rhythm disturbances
Exercise stress test	Monitoring of heart rate, BP, ECG, and oxygen consumption at rest and during progressive exercise on a treadmill or bicycle
Cardiac MRI	Noninvasive imaging technique; used in evaluation of vascular anatomy outside of the heart (e.g., COA, vascular rings), estimates of ventricular mass and volume

BP, Blood pressure; *COA,* coarctation of the aorta; *MRI,* magnetic resonance imaging.

! NURSING ALERT

Electrodes for cardiac monitoring are often color coded: white for right, green (or red) for ground, and black for left. Always check to ensure that these colors are placed correctly.

Echocardiography

Echocardiography involves the use of ultra-high-frequency sound waves to produce an image of the heart's structure. A transducer placed directly on the chest wall delivers repetitive pulses of ultrasound and processes the returned signals (echoes). It is the most frequently used test for describing cardiac anatomy and detecting cardiac dysfunction in children. In many cases, a prenatal diagnosis of CHD can be made by fetal echocardiography.

Although the test is noninvasive, painless, and associated with no known side effects, it can be stressful for children. A full echocardiogram can take an hour, and the child must lie quietly in the standard echocardiographic positions. Therefore infants and young children may need conscious sedation or anesthesia, and older children benefit from preparation for the test. The distraction of a video or movie is often helpful.

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (MRI) uses magnetic field and pulses of radio wave energy to produce real time three-dimensional (3D) images of the intracardiac and extracardiac vascular structures and assessments of ventricular function. It is often used in older children and adolescents when more quantitative information (i.e., volume of ventricular chambers, measurement of valve regurgitation) is needed that cannot be obtained by echocardiography or if echocardiography imaging windows have become limited. The use of MRI has rapidly expanded in the last decade. Although MRI is noninvasive, it can take an hour or more, and patients must lie still inside the scanner. Children under the age of 7 years, patients with claustrophobia, and those with developmental delays or other issues that limit cooperation will require anesthesia, deep sedation, or conscious sedation (depending on institutional preferences). Because the MRI is a magnet, patients with metal implants such as pacemakers, automatic implantable cardioverter defibrillators (AICDs), or cochlear implants cannot be scanned, and all patients are carefully screened for safety compatibility.

Cardiac Catheterization

Cardiac catheterization is an invasive diagnostic procedure in which a radiopaque catheter is introduced through a large-bore needle into a peripheral vessel (usually the femoral artery or vein in children) and then guided into the heart with the aid of fluoroscopy. After the tip of the catheter is within a heart chamber, measurements of pressures and saturations in the different cardiac chambers are obtained. Contrast material is injected, and images are taken of the circulation inside the heart (**angiography**). Types of cardiac catheterizations include:

Diagnostic catheterizations: These studies are used to diagnose congenital cardiac defects, particularly in symptomatic infants and before surgical repair. They can include right-sided catheterizations, in which the catheter is introduced through a vein (usually the femoral vein) and threaded to the right atrium, and left-sided catheterizations, in which the catheter is threaded through an artery into the aorta and into the heart.

Interventional catheterizations (therapeutic catheterizations): A balloon catheter or other device is used to alter the cardiac anatomy. Examples include dilating stenotic valves or vessels or closing abnormal connections (Table 23.2).

Electrophysiology studies: Catheters with tiny electrodes that record the impulses of the heart directly from the conduction system are used to evaluate dysrhythmias. Other catheters can destroy abnormal pathways that cause rapid rhythms (called ablation).

TABLE 23.2 Current Interventional Cardiac Catheterization Procedures in Children

Intervention	Diagnosis
Balloon atrial septostomy	Transposition of the great vessels Other complex defects
Balloon dilation	Valvar pulmonary stenosis Branch pulmonary artery stenosis Congenital valvar aortic stenosis Rheumatic mitral stenosis Recurrent coarctation of the aorta
Stent placement	Pulmonary artery stenosis Coarctation of the aorta in adolescents
Coil occlusion	Small patent ductus arteriosus Collateral vessels in single-ventricle patients
Transcatheter device closure	Some atrial septal defects (secundum type) Larger patent ductus arteriosus Fenestrations following Fontan procedures
Transcatheter pulmonary valve replacement	Incompetent pulmonary valves following surgery to repair right ventricular outflow tract
Radiofrequency (RF) ablation	Some tachydysrhythmias

Nursing Care Management

Cardiac catheterization has become a routine procedure and may be done on an outpatient basis. Catheterization is not without risks, however, especially in neonates and seriously ill infants and children. Patients are exposed to radiation, general anesthesia for many cases, and contrast materials and medications that can cause allergic reactions or renal insufficiency. Possible complications include acute hemorrhage from the entry site requiring transfusion (more likely with interventional procedures because larger catheters are used), loss of a pulse due to vascular injury in the catheterized extremity (usually transient, resulting from a clot, hematoma, or intimal tear), and transient dysrhythmias (generally catheter induced). Serious complications such as valve damage, perforation of the heart, central nervous system (CNS) injury, stroke, or death is rare (Feltes, Bacha, Beekman, et al., 2011).

Preprocedural Care

A complete nursing assessment is necessary to ensure a safe procedure with minimum complications. This assessment should include accurate height (essential for correct catheter selection) and weight. Obtaining a history of allergic reactions is important because some of the contrast agents are iodine based. Specific attention to signs and symptoms of infection is crucial. Severe diaper rash may be a reason to cancel the procedure if femoral access is required. Because assessment of pedal pulses is important after catheterization, the nurse should assess and mark the pulses (dorsalis pedis, posterior tibial) before the child goes to the catheterization room. Baseline oxygen saturation using pulse oximetry in children with cyanosis is also recorded.

Preparing the child and family for the procedure is the joint responsibility of the patient care team. School-age children and adolescents benefit from a description of the catheterization laboratory and a chronologic explanation of the procedure, emphasizing what they will see, feel, and hear. Older children and adolescents may bring earphones and favorite music so that they can listen to music during the catheterization procedure. Preparation materials such as picture books, videotapes, or tours of the catheterization laboratory may be helpful. Preparation should be geared to the child's developmental level. The child's caregivers often benefit from the same explanations. Additional information, such as the expected length of the catheterization, description of the child's appearance after catheterization, and usual postprocedure care, should be outlined (see also Prepare the

Child and Family for Invasive Procedures later in the chapter). Written informed consent is completed prior to the procedure.

Methods of sedation vary among institutions and may include oral or intravenous (IV) medications (see Chapter 20). The child's age, heart defect, clinical status, and type of catheterization procedure planned are considered when sedation is determined. General anesthesia is needed for most interventional procedures. Children are allowed nothing by mouth (NPO) for 6 to 8 hours or more before the procedure. Infants and patients with polycythemia may need IV fluids to prevent dehydration and hypoglycemia.

Postprocedural Care Important!!

Postcatheterization care may occur in a recovery unit, hospital room, or intensive care unit (ICU) depending on the patient's acuity and care needs. Some catheterizations may be done as outpatient procedures, but most patients having interventional procedures are observed overnight in the hospital. Patients are placed on a cardiac monitor and a pulse oximeter for the first few hours of recovery. The most important nursing responsibility is observation of the following for signs of complications:

- **Pulses,** especially below the catheterization site, for equality and symmetry (Pulse distal to the site may be weaker for the first few hours after catheterization but should gradually increase in strength.)
- **Temperature and color of the affected extremity** because coolness or blanching may indicate arterial obstruction
- **Vital signs,** which are taken as frequently as every 15 minutes, with special emphasis on heart rate, which is counted for 1 full minute for evidence of dysrhythmias or bradycardia
- **Blood pressure (BP),** especially for hypotension, which may indicate hemorrhage from cardiac perforation or bleeding at the site of initial catheterization
- **Dressing,** for evidence of bleeding or hematoma formation in the femoral or antecubital area
- **Fluid intake,** both IV and oral, to ensure adequate hydration (Blood loss in the catheterization laboratory, the child's NPO status, and diuretic actions of dyes used during the procedure put children at risk for hypovolemia and dehydration.)
- **Blood glucose levels** for hypoglycemia, especially in infants, who should receive IV fluids containing dextrose

! NURSING ALERT

If bleeding occurs, direct continuous pressure is applied 2.5 cm (1 inch) above the percutaneous skin site to localize pressure over the vessel puncture.

Depending on hospital policy, the child may be kept in bed with the affected extremity maintained straight for 4 to 6 hours after venous catheterization and 6 to 8 hours after arterial catheterization to facilitate healing of the cannulated vessel. If younger children have difficulty complying, they can be held in the parent's lap with the leg maintained in the correct position. The child's usual diet can be resumed as soon as tolerated, beginning with sips of clear liquids and advancing as the condition allows. The child is encouraged to void to clear the contrast material from the blood. Generally there is only slight discomfort at the percutaneous site. To prevent infection, the catheterization area is protected from possible contamination. If the child wears diapers, the dressing can be kept dry by covering it with a piece of plastic film and sealing the edges of the film to the skin with tape. However, the nurse must be careful to continue observing the site for any evidence of bleeding (see Family-Centered Care box and Critical Thinking Case Study).

FAMILY-CENTERED CARE

After Cardiac Catheterization

Cover catheter insertion site with an adhesive bandage strip and change daily for 2 days.
Keep site clean and dry. Avoid tub baths and swimming for several days; patient may shower or have a sponge bath.
Observe site for redness, swelling, drainage, and bleeding. Monitor for fever. Notify practitioner if these occur.
Encourage rest and quiet activities for the first 3 days and avoid strenuous exercise.
Discuss returning to school and resuming other activities with the practitioner.
Resume regular diet without restrictions.
Use acetaminophen for pain.
Keep follow-up appointments per practitioner's instruction.

CRITICAL THINKING CASE STUDY

Cardiac Catheterization

Tommy, a 3-year-old boy with tetralogy of Fallot, has just returned to his hospital room from the cardiac catheterization recovery room. His mother calls you to the bedside to tell you that he is vomiting and bleeding. You arrive to find Tommy anxious, pale, crying, and sitting in a puddle of blood.

Initial Assessment. What is the most likely explanation of what is going on?

Expected Nursing Action. What are the most appropriate immediate interventions?

Teaching Points

- Children must be kept in bed with the affected extremity maintained straight for 4 to 6 hours after venous catheterization and for 6 to 8 hours after arterial catheterization to facilitate healing of the cannulated vessel.
- Hematocrit and hemoglobin are usually checked 6 hours after catheterization but may be checked sooner if there are clinical signs of bleeding. If the level is low, a blood transfusion may be necessary.

Critical Thinking Answers

Initial Assessment. Tommy is experiencing bleeding at the catheterization site.

Expected Nursing Action. Lay Tommy flat and apply pressure. Tommy may also need his hemoglobin and hematocrit levels checked and a blood transfusion if these levels are low.

CONGENITAL HEART DISEASE

The incidence of CHD in children is approximately 1 in 110 live births in the United States (Reller, Strickland, Riehle-Colarusso, et al., 2008). Of these, approximately 25% of infants have a critical congenital heart defect and will require treatment within the first year of life (Botto, Correa, & Erickson, 2001). Nearly half (48%) of deaths due to CHD occur during the first year of life (Gilboa, Salemi, Nembhard, et al., 2010). Despite these statistics, mortality due to CHD has improved over the last few decades due to surgical and catheter interventions, early detection, and ongoing pharmaceutical advancements. In 2010 it was estimated that there were approximately 2.4 million people

living with CHD in the United States, 1 million of whom were children (Gilboa, Devine, Kucik, et al., 2016).

The exact cause of most congenital cardiac diseases is unknown. Most are thought to be a result of multiple factors—a complex interaction of genetic and environmental influences. Some risk factors are known to be associated with increased incidence of congenital heart defects. Maternal risk factors include chronic illnesses such as diabetes or poorly controlled phenylketonuria, alcohol consumption, and exposure to environmental toxins and infections. Family history of a cardiac defect in a parent or sibling increases the likelihood of a cardiac anomaly. The risk of CHD increases if a first-degree relative (parent or sibling) is affected. The familial risk is higher with left-sided obstructive lesions.

Congenital heart anomalies are often associated with chromosomal abnormalities, specific syndromes, or congenital defects in other body systems. Down syndrome (trisomy 21) and trisomy 13 and 18 are highly correlated with congenital heart defects. Syndromes associated with heart defects include DiGeorge syndrome, also known as 22q11.2 deletion syndrome (heart defects, poor immune system function, a cleft palate, complications related to low levels of calcium in the blood, and delayed development with behavioral and emotional problems); Noonan syndrome (pulmonic valve anomalies and cardiomyopathy); Williams syndrome (aortic and pulmonic stenosis); and Holt-Oram syndrome (upper limb anomalies and atrial septal defect). Extracardiac defects such as tracheoesophageal fistula, renal abnormalities, and diaphragmatic hernia are seen in association with heart anomalies.

CIRCULATORY CHANGES AT BIRTH

Blood carrying oxygen and nutritive materials from the placenta enters the fetal system through the umbilicus via the large umbilical vein. The blood then travels to the liver, where it divides. Part of the blood enters the portal and hepatic circulation of the liver, and the remainder travels directly to the inferior vena cava (IVC) by way of the ductus venosus. Oxygenated blood enters the heart by way of the IVC. Because of the higher pressure of blood entering the right atrium, it is directed posteriorly in a straight pathway across the right atrium and through the **foramen ovale** to the left atrium. In this way, the better-oxygenated blood enters the left atrium and ventricle to be pumped through the aorta to the head and upper extremities. Blood from the head and upper extremities entering the right atrium from the superior vena cava is directed downward through the tricuspid valve into the right ventricle. From there it is pumped through the pulmonary artery, where the major portion is shunted to the descending aorta via the **ductus arteriosus**. Only a small amount flows to and from the nonfunctioning fetal lungs (Fig. 23.2A).

Before birth, the high pulmonary vascular resistance created by the collapsed fetal lung causes greater pressures in the right side of the heart and the pulmonary arteries. At the same time, the free-flowing placental circulation and the ductus arteriosus produce a low vascular resistance in the remainder of the fetal vascular system. With the cessation of placental blood flow from clamping of the umbilical cord and the expansion of the lungs at birth, the hemodynamics of the fetal vascular system undergo pronounced and abrupt changes (see Fig. 23.2B).

With the first breath, the lungs are expanded, and increased oxygen causes pulmonary vasodilation. Pulmonary pressures start to fall as systemic pressures, given the removal of the placenta, start to rise. Normally the foramen ovale closes as the pressure in the left atrium exceeds the pressure in the right atrium. The ductus arteriosus starts to close in the presence of increased oxygen concentration in the blood and other factors.

ALTERED HEMODYNAMICS

The physiology of heart defects is defined by pressure gradients, blood flow, and resistance within the circulation. As blood is pumped through the heart, it (1) flows from an area of high pressure to one of low pressure and (2) takes the path of least resistance. In general, the higher the pressure gradient, the faster the rate of flow; and the higher the resistance, the slower the rate of flow.

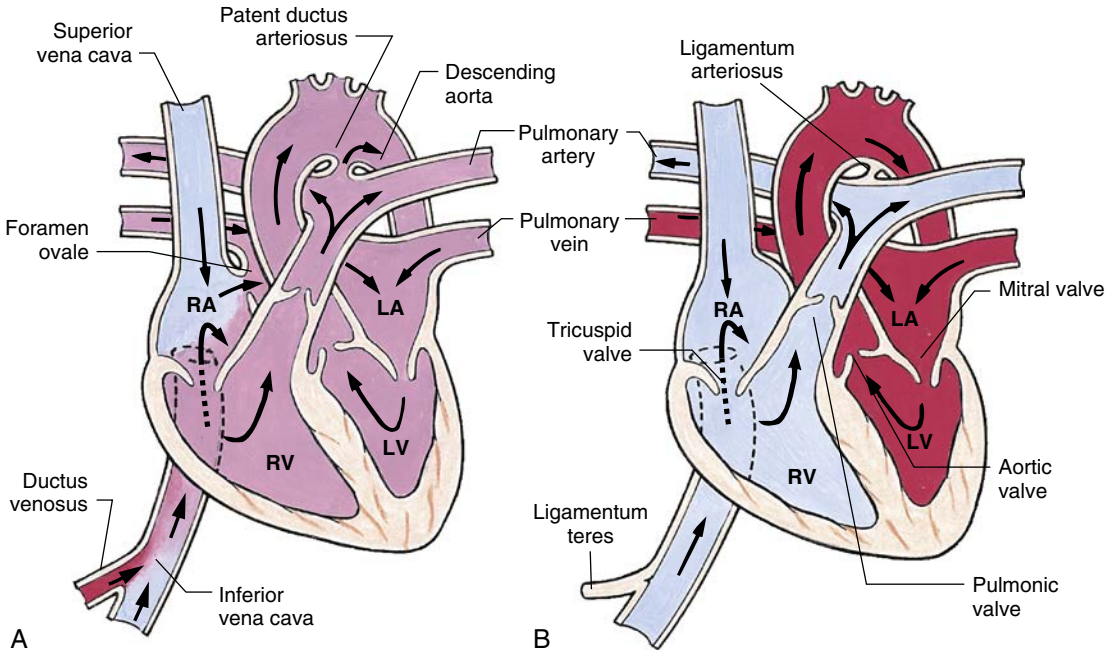

Fig. 23.2 Changes in circulation at birth. **A,** Prenatal circulation. **B,** Postnatal circulation. *Arrows* indicate direction of blood flow. Although four pulmonary veins enter the left atrium *(LA),* for simplicity, this diagram shows only two. *LV,* Left ventricle; *RA,* right atrium; *RV,* right ventricle.

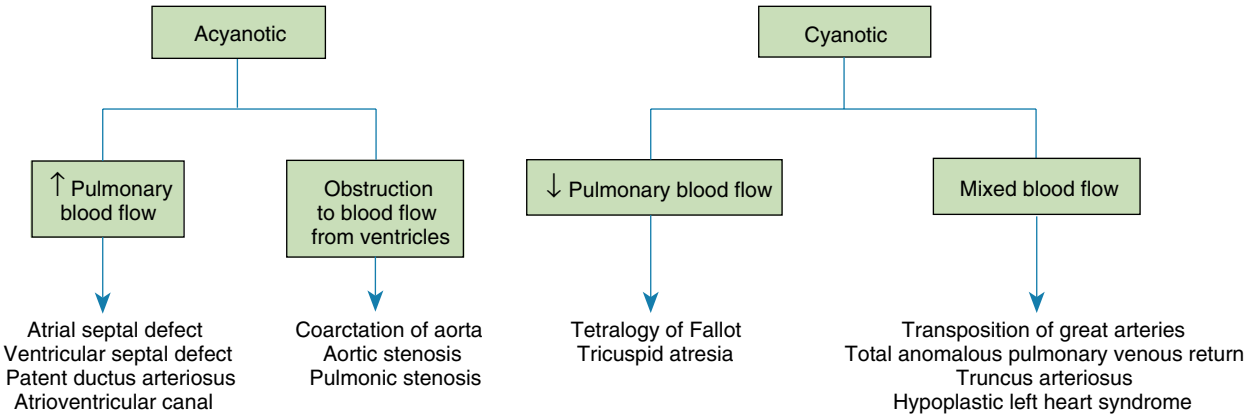

Fig. 23.3 Comparison of acyanotic-cyanotic and hemodynamic classification systems of congenital heart disease (CHD).

Normally, the pressure on the right side of the heart is lower than that on the left side, and the resistance in the pulmonary circulation is less than that in the systemic circulation. Likewise, vessels entering or exiting these chambers have corresponding pressures (e.g., lower pressure in the pulmonary artery and higher pressure in the aorta). Therefore if an abnormal connection exists between the heart chambers, such as a septal defect, blood flows from an area of higher pressure (left side) to one of lower pressure (right side). This directional flow of blood is termed a **left-to-right shunt**. If the opening is small, the amount of blood shunted to the atrium or ventricle may be minimal. Anomalies resulting in cyanosis may result from a change in pressure so that the blood is shunted from the right side to the left side of the heart (**right-to-left shunt**) because of either increased pulmonary vascular resistance or obstruction to blood flow through the pulmonic valve and artery. Cyanosis may also result from a defect that allows mixing of oxygenated and deoxygenated blood within the heart chambers or great arteries, such as occurs in truncus arteriosus.

CLASSIFICATION OF DEFECTS

There are typically two classification systems used to categorize congenital heart defects. Traditionally, cyanosis, a physical characteristic, has been used as the distinguishing feature, dividing anomalies into **acyanotic defects** and **cyanotic defects**. In clinical practice this system is problematic, since children with acyanotic defects may develop cyanosis. Also, more often, those with cyanotic defects may be pink and have more clinical signs of HF. Because of the complexity of many defects and the variability of their clinical manifestations, the cyanotic-acyanotic classification system has proven to be inadequate and misleading.

A more useful classification system is based on hemodynamic characteristics (blood flow patterns within the heart). These blood flow patterns are (1) **increased pulmonary blood flow**; (2) **decreased pulmonary blood flow**; (3) **obstruction to blood flow** out of the heart; and (4) **mixed blood flow**, in which saturated and desaturated blood mix within the heart or great arteries. Fig. 23.3 outlines both classification systems.

With the hemodynamic classification system, the clinical manifestations of each group are more uniform and predictable. Defects that allow blood flow from the higher pressure left side of the heart to the lower pressure right side (left-to-right shunt) result in increased pulmonary blood flow and cause HF. Obstructive defects impede blood flow out of the ventricles; obstruction on the left side of the heart results in HF, whereas severe obstruction on the right side causes cyanosis. Defects that cause decreased pulmonary blood flow result in cyanosis. Mixed lesions present a variable clinical picture based on the degree of mixing and amount of pulmonary blood flow; hypoxemia (with or without cyanosis) and HF usually occur together. Using this classification system, the clinical presentation and management of the most common defects are outlined in the following sections and in Boxes 23.1 to 23.4.

The outcomes of surgical treatment for patients with moderate to severe disease are variable. Patient risk factors for increased morbidity and mortality include prematurity or low birth weight, a genetic syndrome, multiple cardiac defects, a noncardiac congenital anomaly, and age at time of surgery (neonates are a higher risk group). The more common defects require no intervention or are treated with a single surgical intervention. Severe critical congenital heart defects often require multiple surgical and catheterization interventions and lifelong management by a cardiologist. Severe defects include all cyanotic heart disease and other complex defects such as hypoplastic left heart syndrome, atrioventricular (AV) canal, critical aortic stenosis, critical coarctation of the aorta, and some complex ventricular septal defects.

Defects With Increased Pulmonary Blood Flow

In this group of cardiac defects, intracardiac communications along the septum or an abnormal connection between the great arteries allows blood to flow from the higher pressure left side of the heart to the lower pressure right side of the heart (Fig. 23.4). Increased blood volume on the right side of the heart increases pulmonary blood flow at the expense of systemic blood flow. Clinically, patients demonstrate signs and symptoms of HF. Atrial and ventricular septal defects and patent ductus arteriosus are typical anomalies in this group (Box 23.1).

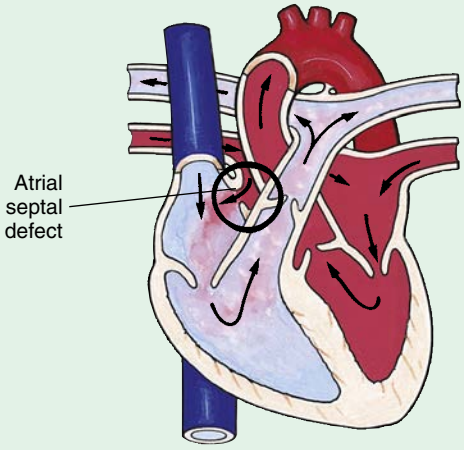
Obstructive Defects

Obstructive defects are those in which blood exiting the heart meets an area of anatomic narrowing (**stenosis**), causing obstruction to blood flow. The pressure in the ventricle and in the great artery before the obstruction is increased, and the pressure in the area beyond the obstruction is decreased. The location of the narrowing is usually near the valve (Fig. 23.5):

Valvar—Narrowing at the site of the valve itself
Subvalvar—Narrowing in the ventricle below the valve (also referred to as the **ventricular outflow tract**)
Supravalvar—Narrowing in the great artery above the valve

BOX 23.1 Defects With Increased Pulmonary Blood Flow

Atrial Septal Defect



Description—Abnormal opening between the atria, allowing blood from the higher pressure left atrium to flow into the lower pressure right atrium. There are three types of atrial septal defect (ASD):

Ostium primum (ASD 1)—Opening at lower end of septum; may be associated with mitral valve abnormalities

Ostium secundum (ASD 2)—Opening near center of septum

Sinus venosus defect—Opening near junction of superior vena cava and right atrium; may be associated with partial anomalous pulmonary venous connection

Pathophysiology—Because left atrial pressure slightly exceeds right atrial pressure, blood flows from the left to the right atrium, causing an increased flow of oxygenated blood into the right side of the heart. Despite the low pressure difference, a high rate of flow can still occur because of low pulmonary vascular resistance and the greater distensibility of the right atrium, which further reduces flow resistance. This volume is well tolerated by the right ventricle because it is delivered under much lower pressure than with a ventricular septal defect. Although there is right atrial and ventricular enlargement, cardiac failure is unusual in an uncomplicated ASD. Pulmonary vascular changes usually occur only after several decades if the defect is left unrepaired.

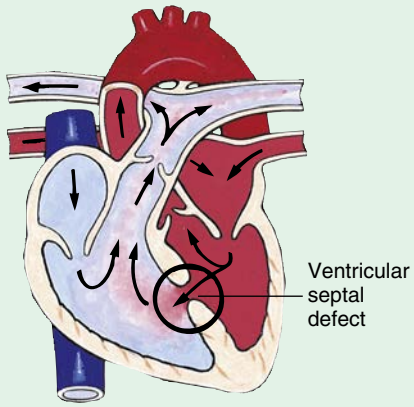
Clinical manifestations—Patients may be asymptomatic. Spontaneous closure of ASDs are most likely to occur in younger patients and those with small defects (Vick & Bezold, 2018). They may develop heart failure (HF), particularly in the third or fourth decade of life if the ASD goes undiagnosed, as the pulmonary artery pressure then begins to rise. There is a characteristic murmur. Patients are at risk for atrial dysrhythmias (probably caused by atrial enlargement and stretching of conduction fibers) and pulmonary vascular obstructive disease and emboli formation later in life from chronically increased pulmonary blood flow.

Surgical closure—Surgical patch closure (pericardial patch or Dacron patch) is done for moderate to large defects. Open repair with cardiopulmonary bypass is usually performed before school age. In addition, the sinus venosus defect requires patch placement, so the anomalous right pulmonary venous return is directed to the left atrium with a baffle. The ASD 1 type may require mitral valve repair or, rarely, replacement of the mitral valve.

Transcatheter closure—ASD 2 closure with a device during cardiac catheterization is becoming commonplace and can be done as an outpatient procedure. The Amplatzer septal occluder is most commonly used. Smaller defects that have a rim around them for attachment of the device can be closed with a device; large, irregular defects without a rim require surgical closure. Successful closure in appropriately selected patients yields results similar to surgery but involves shorter hospital stays and fewer complications. Patients receive low-dose aspirin for 6 months (Moore, Hegde, El-Said, et al., 2013).

Prognosis—Outcomes for both treatment options are very good. Limited data also suggest that the rates of procedural success may be comparable to or possibly better with surgery versus transcatheter closure, but that there may be an increased rate of reintervention associated with percutaneous closure (Du, Hijazi, & Kleinman, 2002).

Ventricular Septal Defect



Description—Abnormal opening between the ventricles. May be classified according to location: membranous (accounting for 80%) or muscular. May vary in size from a small pinhole to absence of the septum, which results in a common ventricle. Ventricular septal defects (VSDs) are frequently associated with other defects, such as pulmonic stenosis, transposition of the great vessels, patent ductus arteriosus, atrial defects, and coarctation of the aorta. Many VSDs (20% to 60%) close spontaneously. Spontaneous closure is most likely to occur during the first year of life in children having small or moderate defects.

Pathophysiology—Because of the higher pressure within the left ventricle and because the systemic arterial circulation offers more resistance than the pulmonary circulation, blood flows through the defect into the pulmonary artery. The increased blood volume is pumped into the lungs, which may eventually result in increased pulmonary vascular resistance. Increased pressure in the right ventricle as a result of left-to-right shunting and pulmonary resistance causes the muscle to hypertrophy. If the right ventricle is unable to accommodate the increased workload, the right atrium may also enlarge as it attempts to overcome the resistance offered by incomplete right ventricular emptying.

Clinical manifestations—HF is common. There is a characteristic murmur.

Surgical treatment

Palliative—Pulmonary artery banding (placement of a band around the main pulmonary artery to decrease pulmonary blood flow) may be done in infants with multiple muscular VSDs or complex anatomy. Improvements in surgical techniques and postoperative care make complete repair in infancy the preferred approach.

Complete repair (procedure of choice)—Small defects are repaired with sutures. Large defects usually require sewing a knitted Dacron patch over the opening. Cardiopulmonary bypass is used for both procedures. The approach for the repair is generally through the right atrium and the tricuspid valve. Postoperative complications include residual VSD and conduction disturbances.

Transcatheter Closure

Description—Catheter closure of muscular, postoperative, or fenestrated defects is also widely used in centers nationwide. Device closures of VSDs carry more risk than with ASDs. The most common complication noted in one study was complete atrioventricular (AV) block requiring pacemaker placement in 5.7% of the subjects (Butera, Carminati, Chessa, et al., 2007).

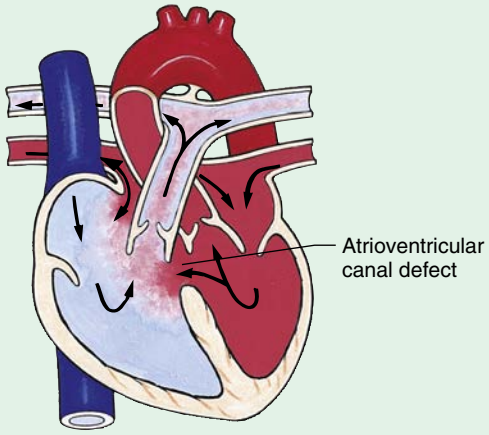
Prognosis—Risks depend on the location of the defect, the number of defects, surgical versus transcatheter closure, and the presence of other associated cardiac defects. Single membranous defects are associated with low

Continued

BOX 23.1 Defects With Increased Pulmonary Blood Flow—cont'd

mortality (<2%); multiple muscular defects can carry a higher risk (Jacobs, Mavroudis, Jacobs, et al., 2004).

Atrioventricular Canal Defect



Description—Also referred to as *AV septal defects* or *endocardial cushion defects*. Incomplete fusion of the endocardial cushions. Consists of a low ASD that is continuous with a high VSD and clefts of the mitral and tricuspid valves, which creates a large central AV valve that allows blood to flow between all four chambers of the heart. The directions and pathways of flow are determined by pulmonary and systemic resistance, left and right ventricular pressures, and the compliance of each chamber, although flow is generally from left to right. It is the most common cardiac defect in children with Down syndrome.

Pathophysiology—The alterations in hemodynamics depend on the severity of the defect and the child's pulmonary vascular resistance. Immediately after birth, while the newborn's pulmonary vascular resistance is high, there is minimum shunting of blood through the defect. Once this resistance falls, left-to-right shunting occurs and pulmonary blood flow increases. The resultant pulmonary vascular engorgement predisposes the child to development of HF.

Clinical manifestations—Patients usually have moderate to severe HF. There is a characteristic murmur. There may be mild cyanosis that increases with crying. Patients are at high risk for developing pulmonary vascular obstructive disease.

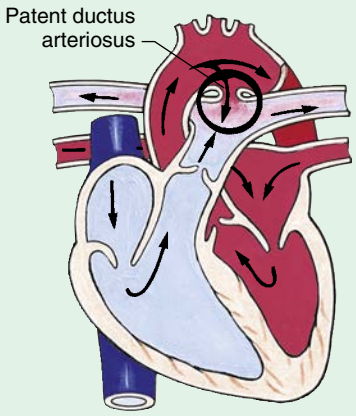
Surgical treatment

Palliative—Pulmonary artery banding is occasionally done in small infants with severe symptoms. Single ventricle palliation is necessary for some infants who have a right or left ventricle dominant canal defect.

Complete repair—Surgical repair consists of patch closure of the septal defects and reconstruction of the AV valve tissue (either repair of the mitral valve cleft or fashioning of two AV valves). Postoperative complications include heart block, HF, mitral regurgitation, dysrhythmias, and pulmonary hypertension.

Prognosis—Operative mortality is generally low, with patients who are younger (>2.5 months) and smaller (<3.5 kg) having worse outcomes (Jacobs et al., 2004; St. Louis, Jodhka, Jacobs, et al., 2014). A potential later problem is mitral regurgitation, which may require valve replacement.

Patent Ductus Arteriosus



Description—Failure of the fetal ductus arteriosus (artery connecting the aorta and pulmonary artery) to close within the first weeks of life. The continued patency of this vessel allows blood to flow from the higher pressure aorta to the lower pressure pulmonary artery, which causes a left-to-right shunt.

Pathophysiology—The hemodynamic consequences of patent ductus arteriosus (PDA) depend on the size of the ductus and the pulmonary vascular resistance. At birth the resistance in the pulmonary and systemic circulations is almost identical, so the resistance in the aorta and pulmonary artery is equalized. As the systemic pressure comes to exceed the pulmonary pressure, blood begins to shunt from the aorta across the duct to the pulmonary artery (left-to-right shunt). The additional blood is recirculated through the lungs and returned to the left atrium and left ventricle. The effect of this altered circulation is increased workload on the left side of the heart, increased pulmonary vascular congestion and possibly resistance, and potentially increased right ventricular pressure and hypertrophy.

Clinical manifestations—The amount of shunting will determine the degree of clinical manifestations. There is a characteristic machinery-like murmur. Patients may be asymptomatic or show signs of HF. Moderate to large PDAs may present as left-sided volume overload or reversible pulmonary arterial hypertension.

Medical management—Administration of indomethacin (prostaglandin inhibitor) has proved successful in closing a patent ductus in premature infants and some newborns.

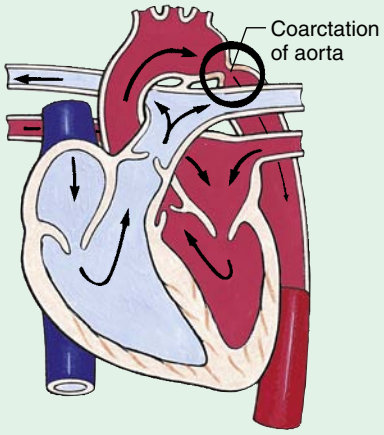
Surgical treatment—Surgical division or ligation of the patent vessel is performed via a left thoracotomy. In video-assisted thoracoscopic surgery, a thoracoscope and instruments are inserted through three small incisions on the left side of the chest to place a clip on the ductus. The surgical approach is dependent on the size and age of the patient.

Transcatheter treatment—Coils to occlude the PDA are placed in the catheterization laboratory in many centers. Premature or small infants (with small-diameter femoral arteries) and patients with large or unusual PDAs may require surgery.

Prognosis—Both surgical and nonsurgical procedures can be done at low risk with less than 1% mortality. PDA closure in very premature infants has a higher mortality rate because of the additional significant medical problems.

BOX 23.2 Obstructive Defects

Coarctation of the Aorta



Description—Localized narrowing near the insertion of the ductus arteriosus, which results in increased pressure proximal to the defect (head and upper extremities) and decreased pressure distal to the obstruction (body and lower extremities).

Pathophysiology—The effect of a narrowing within the aorta is increased pressure proximal to the defect (upper extremities) and decreased pressure distal to it (lower extremities).

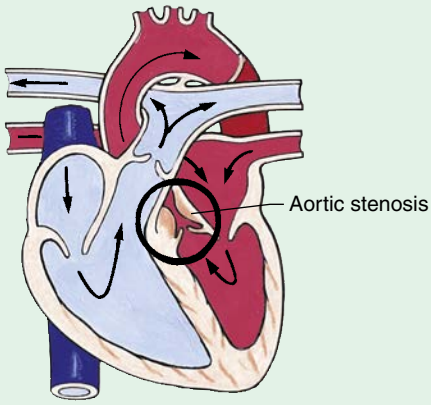
Clinical manifestations—There may be high blood pressure and bounding pulses in the arms, weak or absent femoral pulses, and cool lower extremities with lower blood pressure. There are signs of heart failure (HF) in infants. In infants with critical coarctation, the hemodynamic condition may deteriorate rapidly with severe acidosis and hypotension. Mechanical ventilation and inotropic support are often necessary before surgery. Older children may experience dizziness, headaches, fainting, and epistaxis resulting from hypertension. Patients are at risk for hypertension, ruptured aorta, aortic aneurysm, and stroke.

Surgical treatment—Surgical repair is the treatment of choice for infants younger than 6 months of age and for patients with long-segment stenosis or complex anatomy. Repair is by either (1) resection of the narrowed portion with an end-to-end anastomosis of the aorta or (2) enlargement of the section using a graft of prosthetic material or portion of the left subclavian artery. Because this defect is outside the heart and pericardium, cardiopulmonary bypass is not required, and a thoracotomy incision is used. Postoperative hypertension is treated with intravenous sodium nitroprusside, esmolol, or milrinone, followed by oral medications, such as angiotensin-converting enzyme inhibitors or beta-blockers. Residual permanent hypertension after repair of coarctation of the aorta (COA) seems to be related to age and time of repair. To prevent both hypertension at rest and exercise-provoked systemic hypertension after repair, elective surgery for COA is advised within the first 2 years of life. Percutaneous balloon angioplasty techniques have proved to be very effective in relieving residual postoperative coarctation gradients.

Transcatheter treatment—Balloon angioplasty is a primary intervention for COA in older infants and children. In adolescents, stents may be placed in the aorta to maintain patency. The goal of the procedure is to achieve a reduction in gradient to less than 10%, or more than 90% relief of obstruction angiographically. Dilation and/or stent implantation for native or recurrent coarctation seems to immediately relieve obstruction in more than 90% of cases (Holzer, Chisolm, Hill, et al., 2008).

Prognosis—There are low rates of morbidity, mortality, and reintervention for infants and children who underwent COA repair via a left thoracotomy (Mery, Guzmán-Pruneda, Trost, et al., 2015). Major long-term complications include recoarctation, aortic aneurysm, and systemic hypertension (Brown, Burkhart, Connolly, et al., 2013).

Aortic Stenosis



Description—Narrowing or stricture of the aortic valve, causing resistance to blood flow in the left ventricle, decreased cardiac output, left ventricular hypertrophy, and pulmonary vascular congestion. Valvular aortic stenosis (AS), the most common type, is usually caused by malformed cusps that result in a bicuspid rather than tricuspid valve or fusion of the cusps. Subvalvular stenosis is a stricture caused by a fibrous ring below a normal valve; supravalvular stenosis occurs infrequently. Valvular AS is a serious defect because (1) the obstruction tends to be progressive; (2) sudden episodes of myocardial ischemia, or low cardiac output, can result in sudden death; and (3) surgical repair rarely results in a normal valve. This is one of the rare instances in which strenuous physical activity may be curtailed because of the cardiac condition.

Pathophysiology—A stricture in the aortic outflow tract causes resistance to ejection of blood from the left ventricle. The extra workload on the left ventricle causes hypertrophy. If left ventricular failure develops, left atrial pressure will increase; this causes increased pressure in the pulmonary veins, which results in pulmonary vascular congestion (pulmonary edema).

Clinical manifestations—Newborns with critical AS demonstrate signs of decreased cardiac output with faint pulses, hypotension, tachycardia, and poor feeding. Children show signs of exercise intolerance, chest pain, and dizziness when standing for a long period. There is a characteristic murmur. Patients are at risk for infective endocarditis, coronary insufficiency, and ventricular dysfunction.

Valvular Aortic Stenosis

Surgical treatment—Aortic valvotomy is performed under inflow occlusion. Used rarely, since balloon dilation in the catheterization laboratory is the first-line procedure. Newborns with critical AS and small left-sided structures may undergo a stage 1 Norwood procedure (see Hypoplastic Left Heart Syndrome in Box 23.4).

Prognosis—Aortic valvotomy remains a palliative procedure, and the patient may require further surgery to repair or even replace the aortic valve. An aortic homograft with a valve may also be used (extended aortic root replacement), or the pulmonic valve may be moved to the aortic position and replaced with a homograft valve (Ross procedure). If the obstruction is at the subvalvular region and results from narrowing of the left ventricular outflow tract with a small aortic valve annulus, a patch may be required to enlarge the entire left ventricular outflow tract and annulus and replace the aortic valve, an approach known as the Konno procedure. Patients who have obstruction at both the valvular and the subvalvular regions may undergo a combination of these two procedures, also called a Ross-Konno procedure.

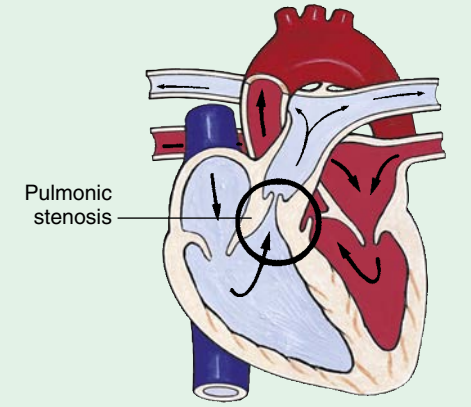
Nonsurgical treatment—The narrowed valve is dilated using balloon angioplasty in the catheterization laboratory. This procedure is usually the first intervention.

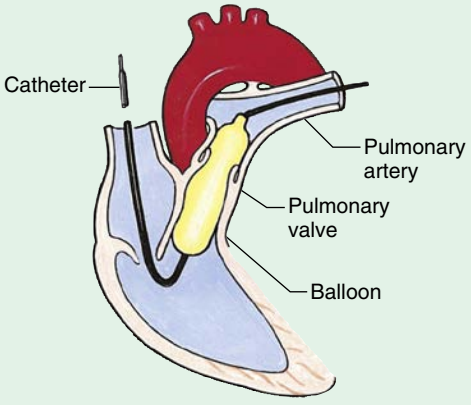
Prognosis—Complications include aortic insufficiency or valvular regurgitation, tearing of the valve leaflets, and loss of pulse in the catheterized limb.

Continued

BOX 23.2 Obstructive Defects—cont'd

Pulmonic Stenosis





Description—Narrowing at the entrance to the pulmonary artery. Resistance to blood flow causes right ventricular hypertrophy and decreased pulmonary blood flow. Pulmonary atresia is the extreme form of pulmonic stenosis (PS) in that there is total fusion of the commissures and no blood flows to the lungs. The right ventricle may be hypoplastic.

Pathophysiology—When PS is present, resistance to blood flow causes right ventricular hypertrophy. If right ventricular failure develops, right atrial pressure increases, and this may result in reopening of the foramen ovale, shunting of deoxygenated blood into the left atrium, and systemic cyanosis. If PS is severe, HF occurs, and systemic venous engorgement is noted. An associated defect such as a patent ductus arteriosus partially compensates for the obstruction by shunting blood from the aorta to the pulmonary artery and into the lungs.

Clinical manifestations—Patients may be asymptomatic; some have mild cyanosis or HF. Progressive narrowing causes increased symptoms. Newborns with severe narrowing are cyanotic. There is a characteristic murmur. Cardiomegaly is evident on chest radiographic films. Patients are at risk for infective endocarditis.

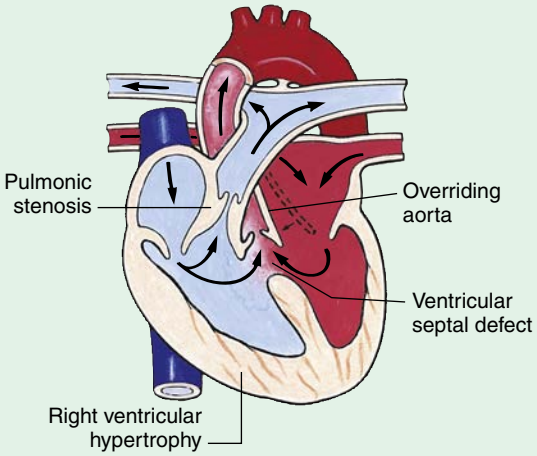
Surgical treatment—Need for surgical treatment is rare, with widespread use of balloon angioplasty techniques, but in some cases pulmonary valvotomy with cardiopulmonary bypass is necessary.

Transcatheter treatment—Balloon angioplasty in the cardiac catheterization laboratory to dilate the valve. A catheter is inserted across the stenotic pulmonic valve into the pulmonary artery, and a balloon at the end of the catheter is inflated and rapidly passed through the narrowed opening. The procedure is associated with few complications and has proved to be highly effective. It is the treatment of choice for discrete PS in most centers and can be done safely in neonates.

Prognosis—Risk is low for both surgical and transcatheter procedures; mortality is low, slightly higher in neonates. Both balloon dilation and surgical valvotomy leave the pulmonary valve incompetent because they involve opening the fused valve leaflets; however, these patients are clinically asymptomatic. Long-term problems with restenosis or valve incompetence may occur.

BOX 23.3 Defects With Decreased Pulmonary Blood Flow

Tetralogy of Fallot



Description—The classic form includes four defects: (1) ventricular septal defect (VSD), (2) pulmonic stenosis, (3) overriding aorta, and (4) right ventricular hypertrophy.

Pathophysiology—The alteration in hemodynamics varies widely, depending primarily on the degree of pulmonary stenosis, but also on the size of the VSD and the pulmonary and systemic resistance to flow. Because the VSD is usually large, pressures may be equal in the right and left ventricles. Therefore the shunt direction depends on the difference between pulmonary and systemic vascular resistance. If pulmonary vascular resistance is higher than systemic resistance, the shunt is from right to left. If systemic resistance is higher than pulmonary resistance, the shunt is from left to right. Pulmonary stenosis decreases blood flow to the lungs and consequently the amount of oxygenated blood that returns to the left side of the heart. Depending on the position of the aorta, blood from both ventricles may be distributed systemically.

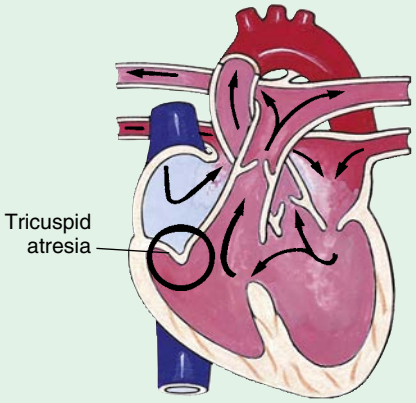
Clinical manifestations—Some infants may be acutely cyanotic at birth; others have mild cyanosis that progresses over the first year of life as the pulmonary stenosis worsens. There is a characteristic murmur. There may be acute episodes of cyanosis and hypoxia, called *blue spells* or *tet spells.* Anoxic spells occur when the infant's oxygen requirements exceed the blood supply, usually during crying or after feeding. Patients are at risk for emboli, seizures, and loss of consciousness or sudden death following an anoxic spell.

Surgical treatment—Elective repair is usually performed in the first year of life. Indications for repair include increasing cyanosis and the development of hypercyanotic spells. Complete repair involves closure of the VSD and resection of the

BOX 23.3 Defects With Decreased Pulmonary Blood Flow—cont'd

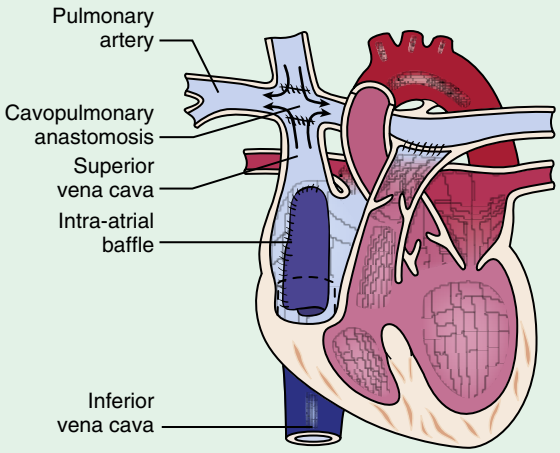
infundibular stenosis, with placement of a pericardial patch to enlarge the right ventricular outflow tract. In some repairs, the patch may extend across the pulmonic valve annulus (transannular patch), making the pulmonic valve incompetent. The procedure requires a median sternotomy and the use of cardiopulmonary bypass.

Prognosis—The operative mortality for total correction of tetralogy of Fallot is less than 3% (Jacobs et al., 2004). Long-term complications include chronic pulmonary regurgitation with right ventricular enlargement and decreased function requiring pulmonary valve replacement, residual right ventricular outflow tract obstruction, aortic root dilation and aortic valve insufficiency, arrhythmias, and sudden cardiac death. Pulmonary valve replacement is performed either surgically or in the catheterization lab using a transcatheter approach (Doyle, Kavanaugh-McHugh, & Fish, 2019).



Tricuspid Atresia

Description—The tricuspid valve fails to develop; consequently, there is no communication from the right atrium to the right ventricle. Blood flows through an atrial septal defect (ASD) or a patent foramen ovale to the left side of the heart and through a VSD to the right ventricle and out to the lungs. The condition is often associated with pulmonary stenosis and transposition of the great arteries. There is complete mixing of deoxygenated and oxygenated blood in the left side of the heart, which results in systemic desaturation, and varying amounts of pulmonary obstruction, which causes decreased pulmonary blood flow.



Pathophysiology—At birth the presence of a patent foramen ovale (or other atrial septal opening) is required to permit blood flow across the septum into the left atrium; the patent ductus arteriosus allows blood flow to the pulmonary artery into the lungs for oxygenation. A VSD allows a modest amount of blood to enter the right ventricle and pulmonary artery for oxygenation. Pulmonary blood flow is often diminished.

Clinical manifestations—Cyanosis is usually seen in the newborn period. There may be tachycardia and dyspnea. Older children have signs of chronic hypoxemia with clubbing.

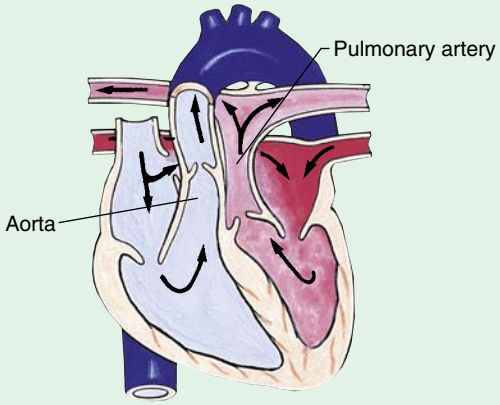
Therapeutic management—For the neonate whose pulmonary blood flow depends on the patency of the ductus arteriosus, a continuous infusion of prostaglandin E1 is started at 0.1 mcg/kg/min until surgical intervention can be arranged.

Surgical treatment—Patients with tricuspid atresia follow the staged surgical approach for single ventricle anatomywith the left ventricle becoming the ventricular pump.

Prognosis—Surgical mortality is less than 5% (Jacobs et al., 2004); the rate increases when the anatomy is more complex and other risk factors are present. Postoperative complications include dysrhythmias, systemic venous hypertension, pleural and pericardial effusions, and ventricular dysfunction.

BOX 23.4 Mixed Defects

Transposition of the Great Arteries, or Transposition of the Great Vessels



Description—The pulmonary artery leaves the left ventricle, and the aorta exits from the right ventricle, with no communication between the systemic and pulmonary circulations.

Pathophysiology—Associated defects such as septal defects or patent ductus arteriosus must be present to permit blood to enter the systemic circulation or the pulmonary circulation for mixing of saturated and desaturated blood. The most common defect associated with transposition of the great arteries (TGA) is a patent foramen ovale. At birth there is also a patent ductus arteriosus, although in most instances this closes after the neonatal period. Another associated defect may be a ventricular septal defect (VSD). The presence of a VSD increases the risk of heart failure (HF) because it permits blood to flow from the right to the left ventricle, into the pulmonary artery, and finally to the lungs. However, it also produces increased pulmonary blood flow under high pressure, which can result in high pulmonary vascular resistance.

Clinical manifestations—Vary according to the type and size of the associated defects. Newborns with minimum communication are severely cyanotic

Continued

and have depressed function at birth. Those with large septal defects or a patent ductus arteriosus may be less cyanotic but have symptoms of HF. Heart sounds vary according to the type of defect present. Cardiomegaly is usually evident a few weeks after birth.

Therapeutic management (to provide intracardiac mixing)—Intravenous prostaglandin E1 may be administered preoperatively to maintain ductal patency and ensure adequate systemic blood flow. During cardiac catheterization or under echocardiographic guidance, a balloon atrial septostomy (Rashkind procedure) may also be performed to increase mixing by opening the atrial septum.

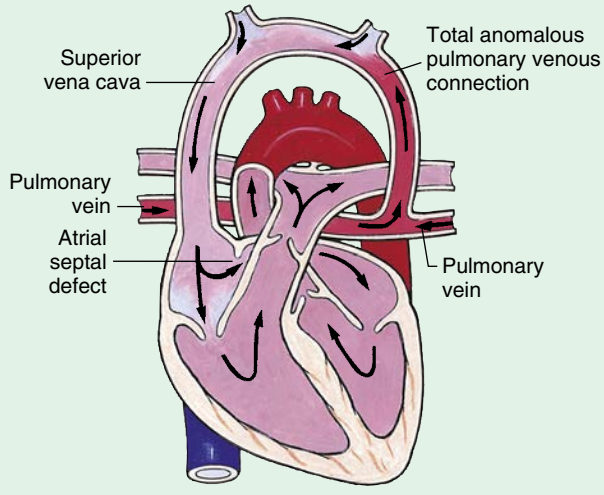
Surgical treatment—An arterial switch operation (also called a Jatene procedure) is the procedure of choice performed in the first weeks of life. It involves transecting the great arteries and anastomosing the main pulmonary artery to the proximal aorta (just above the aortic valve) and anastomosing the ascending aorta to the proximal pulmonary artery. The coronary arteries are switched from the proximal aorta to the proximal pulmonary artery to create a new aorta. Reimplantation of the coronary arteries is critical to the infant's survival, and they must be reattached without torsion or kinking to provide the heart with its supply of oxygen. The advantage of the arterial switch procedure is the reestablishment of normal circulation, with the left ventricle acting as the systemic pump. Potential complications of the arterial switch include narrowing at the great artery anastomoses and coronary artery insufficiency.

Intra-atrial baffle repairs—Intra-atrial baffle repairs are rarely performed, although many adolescents and adults survive today with repairs that were done more than 15 years ago. An intra-atrial baffle is created to divert venous blood to the mitral valve and pulmonary venous blood to the tricuspid valve using the patient's atrial septum (Senning procedure) or a prosthetic material (Mustard procedure). A disadvantage is the continuing role of the right ventricle as the systemic pump and the late development of right ventricular failure and rhythm disturbances. Other potential postoperative complications include loss of normal sinus rhythm, baffle leaks, and ventricular dysfunction.

Rastelli procedure—This procedure is the operative choice in infants with TGA, VSD, and severe pulmonary stenosis. It involves closure of the VSD with a baffle so that left ventricular blood is directed through the VSD into the aorta. The pulmonary valve is then closed, and a conduit is placed from the right ventricle to the pulmonary artery to create a physiologically normal circulation. Unfortunately, this procedure requires multiple conduit replacements as the child grows.

Prognosis—Outcomes after the arterial switch operation are quite good. There are some long-term complications, including neoaortic, pulmonary, and coronary artery complications, but most patients maintain normal cardiovascular function and exercise capacity (Khairy, Clair, Fernandes, et al., 2013). Patients who undergo a Senning or Mustard procedure demonstrate diminished long-term survival rates and substantial morbidity (Cuypers, Eindhoven, Slager, et al., 2014).

Total Anomalous Pulmonary Venous Connection



Description—Rare defect characterized by failure of the pulmonary veins to join the left atrium. Instead, the pulmonary veins are abnormally connected to the systemic venous circuit via the right atrium or various veins draining toward the right atrium, such as the superior vena cava. The abnormal attachment results in mixed blood being returned to the right atrium and shunted from the right to the left through an atrial septal defect (ASD). Total anomalous pulmonary venous connection (TAPVC; also called *total anomalous pulmonary venous return* or *total anomalous pulmonary venous drainage*) is classified according to the pulmonary venous point of attachment as follows:

Supracardiac—Attachment above the diaphragm, such as to the superior vena cava (most common form) but not directly to the heart (see accompanying figure).

Cardiac—Direct attachment to the heart, such as to the right atrium or coronary sinus

Infradiaphragmatic—Attachment below the diaphragm, such as to the inferior vena cava (most severe form)

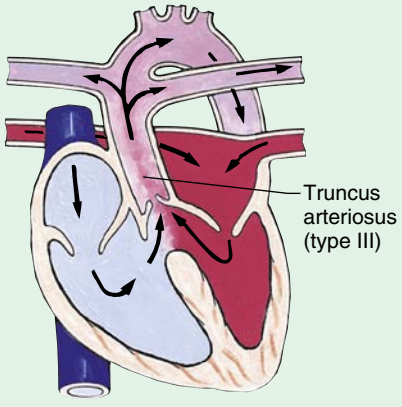
Pathophysiology—The right atrium receives all the blood that normally would flow into the left atrium. As a result, the right side of the heart hypertrophies, whereas the left side, especially the left atrium, may remain small. An associated ASD or patent foramen ovale allows systemic venous blood to shunt from the higher pressure right atrium to the left atrium and into the left side of the heart. As a result, the oxygen saturation of the blood in both sides of the heart (and ultimately in the systemic arterial circulation) is the same. If the pulmonary blood flow is large, pulmonary venous return is also large, and the amount of saturated blood is relatively high. However, if there is obstruction to pulmonary venous drainage, pulmonary venous return is impeded, pulmonary venous pressure rises, and pulmonary interstitial edema develops and eventually contributes to HF. Infradiaphragmatic TAPVC is often associated with obstruction to pulmonary venous drainage and is a surgical emergency.

Clinical manifestations—Most infants develop cyanosis early in life. The degree of cyanosis is inversely related to the amount of pulmonary blood flow—the more pulmonary blood, the less cyanosis. Children with unobstructed TAPVC may be asymptomatic until pulmonary vascular resistance decreases during infancy, increasing pulmonary blood flow, with resulting signs of HF. Cyanosis becomes worse with pulmonary vein obstruction; once obstruction occurs, the infant's condition usually deteriorates rapidly. Without intervention, cardiac failure progresses to death.

Surgical treatment—Corrective repair is performed in early infancy. The surgical approach varies with the anatomic defect. In general, however, the common pulmonary vein is anastomosed to the back of the left atrium, the ASD is closed, and the anomalous pulmonary venous connection is ligated. The cardiac type is most easily repaired; the infradiaphragmatic type carries the highest morbidity and mortality because of the higher incidence of pulmonary vein obstruction. Potential postoperative complications include reobstruction; bleeding; dysrhythmias, particularly heart block; pulmonary artery hypertension; and persistent heart failure.

Prognosis—Mortality for all types is less than 10% (Jacobs et al., 2004) and is lowest for the cardiac type; morbidity increases with the presence of pulmonary vein obstruction.

Truncus Arteriosus



BOX 23.4 Mixed Defects—cont'd

Description—Failure of normal septation and division of the embryonic bulbar trunk into the pulmonary artery and the aorta, which results in development of a single vessel that overrides both ventricles. Blood from both ventricles mixes in the common great artery, which leads to desaturation and hypoxemia. Blood ejected from the heart flows preferentially to the lower pressure pulmonary arteries, so pulmonary blood flow is increased and systemic blood flow is reduced. There are three types:

Type I—A single pulmonary trunk arises near the base of the truncus and divides into the left and right pulmonary arteries.

Type II—The left and right pulmonary arteries arise separately but in close proximity and at the same level from the back of the truncus.

Type III—The pulmonary arteries arise independently from the sides of the truncus.

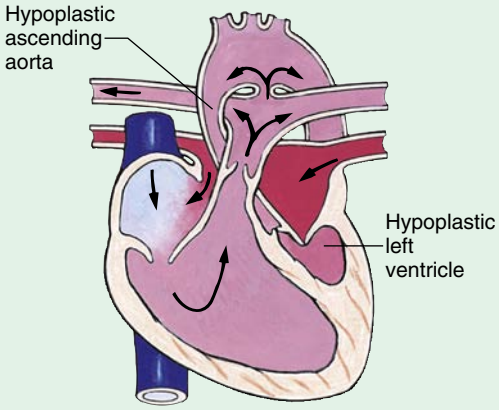
Pathophysiology—Blood ejected from the left and right ventricles enters the common trunk, so pulmonary and systemic circulations are mixed. Blood flow is distributed to the pulmonary and systemic circulations according to the relative resistances of each system. The amount of pulmonary blood flow depends on the size of the pulmonary arteries and the pulmonary vascular resistance. Generally, resistance to pulmonary blood flow is less than systemic vascular resistance, which results in preferential blood flow to the lungs. Pulmonary vascular disease develops at an early age in patients with truncus arteriosus.

Clinical manifestations—Most infants are symptomatic with moderate to severe HF and variable cyanosis, poor growth, and activity intolerance. There is a characteristic murmur. Thirty-five percent of patients have 22q11.2 deletions (Goldmuntz & Lin, 2008).

Surgical treatment—Early repair is performed in the first month of life. It involves closing the VSD so that the truncus arteriosus receives the outflow from the left ventricle, excising the pulmonary arteries from the aorta and attaching them to the right ventricle using a right ventricle to pulmonary artery conduit, and possible repair of the truncal valve. Postoperative complications include truncal valve insufficiency, persistent heart failure, bleeding, pulmonary artery hypertension, dysrhythmias, and residual VSD. Because conduits are not living tissue, they will not grow along with the child and may also become narrowed with calcifications. One or more conduit replacements will be needed in childhood.

Prognosis—Perioperative mortality is about 10%, with highest mortality in patients who required repair for both truncal valve and aortic arch interruption (Russell, Pasquali, Jacobs, et al., 2012). Long-term complications include truncal valve regurgitation and conduit stenosis.

Hypoplastic Left Heart Syndrome



Description—Underdevelopment of the left side of the heart with significant hypoplasisa of the left ventricle including atresia, stenosis or hypoplasia of the aortic and/or mitral valves, and hypoplasia of the ascending arota and arch. Most blood from the left atrium flows across the patent foramen ovale to the right atrium, to the right ventricle, and out the pulmonary artery. The descending aorta receives blood from the patent ductus arteriosus supplying systemic blood flow.

Pathophysiology—An ASD or patent foramen ovale allows saturated blood from the left atrium to mix with desaturated blood from the right atrium and to flow through the right ventricle and out into the pulmonary artery. From the pulmonary artery, the blood flows both to the lungs and through the ductus arteriosus into the aorta and out to the body. The amount of blood flow to the pulmonary and systemic circulations depends on the relationship between the pulmonary and systemic vascular resistances. The coronary and cerebral vessels receive blood by retrograde flow through the hypoplastic ascending aorta.

Clinical manifestations—There is mild cyanosis and signs of HF until the patent ductus arteriosus closes, then progressive deterioration with cyanosis and decreased cardiac output, leading to cardiovascular collapse. The condition is usually fatal in the first months of life without intervention.

Therapeutic management—Neonates require stabilization with mechanical ventilation and inotropic support preoperatively. A prostaglandin E1 infusion is needed to maintain ductal patency and ensure adequate systemic blood flow until surgical intervention can occur.

Surgical treatment—Patients with hypoplastic left heart syndrome (HLHS) follow the staged surgical approach for single ventricle anatomy with the right ventricle becoming the ventricular pump. Postoperative complications include dysrhythmias, systemic venous hypertension, pleural and pericardial effusions, thrombotic events, and ventricular dysfunction.

Transplantation—Heart transplantation in the newborn period is another option for these infants. Problems include the shortage of newborn organ donors, risk of rejection, long-term problems with chronic immunosuppression, and infection.

Prognosis—Thirty years ago a diagnosis of HLHS was uniformly fatal. Today, for children who survive to the age of 12 months, long-term survival is approximately 90% (Alsoufi, Mori, Gillespie, et al., 2015; Siffel, Riehle-Colarusso, Oster, et al., 2015). Improved outcomes have been associated with early diagnosis and repair and increased monitoring in the hospital and at home, particularly between the first- and second-stage surgeries. Long-term problems include worsening ventricular function, tricuspid regurgitation, recurrent aortic arch narrowing, dysrhythmias, thrombotic complications, and developmental delays.

TABLE 23.3 Selected Shunt Procedures for Children With Cardiac Defects

Shunt Type	Comments
Modified Blalock-Taussig shunt—Subclavian artery to pulmonary artery using Gore-Tex or Impra tube graft	Shunt flow sometimes excessive, requiring use of diuretics Possibility of thrombosis; aspirin usually prescribed postoperatively Easy to ligate at time of definitive correction Shunt size fixed and may become too small as child grows
Sano modification—Right ventricular to pulmonary artery conduit using Gore-Tex graft	Prevents diastolic runoff of systemic blood into the pulmonary arteries Provides a higher diastolic blood pressure and seemingly better coronary perfusion Used in place of the modified Blalock-Taussig shunt in the Norwood procedure
Bidirectional Glenn shunt (cavopulmonary anastomosis)—Superior vena cava to side of right pulmonary artery; blood flows to both lungs	Done as a second shunt; often used as a staging step to a Fontan procedure Can be incorporated into eventual modified Fontan procedure Relieves severe cyanosis and decreases volume overload on ventricle Carries risk of embolic events (mixing defect); aspirin often prescribed Pulmonary arteriovenous fistulas may occur months or years later, causing desaturation (uncommon finding)
Central shunt—Ascending aorta to main pulmonary artery using Gore-Tex graft	Length of shunt acts to restrict blood flow; symptoms of heart failure may occur; diuretic therapy may be required Uncommon; used when modified Blalock-Taussig shunt cannot be used Easy to insert and remove at time of repair Possibility of thrombosis; aspirin usually prescribed postoperatively

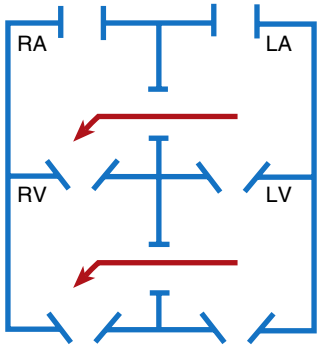


Fig. 23.4 Hemodynamics in defects with increased pulmonary blood flow. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

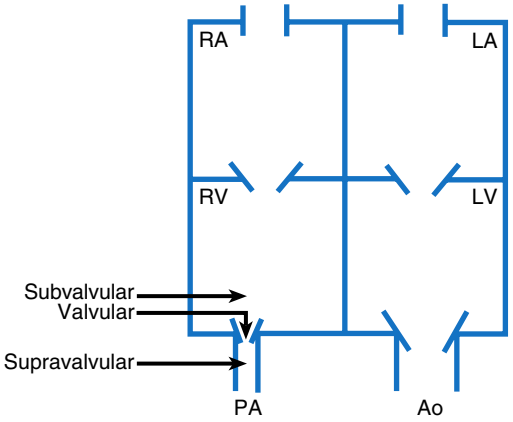

Fig. 23.5 Obstruction to ventricular ejection can occur at the valvular level (shown), below the valve (subvalvular), or above the valve (supravalvular). Pulmonic stenosis is shown here. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle.

Coarctation of the aorta (narrowing of the aortic arch), aortic stenosis, and pulmonic stenosis are typical defects in this group (Box 23.2). Hemodynamically, there is a pressure load on the ventricle and decreased cardiac output. Clinically, infants and children exhibit signs of HF. Children with mild obstruction may be asymptomatic. Rarely, as in severe pulmonic stenosis, hypoxemia may occur.

Defects With Decreased Pulmonary Blood Flow

In this group of defects, there is obstruction of pulmonary blood flow and an anatomic defect (atrial septal defect or ventricular septal defect) between the right and left sides of the heart (Fig. 23.6). Because blood has difficulty exiting the right side of the heart via the pulmonary artery, pressure on the right side increases, exceeding left-sided pressure. This allows desaturated blood to shunt right to left, causing desaturation in the left side of the heart and in the systemic circulation. Clinically, these patients have hypoxemia and usually appear cyanotic. Tetralogy of Fallot and tricuspid atresia are the most common defects in this group (Box 23.3).

Mixed Defects

Many complex cardiac anomalies are classified together in the mixed category (Box 23.4), since survival in the postnatal period depends on mixing of blood from the pulmonary and systemic circulations within the heart chambers. Hemodynamically, fully saturated systemic blood flow mixes with the desaturated pulmonary blood flow, which causes a relative desaturation of the systemic blood. Pulmonary congestion occurs because the differences in pulmonary artery pressure and aortic pressure favor pulmonary blood flow. Cardiac output decreases because of a volume load on the ventricle. Clinically, these patients have a variable picture that combines some degree of desaturation (although cyanosis is not always visible) and signs of congestive heart failure, often requiring multiple surgical interventions, the first being in the first week of life.

Single Ventricle Anatomy

Many of the mixed defects are cardiac anomalies that have a single functioning ventricle. These defects (e.g., hypoplastic left heart syndrome, unbalanced complete atrioventricular canal, double-inlet left ventricle, tricuspid atresia, pulmonary atresia with intact ventricular septum) require a staged approach to single ventricle palliation, allowing the single functioning ventricle to do the work normally done by two ventricles and separating oxygenated blood from deoxygenated blood.

Stage I or Norwood (first week of life)—(1) Establishes systemic blood flow by connecting the right ventricle to the aorta, (2) rebuilds a small aorta and connects it to the ventricle, and (3) creates pulmonary blood flow either through a modified Blalock-Taussig shunt

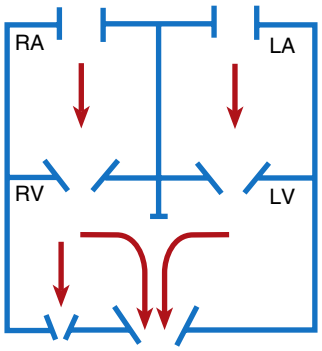

Fig. 23.6 Hemodynamic defects with decreased pulmonary blood flow. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

(3- to 4-mm Gore-Tex tube from the subclavian artery to the pulmonary artery) or a Sano modification (conduit from the right ventricle to the pulmonary artery) (Table 23.3).

Stage II or bidirectional Glenn (3 to 8 months of age)—Creates a direct connection between the superior vena cava and the pulmonary artery, allowing half of the systemic deoxygenated blood to return passively but directly to the lungs (see Table 23.3).

Stage III or Fontan (2 to 4 years of age)—Directs systemic venous return to the lungs without a ventricular pump through surgical connections between the right atrium and the pulmonary artery (Fig. 23.7). A fenestration (opening) is sometimes made in the right atrial baffle to relieve pressure. The patient must have normal ventricular function and a low pulmonary vascular resistance for the procedure to be successful. The modified Fontan procedure separates oxygenated and deoxygenated blood inside the heart and eliminates the excess volume load on the ventricle but does not restore normal anatomy or hemodynamics.

Between the first- and second-stage surgeries, the cardiac circulation is particularly fragile, and the infant requires extra care and careful monitoring at home (Ghanayem, Hoffman, Mussatto, et al., 2003; Petit, Fraser, Mattamal, et al., 2011). Long-term concerns for individuals who have completed single ventricle palliation and are living with Fontan physiology include the development of protein-losing enteropathy, atrial dysrhythmias, late ventricular dysfunction, and developmental delays. They will need lifelong care, including frequent follow-ups, procedures, and medications for most of their life.

CONGESTIVE HEART FAILURE

Congestive heart failure is the inability of the heart to pump an adequate amount of blood to the systemic circulation at normal filling pressures to meet the body's metabolic demands. It can be referred to as either congestive heart failure (CHF) or heart failure (HF). In children, HF occurs secondary to structural abnormalities (e.g., septal defects) that result in increased blood volume and pressure within the heart. It can also result from myocardial failure in which the contractility or relaxation of the ventricle is impaired. This can occur with cardiomyopathy, dysrhythmias, or severe electrolyte disturbances. HF can also occur because of excessive demands on a normal heart muscle, such as sepsis or severe anemia.

Pathophysiology

HF is often separated into two categories, right-sided and left-sided failure. In **right-sided failure**, the right ventricle is unable to pump blood effectively into the pulmonary artery, resulting in increased pressure in the right atrium and systemic venous circulation.

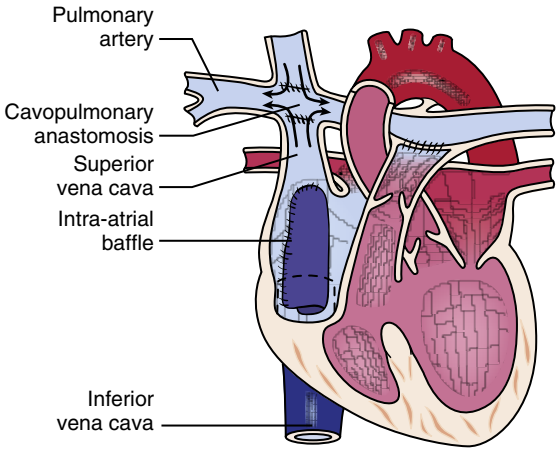

Fig. 23.7 Fontan procedure: third stage of single ventricle palliation.

Systemic venous hypertension causes hepatosplenomegaly and occasionally edema. In **left-sided failure**, the left ventricle is unable to pump blood into the systemic circulation, resulting in increased pressure in the left atrium and pulmonary veins. The lungs become congested with blood, causing elevated pulmonary pressures and pulmonary edema.

Although each type of HF produces different signs and symptoms, clinically it is unusual to observe solely right- or left-sided failure in children. Because each side of the heart depends on adequate function of the other side, failure of one chamber causes a reciprocal change in the opposite chamber.

If the abnormalities precipitating HF are not corrected, the heart muscle becomes damaged. Despite compensatory mechanisms, the heart is unable to maintain an adequate cardiac output. Decreased blood flow to the kidneys continues to stimulate sodium and water reabsorption, leading to fluid overload, increased workload on the heart, and congestion in the pulmonary and systemic circulations (Fig. 23.8).

Clinical Manifestations

The signs and symptoms of HF can be divided into three groups: (1) impaired myocardial function, (2) pulmonary congestion, and (3) systemic venous congestion (Box 23.5). Because these hemodynamic changes occur from different causes and at differing times, the clinical presentation may vary among children.

Diagnostic Evaluation

Diagnosis is made based on clinical symptoms, such as tachypnea and tachycardia at rest, dyspnea, retractions, activity intolerance (especially during feeding in infants), feeding intolerance, weight gain caused by fluid retention, and hepatomegaly. Chest radiography demonstrates cardiomegaly and increased pulmonary blood flow. Ventricular hypertrophy, abnormal rhythm, or decreased voltages appear on the ECG. An echocardiogram is done to determine the cause of HF, such as a congenital heart defect or poor ventricular function.

Therapeutic Management

The goals of treatment are to (1) improve cardiac function (increase contractility and decrease afterload), (2) remove accumulated fluid and sodium (decrease preload and minimize fluid overload), (3) decrease cardiac demands, and (4) improve tissue oxygenation and decrease oxygen consumption. For most infants diagnosed with HF, the cause is CHD. Infants are stabilized on medical therapy and then referred for surgical repair. Today many children are being surgically

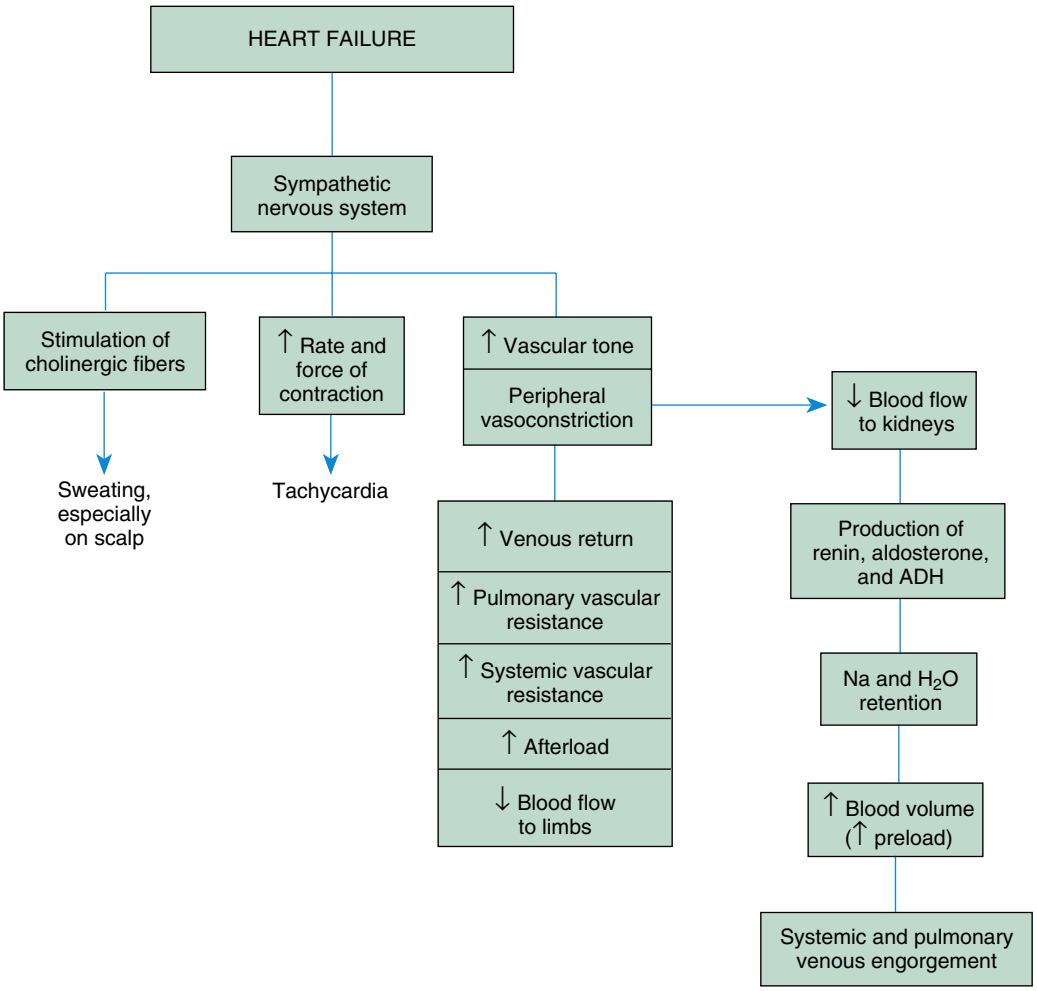

Fig. 23.8 Pathophysiology of heart failure. *ADH,* Antidiuretic hormone.

BOX 23.5 Clinical Manifestations of Heart Failure

Impaired Myocardial Function
Tachycardia
Sweating (inappropriate)
Decreased urinary output
Fatigue
Weakness
Restlessness
Anorexia
Pale, cool extremities
Weak peripheral pulses
Decreased blood pressure (BP)
Gallop rhythm
Cardiomegaly

Pulmonary Congestion
Tachypnea
Dyspnea
Retractions (infants)
Flaring nares
Exercise intolerance
Orthopnea
Cough, hoarseness
Cyanosis
Wheezing
Grunting

Systemic Venous Congestion
Weight gain
Hepatomegaly
Peripheral edema, especially periorbital
Ascites
Neck vein distention (children)

repaired in the neonatal and early infancy stages before the onset of HF symptoms (Margossian, 2008). For children newly diagnosed with HF, the cause may be worsening ventricular function following a previous cardiac repair, cardiomyopathy, arrhythmia, or other conditions. In addition to management of HF, the underlying cause is treated if possible.

Improve Cardiac Function

Three groups of drugs are used to enhance myocardial function in HF: (1) digitalis glycosides (digoxin), which improve contractility, (2) angiotensin-converting enzyme (ACE) inhibitors, which reduce the afterload on the heart and thus make it easier for the heart to pump, and (3) beta-blockers. Myocardial efficiency is improved through administration of digitalis glycosides. The beneficial effects are increased cardiac output, decreased heart size, decreased venous pressure, and relief of edema. In children, digoxin (Lanoxin) is used almost exclusively because of its more rapid onset. Note that the dose is calculated in micrograms (1000 mcg = 1 mg). During initiation, the child is monitored by means of an ECG to observe for the desired effects (prolonged PR interval and reduced ventricular rate) and detect side effects, especially dysrhythmias.

NURSING ALERT

A fall in the serum potassium level enhances the effects of digitalis, increasing the risk of digoxin toxicity. Increased serum potassium levels diminish digoxin's effect. Therefore serum potassium levels must be monitored carefully.

Digoxin is the only oral inotropic agent generally available for infants and children, although other oral inotropic agents are being used in clinical trials in adults. For patients with severe HF, IV inotropic agents such as dopamine or milrinone are used to improve contractility. They are generally given in the ICU setting.

Another group of drugs used in the treatment of HF, the ACE inhibitors, inhibit the normal function of the renin-angiotensin system in the kidney. The ACE inhibitors block the conversion of angiotensin I to angiotensin II so that, instead of vasoconstriction, vasodilation occurs. Vasodilation results in decreased pulmonary and systemic vascular resistance, decreased BP, and a reduction in afterload. It also reduces the secretion of aldosterone, which reduces preload by preventing volume expansion from fluid retention and decreases the risk of hypokalemia. Common medications used in children are captopril (Capoten), enalapril (Vasotec), and lisinopril. The principal side effects of ACE inhibitors are hypotension, cough, and renal dysfunction.

NURSING ALERT

Because angiotensin-converting enzyme (ACE) inhibitors also block the action of aldosterone, the addition of potassium supplements or spironolactone (Aldactone) to the drug regimen of patients taking diuretics is usually not needed and may cause hyperkalemia.

Beta-blockers, specifically carvedilol (Coreg), are the newest medications to be added to the treatment of some children with chronic HF. The α- and β-adrenergic receptors are blocked, causing decreased heart rate, decreased BP, and vasodilation. These medications have been shown to decrease morbidity and mortality in some adults with HF and are being used selectively in children. Side effects included dizziness, headache, and hypotension.

Cardiac resynchronization therapy (CRT) using biventricular pacing is an effective treatment in adult patients with HF and is beginning to be applied in the pediatric population. With pharmacologic therapies described earlier, CRT has the potential to improve cardiac function in this group of patients, including those with a single ventricle (Cecchin, Frangini, Brown, et al., 2009; Dubin, Janousek, Rhee, et al., 2005).

Remove Accumulated Fluid and Sodium

Treatment consists of administration of diuretics, possible fluid restriction, and possible sodium restriction. Diuretics are the mainstay of therapy to eliminate excess water and salt to prevent reaccumulation. The most commonly used agents are listed in Table 23.4. Because furosemide (Lasix) and the thiazides cause potassium depletion, oral potassium supplements and rich dietary sources are often necessary.

Fluid restriction may be required in the acute stages of CHF and must be calculated carefully to avoid dehydrating the child, especially if cyanosis and significant polycythemia are present. Infants rarely need fluid restriction, since CHF makes feeding so difficult that they struggle to take maintenance fluids.

Sodium-restricted diets are used less often in children than in adults to control HF because of their potential negative effects on the child's appetite and ultimate growth. If salt intake is restricted, additional table salt and highly salted foods are avoided. Low-salt formulas are available but are used infrequently, since infants need a normal sodium source to offset the sodium depletion of chronic diuretic therapy.

Decrease Cardiac Demands

To lessen the workload on the heart, metabolic needs are minimized by (1) providing a neutral thermal environment to prevent cold stress in infants, (2) treating any existing infections, (3) reducing the effort of breathing (by placement in semi-Fowler position), (4) using medication to sedate an irritable child, and (5) providing for rest and decreasing environmental stimuli.

Improve Tissue Oxygenation

The preceding measures serve to increase tissue oxygenation, either by improving myocardial function or by lessening tissue oxygen demands. In addition, supplemental cool humidified oxygen may be administered to increase the amount of available oxygen during inspiration. Oxygen administration is especially helpful in patients with pulmonary edema, intercurrent respiratory tract infections, and increased pulmonary vascular resistance (oxygen is a vasodilator that decreases pulmonary vascular resistance).

NURSING ALERT

Oxygen is a drug and is administered only with an appropriate order. There are some uncommon circumstances in patients with complex hemodynamics in which oxygen can be detrimental.

An oxygen hood, nasal cannula, or face tent is used to deliver oxygen. Nasal cannulas are ideal for long-term oxygen administration because the child can be ambulatory and can easily eat and drink. Cool humidification is necessary to counteract the drying effect of oxygen. The amount of cool humidity is carefully regulated to prevent chilling.

QUALITY PATIENT OUTCOMES: Heart Failure

- Adequate cardiac output
- Decreased cardiac demands
- Improved respiratory function
- No evidence of fluid excess
- Adequate support and education

Nursing Care Management

Infants or children with CHF may be acutely ill, and some may require intensive care until their symptoms improve. Expert nursing care is essential to reduce the cardiac demands that strain the failing heart muscle (see Next-Generation NCLEX® Examination-Style Unfolding Case Study box). During this time the child and family require emotional support; for some children, severe HF represents end-stage cardiac disease. Although the objectives of nursing care are the same, interventions for infants often differ from those for older children.

Assist in Measures to Improve Cardiac Function

Digoxin is used to improve cardiac function. Digoxin is a potentially dangerous drug because the margin of safety between therapeutic, toxic, and lethal doses is very narrow. Many toxic responses are extensions of its therapeutic effects. The nurse's responsibility in administering digoxin includes calculating and giving the correct dosage and observing for signs of toxicity. The child's apical pulse is always checked before administering digoxin. As a rule, the drug is not given

TABLE 23.4 Diuretics Used in Heart Failure

Actions	Comments	Nursing Care Management
Furosemide (Lasix)		
Blocks reabsorption of sodium and water in proximal renal tubule and interferes with reabsorption of sodium in the loop of Henle and in the most proximal portion of distal tubule	Drug of choice in severe heart failure Causes excretion of chloride and potassium (hypokalemia may precipitate digitalis toxicity)	Begin to record output as soon as drug is given. Observe for dehydration caused by profound diuresis. Observe for side effects (e.g., nausea and vomiting, diarrhea, ototoxicity, hypokalemia, dermatitis, postural hypotension). Encourage consumption of foods high in potassium and/or give potassium supplements. Monitor chloride and acid-base balance with long-term therapy. Observe for signs of digoxin toxicity.
Chlorothiazide (Diuril)		
Acts directly on distal tubules to decrease sodium, water, potassium, chloride, and bicarbonate absorption	Less frequently used drug Causes hypokalemia, acidosis in large doses	Observe for side effects (e.g., nausea, weakness, dizziness, paresthesia, muscle cramps, skin eruptions, hypokalemia, acidosis). Encourage consumption of foods high in potassium and/or give potassium supplements.
Spironolactone (Aldactone)		
Blocks action of aldosterone, which promotes retention of sodium and excretion of potassium	Weak diuretic Has potassium-sparing effect; frequently used with thiazides, furosemide Poorly absorbed from gastrointestinal tract Takes several days to achieve maximum actions	Observe for side effects (e.g., skin rash, drowsiness, ataxia, hyperkalemia). Do not administer potassium supplements.

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

The Child With Coarctation of the Aorta

Day 1, 8:00 am Hospitalization

1. The nurse is caring for a 3-week-old male with congenital heart disease (CHD). At birth he initially showed no signs or symptoms, but within the second week of life he developed symptoms of heart failure (HF). He was found to have coarctation of the aorta and is now under the care of the cardiology team and scheduled for surgery. The infant is experiencing increased signs of HF and was hospitalized early this morning. His care is focused on preventing further symptoms before he goes to surgery. What are the most important signs of HF that the nurse would look for in this infant? **Select all that apply.**
   - A. Edema
   - B. Tachypnea
   - C. Weight loss
   - D. Tachycardia
   - E. Hypotension
   - F. Warm extremities
   - G. Feeding difficulty
   - H. Slow peripheral pulses
   - I. Prolonged capillary refill, longer than 2 or 3 seconds
   - J. Ineffective peripheral circulation, cool extremities
2. The nurse reviews the history of this 3-week old infant and reads that he is diagnosed with coarctation of the aorta. The nurse realizes that the symptoms experienced by the infant are caused by this congenital disorder. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.** Coarctation of the aorta is described as the _____1_____ of the aortic arch that results in _____2_____ cardiac output. A classic finding is _____3_____ pulses in the arms and _____4_____ femoral pulses.

Options for 1	Options for 2	Options for 3 and 4
widening	Increased	bounding = 3
absence	Decreased	Widening
narrowing	lack of	weak or absent = 4
crossing	Absent	Narrowing
absence	Complex	Unstable

Day 1, 2:00 pm Hospitalization

3. Surgery is planned for tomorrow. The infant's BP is 120/70mmHg, and the pulses in his arms are 220 beats/min and bounding. You find weak femoral pulses at 40 beats/min and his extremities are cool to touch. His breathing is at 36 breaths/min, and no nasal flaring or intercostal retractions are noted at this time. His color is pale without mottling. The infant is not on mechanical ventilation at this time. What are **priority** nursing actions? **Use an X to indicate which nursing actions listed below are Emergent (appropriate or immediately necessary) or Not Emergent (not appropriate or not immediately necessary) for the patient's care at this time.**

Nursing Action	Emergent	Not Emergent
Frequently assess and record heart rate, respiratory rate, blood pressure (BP), and any signs or symptoms of decreased cardiac output.		
Administer cardiac drugs on schedule. Assess and record any side effects or any signs and symptoms of toxicity. Follow hospital protocol for administration.		
Administer cool humidified oxygen to increase available oxygen during inspiration.		
Change the infant's position every 2 hours to prevent skin breakdown.		
Keep accurate record of intake and output.		
Weigh infant on same scale at same time of day.		
Maintain a 3-hour feeding schedule.		
Restrict fluids if the intake and output is unbalanced.		

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—cont'd

The Child With Heart Failure

Day 1, 4:00 pm

4. The nurse continues to closely observe the infant since there are obvious signs of heart failure related to the congenital defect. **Indicate which nursing action listed in the far-left column is appropriate for each potential complication listed in the middle column. Indicate the nursing action number in the far-right column. Note that not all actions will be used.**

Nursing Action	Potential Complication	Nursing Action to Prevent Complication
1. Assess and record heart rate, respiratory rate, blood pressure (BP), and any signs or symptoms of altered cardiac output every 2 to 4 hours.	Decreased urinary output is a symptom of heart failure and could go unnoticed	
2. Administer cardiac drugs on schedule. Assess and record any side effects or any signs and symptoms of toxicity. Follow hospital protocol for administration.	Undetected changes in vital signs and infant's physical status that reflect altered cardiac output and high blood pressure	
3. Keep accurate record of intake and output.	Excess water and salt because fluid retention commonly occurs with heart failure	`
4. Weigh infant on same scale at same time of day as previously. Document results and compare to previous weight.	Dangers inherent in failure to administer cardiac drugs as prescribed and to perform careful assessment before administration	
5. Administer diuretics on schedule. Assess and record effectiveness and any side effects noted.		
6. Offer small, frequent feedings to infant's tolerance.		
7. Organize nursing care to allow infant uninterrupted rest.		

Day 5 Hospitalization, 3 days post-surgery

5. The infant underwent surgery 3 days ago. Resection of the coarcted portion of the aorta was performed. Cardiopulmonary bypass was not required due to this defect being outside the heart and pericardium. The infant is in stable condition. The nurse is performing a change of shift assessment of the infant. What assessment findings demonstrate that the infant is stable at this time? **Select all that apply.**
   - A. Color pink
   - B. Lack of edema
   - C. Successful feeding
   - D. Heart rate 120 beats/min
   - E. Skin warm to touch
   - F. Weight gain (0.5kg/day)
   - G. Respiratory 48 breaths/min
   - H. Lack of distended neck veins
   - I. Strong and equal peripheral pulses
   - J. Brisk capillary refill within 5 seconds
   - K. Adequate urinary output (1 to 2 ml/kg/h)

Day of Discharge

6. The infant has recovered well from surgery with no complications. The nurse is preparing for discharge and notes that both parents are nervous and afraid of taking their infant home. What education would the nurse provide to the family at this time? **Use an X for the health teaching evaluation below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
Discuss the characteristics of COA and the surgery done to repair the obstructive defect.			
Review the infant's daily care including medication administration.			
Review signs and symptoms that could be of concern (fever, blue skin color, poor eating).			
Inform parents to purchase a pulse oximeter before taking the infant home so they can constantly monitor the oxygen level.			
Keep the infant supine at all times to assist with blood flow.			
Parents want to purchase another bed for the infant to keep her close to them at night.			
Give parents the opportunity to express their fears and concerns.			

BOX 23.6 Common Signs of Digoxin Toxicity in Children

Gastrointestinal	Cardiac
Nausea	Bradycardia
Vomiting	Dysrhythmias
Anorexia	

if the pulse is below 90 to 110 beats/min in infants and young children or below 70 beats/min in older children (the cutoff point for adults is 60 beats/min). The nurse should also use judgment in evaluating the pulse rate. If it is significantly lower than the previous recording, the dose should be withheld until the practitioner is notified.

The apical rate is measured because a pulse deficit (radial pulse rate lower than apical) may be present with decreased cardiac output. The pulse is auscultated for 1 full minute to evaluate alterations in rhythm. If the child is monitored by ECG, a rhythm strip is obtained and attached to the chart for rate and rhythm analysis, such as abnormal lengthening of the PR interval (>50% increase over the predigitalization interval) and dysrhythmias.

Digoxin is a potentially dangerous drug because of its narrow margin of safety of therapeutic, toxic, and lethal doses. Many toxic responses are extensions of its therapeutic effects. Therefore the nurse must maintain a high index of suspicion for signs of toxicity when administering digoxin (Box 23.6).

Because digoxin toxicity can occur from accidental overdose, great care must be taken in properly calculating and measuring the dosage. When converting milligrams to micrograms to milliliters, the nurse carefully checks the placement of the decimal point, because an error causes a significant change in dosage. For example, 0.1 mg is 10 times the dosage of 0.01 mg.

These same principles are taught to parents in preparation for the child's discharge, although the correct dose in milliliters is usually specified on the container, which reduces potential errors in calculation. The nurse watches the parent measure the elixir in the dropper and stresses the level mark as the meniscus of the fluid that is observed at eye level. Parents are also taught the signs of toxicity. According to the practitioner's preference, they may be taught to take the pulse before giving the drug, and a return demonstration of the procedure from the parents or another principal caregiver is included as part of the teaching plan.

Minimize Fluid Overload

Diuresis assists in decreasing preload and minimizing volume overload. When diuretics are given, the nurse records fluid intake and output and monitors body weight at the same time each day to evaluate the benefit of the drug. Because profound diuresis may cause dehydration and electrolyte imbalance (e.g., loss of sodium, potassium, chloride, bicarbonate), the nurse observes for signs indicating one of these complications, as well as signs and symptoms suggesting reactions to the drugs. Give diuretics early in the day to children who are toilet trained to avoid the need to urinate at night. If potassium-losing diuretics are given, the nurse encourages consumption of foods high in potassium, such as bananas, oranges, whole grains, legumes, and leafy vegetables, and administers prescribed supplements.

Fluid restriction is rarely necessary in infants because of their difficulty in feeding. With toddlers and preschoolers, it is psychologically advantageous to give small amounts of liquid in small cups so that the containers appear full. Older children's cooperation is gained by placing them in charge of recording their fluid intake.

Reduce Afterload

For patients receiving ACE inhibitors for afterload reduction, the nurse should carefully monitor BP before and after dose administration, observe for symptoms of hypotension, and notify the practitioner if BP is low. Numerous medications affecting the kidney can potentiate renal dysfunction, so children taking multiple diuretics and an ACE inhibitor require careful assessment of serum electrolytes and renal function.

Decrease Cardiac Demands

The infant requires rest and conservation of energy for feeding. Every effort is made to organize nursing activities to allow for uninterrupted periods of sleep. Whenever possible, parents are encouraged to stay with their infant to provide the holding, rocking, and cuddling that help children sleep more soundly. To minimize disturbing the infant, changing bed linens and complete bathing are done only when necessary. Feeding is planned to accommodate the infant's sleep and wake patterns. The child is fed at the first sign of hunger, such as when sucking on fists, rather than waiting until he or she cries for a bottle because the stress of crying exhausts the limited energy supply. Because infants with HF tire easily and may sleep through feedings, smaller feedings every 3 hours may be helpful. Gavage feedings may be instituted to provide adequate nutrition and allow the infant to rest.

Every effort is made to minimize unnecessary stress. Older children need an explanation of what is happening to them to decrease anxiety about their illness and necessary treatments, such as cardiac monitoring, oxygen administration, and medications. Outlining a plan for the day, preparing the child for tests and procedures, providing quiet activities, and providing adequate rest periods are all helpful interventions with older children. Some infants and children require sedation during the acute phase of illness to allow them to rest.

Temperature is carefully monitored because hyperthermia or hypothermia increases the need for oxygen. Febrile states are reported to the physician because infection must be promptly treated. Maintaining body temperature is important for children who are receiving cool, humidified oxygen and for children who tend to be diaphoretic, losing heat via evaporation.

Skin breakdown from edema is prevented with a change of position every 2 hours (from side to side while in semi-Fowler position) and use of a pressure-relieving mattress or bed. The skin, especially over the sacrum, is checked for evidence of redness from pressure.

Reduce Respiratory Distress

Careful assessment, positioning, and oxygen administration can reduce respiratory distress. Respirations are counted for 1 full minute during a resting state. Any evidence of increased respiratory distress is reported, because this may indicate worsening heart failure.

Infants are positioned to encourage maximum chest expansion, with the head of the bed elevated; they should sit up in an infant seat or be held at a 45-degree angle. Children may prefer to sleep on several pillows and remain in a semi-Fowler or high-Fowler position during waking hours.

The infant or child is often given humidified supplemental oxygen via oxygen hood or tent, nasal cannula, or mask. The child's response to oxygen therapy is carefully evaluated by noting respiratory rate, ease of respiration, color, and especially oxygen saturation as measured by oximetry.

Respiratory tract infections can exacerbate CHF and should be treated appropriately and prevented if possible. The child should be protected from persons with respiratory tract infections and have a noninfectious roommate. Good hand washing is practiced before

and after caring for any hospitalized child. Antibiotics may be given to combat respiratory tract infection. The nurse ensures that the drug is given at equally divided times over a 24-hour schedule to maintain high blood levels of the antibiotic.

Maintain Nutritional Status

Meeting the nutritional needs of infants with CHF or serious cardiac defects is a nursing challenge. The metabolic rate of these infants is greater because of poor cardiac function and increased heart and respiratory rates. Their caloric needs are greater than those of the average infant because of their increased metabolic rate, yet fatigue limits their ability to take in adequate calories. For a fragile infant with serious CHD, feeding is similar to exercise in an adult, and the infant often does not have the energy or cardiac reserve to do extra work. The nurse seeks measures to enable the infant to feed easily without excess fatigue and to increase the caloric density of the formula.

The infant should be well rested before feeding and fed soon after awakening so as not to expend energy on crying. A 3-hour feeding schedule works well for many infants. (Feeding every 2 hours does not provide enough rest between feedings, and a 4-hour schedule requires an increased volume of feeding, which many infants are unable to take.) The feeding schedule should be individualized to the infant's needs. A feeding goal of 150 ml/kg/day and at least 120 kcal/kg/day is common for newborns with significant heart disease (Steltzer, Rudd, & Pick, 2005). Infants should be well supported and fed in a semiupright position. The infant may need to rest frequently and may need to have the jaw and cheeks stroked to encourage sucking. Generally, giving an infant about a half-hour to complete a feeding is reasonable. Prolonging the feeding time can exhaust the infant and decrease the rest period between feedings.

Infants with feeding difficulties are often gavage fed using a nasogastric tube to supplement their oral intake and ensure adequate calories. Feeding team colleagues may be able to recommend bottle nipples and techniques to help the infant. If infants are very stressed and fatigued, in respiratory distress, or tachypneic to 80 to 100 breaths/min, oral feedings may be withheld and all nutrition given by gavage feedings. Gavage feedings are usually a temporary measure until the infant's medical status improves and nutritional needs can be met through oral feedings. Some infants with severe HF, neurologic deficits, or significant gastroesophageal reflux may need placement of a gastrostomy tube to allow adequate nutrition.

The caloric density of formulas is frequently increased by concentration and then adding Polycose, medium-chain triglyceride oil, or corn oil. Infant formulas provide 20 kcal/oz, and the use of additives can increase the calories to 30 kcal/oz or more. This allows the infant to obtain more calories despite a smaller volume intake of formula. The caloric density of the formula needs to be increased slowly (by 2 kcal/oz/day) to prevent diarrhea or formula intolerance. Breastfeeding mothers are encouraged to provide the infant with alternating feedings of breast milk and high-calorie formulas. Some lactating mothers prefer to feed the child expressed breast milk that has been fortified with Similac or Enfamil powder, Polycose, or corn oil to increase caloric intake. A diet plan specific to the individual infant's needs is calculated and prescribed by the nutritionist in collaboration with the other health personnel.

Support the Child and Family

Heart failure is a serious complication of heart disease. Parents and older children are usually acutely aware of the critical nature of the condition. Because stress places additional demands on cardiac function, the nurse should focus on reducing anxiety through anticipatory preparation, frequent communication with the parent regarding the child's progress, and constant reassurance that everything possible is being done.

Home care involves many of the same interventions discussed in Plan for Discharge and Home Care later in the chapter. The nurse teaches the family about the medications that need to be administered and alerts them to the signs of worsening HF that require medical attention, such as increased sweating, decreased urinary output (noted in fewer wet diapers or infrequent use of the toilet), or poor feeding. Every effort is made to improve the family's adherence to the medication schedule by adapting the schedule to their usual home routines, avoiding medications during the night, making it as simple as possible, and using charts or visual aids to remember when to give medications (see Chapter 20). If HF is the end stage of a severe heart defect, the nurse cares for this child as for any child who is terminally ill, using the principles discussed in Chapter 17.

HYPOXEMIA

Hypoxemia refers to an arterial oxygen tension (or pressure, PaO_2) that is lower than normal and can be identified by a decreased arterial saturation or a decreased PaO_2. **Hypoxia** is a reduction in tissue oxygenation that results from low oxygen saturations and PaO_2 and results in impaired cellular processes. **Cyanosis** is a blue discoloration in the mucous membranes, skin, and nail beds of the child with reduced oxygen saturation. It results from the presence of deoxygenated hemoglobin (hemoglobin not bound to oxygen) at a concentration of 5 g/dl of blood. Cyanosis is usually apparent when arterial oxygen saturation is 85% or lower. Determination of cyanosis is subjective. It can vary depending on skin pigment, quality of light, color of the room, or clothing worn by the child. The presence of cyanosis may not accurately reflect arterial hypoxemia because both oxygen saturation and the amount of circulating hemoglobin are involved. Children with severe anemia may not be cyanotic despite severe hypoxemia because the hemoglobin level may be too low to produce the characteristic blue color. Conversely, patients with polycythemia may appear cyanotic despite a near-normal PaO_2. Heart defects that cause hypoxemia and cyanosis result from desaturated venous blood (blue blood) entering the systemic circulation without passing through the lungs.

Clinical Manifestations

Over time, two physiologic changes occur in the body in response to chronic hypoxemia: polycythemia and clubbing. **Polycythemia**, an increased number of red blood cells, increases the oxygen-carrying capacity of the blood. However, anemia may result if iron is not readily available for the formation of hemoglobin. Polycythemia increases the viscosity of the blood and crowds out clotting factors. **Clubbing**, a thickening and flattening of the tips of the fingers and toes, is thought to occur because of chronic tissue hypoxemia and polycythemia (Fig. 23.9). Infants with mild hypoxemia may be asymptomatic except for cyanosis and exhibit near-normal growth and development. Those with more severe hypoxemia may exhibit fatigue with feeding, poor weight gain, tachypnea, and dyspnea. Severe hypoxemia resulting in tissue hypoxia is manifested by clinical deterioration and signs of poor perfusion.

Hypercyanotic spells, also referred to as **blue spells** or **tet spells** because they are often seen in infants with tetralogy of Fallot, may occur in any child whose heart defect includes obstruction to pulmonary blood flow and communication between the ventricles. The infant becomes acutely cyanotic and hyperpneic because sudden infundibular spasm decreases pulmonary blood flow and increases

Fig. 23.9 Clubbing of the fingers.

right-to-left shunting (the proposed mechanism in tetralogy of Fallot). Spells, rarely seen before 2 months of age, occur most frequently in the first year of life. They occur more often in the morning and may be preceded by feeding, crying, defecation, or stressful procedures. Because profound hypoxemia causes cerebral hypoxia, hypercyanotic spells require prompt assessment and treatment to prevent brain damage or possibly death.

Persistent cyanosis as a result of cyanotic heart defects places the child at risk for significant **neurologic complications**. Cerebrovascular accident (CVA; stroke), brain abscess, and developmental delays (especially in motor and cognitive development) may result from chronic hypoxia.

Diagnostic Evaluation

Cyanosis in a newborn can be the result of cardiac, pulmonary, metabolic, or hematologic disease, although cardiac and pulmonary causes occur most often. To distinguish between the two, a hyperoxia test is helpful. The infant is placed in a 100% oxygen environment, and blood parameters are monitored. A PaO_2 of 100 mm Hg or higher suggests lung disease, and a PaO_2 lower than 100 mm Hg suggests cardiac disease (Park, 2014). An accurate history, a chest radiograph, and especially an echocardiogram contribute to the diagnosis of cyanotic heart disease.

Therapeutic Management

Newborns generally exhibit cyanosis within the first few days of life as the ductus arteriosus, which provided pulmonary blood flow, begins to close. Prostaglandin E1, which causes vasodilation and smooth muscle relaxation, thus increasing dilation and patency of the ductus arteriosus, is administered intravenously to reestablish pulmonary blood flow. The use of prostaglandins has been life-saving for infants with ductus-dependent cardiac defects. The increase in oxygenation allows the infant to be stabilized and have a complete diagnostic evaluation performed before further treatment is needed.

In the infant with tetralogy of Fallot, hypercyanotic spells occur suddenly, and prompt recognition and treatment are essential. In the hospital setting, spells are often seen during blood drawing or IV insertion, when the child is highly agitated, or after cardiac catheterization. Treatment of a hypercyanotic spell is outlined in the Nursing Care Guidelines box. Morphine, administered subcutaneously or through an existing IV line, helps reduce infundibular spasm. A spell indicates the need for prompt surgical treatment.

The cyanotic infant and child are well hydrated to keep the hematocrit and blood viscosity within acceptable limits to reduce the risk of CVAs. The infant is monitored closely for anemia because of the risk of CVAs and the reduced arterial oxygen-carrying capacity that occurs. Iron supplementation and possibly blood transfusion are used as needed.

Respiratory tract infections or reduced pulmonary function from any cause can worsen hypoxemia in the cyanotic child. Aggressive pulmonary hygiene, chest physical therapy, administration of antibiotics, and use of oxygen to improve arterial saturations are important interventions.

NURSING CARE GUIDELINES

Treating Hypercyanotic Spells

Place infant in knee-chest position (Fig. 23.10).
Use a calm, comforting approach.
Administer 100% "blow-by" oxygen.
Give morphine subcutaneously or through an existing intravenous (IV) line.
Begin IV fluid replacement and volume expansion if needed.
Repeat morphine administration.

Fig. 23.10 Infant held in a knee-chest position.

Surgical Intervention

Many cardiac causes of hypoxemia can be corrected surgically and are described in the discussion of particular cardiac defects (see Boxes 23.1 to 23.4). However, some severely hypoxemic newborns have cardiac defects, in particular those with single ventricle anatomy, which are not amenable to corrective repair and may undergo a three-stage surgical palliation. In the first surgery, the shunt serves the same purpose as the ductus arteriosus: to increase blood flow to the lungs through a systemic artery–to–pulmonary artery connection. The two most common connections are either (1) a modified Blalock-Taussig operation, in which a 3- to 3.5-mm tube graft is placed between the right or left subclavian artery and the pulmonary artery on the same side or (2) a Sano, in which a Gore-Tex tube is placed between the right ventricle and the pulmonary artery. Table 23.3 outlines the most commonly performed shunt procedures today.

Nursing Care Management

The general appearance of infants and children with significant cyanosis poses unique concerns. Blue lips and fingernails are obvious signs of their hidden cardiac defect. Clubbing and small, thin stature in older children further indicate severe heart disease. Adolescents are especially concerned about their body image; children with cyanosis are

often teased about their appearance and singled out as different. Many children, when asked what surgery will do, reply, "Make me pink." Parents are often fearful of their child's bluish color because cyanosis is usually associated with lack of oxygen and severe illness. They also must deal with comments from relatives, friends, and strangers about their child's abnormal color. They need a simple explanation of hypoxemia and cyanosis, and reassurance that cyanosis does not imply a lack of oxygen to the brain. Their questions and fears need to be addressed in a calm, supportive manner, and positive aspects of their child's growth and development are emphasized.

Dehydration must be prevented in children with hypoxemia because it potentiates the risk of CVAs. Fluid status is carefully monitored, with accurate intake and output and daily weight measurements. Maintenance fluid therapy is the minimum requirement, supplemental fluids should be readily available, and gavage feeding or IV hydration is given to children unable to take adequate oral fluids. Fever, vomiting, and diarrhea can cause dehydration and require prompt treatment. Parents are instructed in the importance of adequate fluid intake and measures to prevent dehydration. An oral electrolyte solution should be available at home in the event that the infant is unable to tolerate the usual formula. The practitioner should be notified of fever, vomiting, diarrhea, or other problems.

Preventive measures and accurate assessment of respiratory infection are important nursing considerations. Any compromise in pulmonary function will increase the infant's hypoxemia. Good hand washing and protection from individuals with an obvious respiratory tract infection are important. Aggressive pulmonary hygiene, treatment with antibiotics or antiviral agents as indicated, and supplemental oxygen to decrease hypoxemia are necessary measures. Infants may need to be gavage fed or given parenteral hydration if respiratory distress prevents oral feeding.

! NURSING ALERT

Intracardiac shunting of blood from the right side (desaturated) to the left side of the heart allows air in the venous system to go directly to the brain, resulting in an air embolism. Therefore all IV lines should have filters in place to prevent air from entering the system, the entire tubing should be checked for air, all connections should be taped securely, and any air should be removed.

NURSING CARE OF THE FAMILY AND CHILD WITH CONGENITAL HEART DISEASE

When a child is born with a severe cardiac anomaly, parents face the immense psychologic and physical tasks of adjusting to the birth of a child with special needs. Family issues and nursing interventions to support the family are similar to those discussed in Chapters 10 and 19. The following discussion is primarily directed (1) toward the family of an infant who has a serious heart defect requiring home care before definitive repair and (2) toward preparation and care of the child and family when invasive procedures (catheterization and surgery) are performed. For nursing care related to the child with hypoxemia and HF, the reader should refer to earlier discussions of these topics.

Nursing care of the child with a congenital heart defect begins as soon as the diagnosis is suspected. Prenatal diagnosis of congenital heart defects is becoming increasingly frequent. New demands are being placed on nurses to counsel and support families as they prepare for the birth of these infants.

HELP THE FAMILY ADJUST TO THE DISORDER

When parents learn of the heart defect, they are often initially in a period of shock, followed by high anxiety and fear that their child may die. The family needs time to grieve before they can assimilate the meaning of the defect. Unfortunately, the demands for medical treatment may not allow this, instead necessitating that the parents immediately give informed consent for diagnostic-therapeutic procedures. The nurse can be instrumental in supporting parents in their loss, assessing their level of understanding, supplying information as needed, and helping other members of the health care team understand the parents' reactions (see Family-Centered Care box).

FAMILY-CENTERED CARE

Diagnosis of Heart Disease

Remember, we don't have your experience. We don't see children every day who have heart disease. We would have been upset finding out our child had to have his tonsils out. How could we ever be prepared for this? Please remember, we only know people who have trivial heart murmurs. How could we ever expect this to happen? And to us, this is the worst problem we've ever heard of.

We still fear most what we don't know and understand. Be honest with us. If you don't know either, tell us. But at least don't leave us wondering about what you know and we don't. Not knowing anything really can be worse than knowing something bad. Be honest but don't strip us of hope.

Please, remember we are trying to learn complex information in a moment of time. And trying to learn it in a context of great pain and emotional investment. This is our lives you're talking about. Please be thorough but keep it simple. Tell us again, maybe even again and again, when we can hear better.

From Schrey, C., & Schrey, M. A. (1994). Parent's perspective: Our needs and our message. *Critical Care Nursing Clinics of North America, 6*(1), 113–119.

Severely ill newborns usually remain in the hospital. Parent-infant attachment is supported by encouraging parents to hold, touch, and look at their child, and providing time and privacy for the parents to spend with their newborn. (See Chapter 8 for suggestions on promoting attachment between parents and their hospitalized newborn.)

The effect of a child with a serious heart defect on the family is complex. No member, regardless of the degree of positive adjustment, is unaffected. Mothers frequently feel inadequate in their mothering ability because of the complex care infants with congenital heart defects require. They often feel exhausted from the pressures of caring for these children and the other family members. Fathers and siblings may feel neglected and resentful, which is a reaction similar to the feelings toward family members with other chronic conditions (see Chapter 17). Parents may not feel confident leaving the child in another person's care. This often sets up a trap for parents, especially mothers, who become locked into the child's care with no relief. Although the fears are justified, they can be minimized by gradually teaching someone (a reliable relative or neighbor) how to care for the child.

The need to maintain discipline and set consistent limits can be difficult for parents. Using behavior modification techniques, in the form of either concrete awards (e.g., a favorite activity) or social reinforcement (e.g., approval), can be effective. To prevent later problems, it is necessary to begin discussions with parents while the child is in infancy regarding managing discipline as the child gets older.

The child also needs opportunities for normal social interaction with peers. These children do not need to be prevented from playing with other children because of concerns regarding overexertion. Children usually limit their activities if allowed to set their own pace.

A child with CHD may constitute a long-term family crisis. Frequently, the continuing unremitting stresses of care—physical exhaustion, financial costs, emotional upset, fear of death, and concern for the child's future—are not fully appreciated by those caring for the family. Even when the child's condition is stabilized or corrected, the family may need to make adjustments in their lifestyle.

EDUCATE THE FAMILY ABOUT THE DISORDER

When parents are ready to hear about the heart condition, they require a clear explanation based on their level of understanding. A review of the basic structure and function of the heart is helpful before describing the defect. A simple diagram, pictures, or a model of the heart can help parents visualize the heart and the congenital defect. Parents appreciate receiving written information about the specific condition. Health care professionals should take advantage of subsequent encounters to assess parental understanding of the condition and clarify information as needed.

Parents often use the Internet and social media to obtain information about their child's heart defect and support through contacts with other parents and parent groups.[a] Social media plays an important role for many families affected by congenital anomalies and offers a place for them to provide support, seek education, and make friends with other families sharing similar experiences (Jacobs, Boyd, Brennan, et al., 2016). It is important for parents to realize that not all websites offer medically accurate information and that information from other parents might not be applicable to their own situation. Some children with rare, complex heart defects require individualized treatment plans, and general information on the Internet or in books may not apply to these children. Parents should discuss information they have received from other sources with their health care team, in particular the cardiologist.

Information given to the child must be tailored to the child's developmental age. As the child matures, the level of information is revised to meet the child's new cognitive level. Preschoolers need basic information about what they will experience more than about what is occurring physiologically. School-age children benefit from a concrete explanation of the defect. Including the child at this age, early in their own health care and education about their condition, will improve self-care and their own accountability (Mickley, Burkhart, & Sigler, 2013). Preadolescents and adolescents often appreciate a more detailed description of how the defect affects their heart. Children of all ages need to express their feelings about the diagnosis.

HELP THE FAMILY MANAGE THE ILLNESS AT HOME

Parents are the child's principal caregivers and need to develop a positive, supportive working relationship with the health care team. Because most children spend most of their time at home with episodic trips to the hospital, parents manage their child's illness on a daily basis. They monitor for signs of illness, give medications and treatments, bring their child to appointments, work with a variety of caregivers, and alert the team about problems. Successful relationships are partnerships between parents and caregivers that are built on mutual trust and respect. Good communication among the family, the cardiology specialists, and the primary care practitioner is essential. As children reach adolescence, they begin to take a larger role in managing their illness and making decisions about their care.

Parents should be aware of the symptoms of their child's cardiac condition and signs of worsening clinical status. Parents of children who may develop HF should be familiar with the symptoms (see Box 23.5) and know when to contact the practitioner. Parents of children with cyanosis should be informed about fluid management and hypercyanotic spells. Parents should have an information sheet with their child's diagnosis, significant treatments such as surgical procedures, allergies, other health care problems, current medications, and health care providers' contact numbers available in case of emergencies and to share with other caregivers such as teachers, babysitters, and daycare providers.

The family also needs to be knowledgeable about the therapeutic management of the disorder and the role that surgery, other procedures, medications, and a healthy lifestyle play in maintaining good health. Medications play a critical role in managing some cardiac conditions, such as dysrhythmias, severe HF, anticoagulation for artificial valves, and antirejection medications after heart transplantation. Some patients must take multiple medications daily for their lifetime. Many medications can be dangerous if taken incorrectly and require close monitoring. Parents are taught the correct procedure for giving medications and cautioned to keep them in a safe area to prevent accidental ingestion.

Another area of parental concern is the child's level of physical activity. Most children do not need to restrict activity, and the best approach is to treat the child normally and allow self-limited activity. Exceptions to self-determined activity primarily involve strenuous recreational and competitive sports in children with specific cardiac problems. Activities and exercise restrictions should be discussed with the child's cardiologist. In 2013 the American Heart Association published guidelines for promotion of physical activity in children and adults with CHD. Regular exercise can assist the child with CHD in maintaining a healthy weight, foster normal development, help with self-esteem, and help with acceptance into peer groups (Longmuir, Brothers, de Ferranti, et al., 2013).

Infants and children with CHD require good nutrition. Breastfeeding is possible for many infants with CHD. Countering a common misconception that breastfeeding would not be possible for these infants because they would get tired or exhibit poor growth, Barbas and Kelleher (2004) found that breastfeeding could be successful with adequate support and education of the mother. Providing adequate nutrition to infants with HF or complex congenital defects is especially difficult due to their high caloric requirements and inability to suck effectively because of fatigue and tachypnea. Instructing parents in feeding methods that decrease the work of the infant and giving high-calorie formula are important interventions.

Infants with heart disease should be immunized according to the current guidelines. Immunization schedules may need to be modified around times of acute illness or surgical procedures (Smith, 2001). Infants and children younger than 2 years of age with unrepaired heart defects, cyanotic lesions, pulmonary hypertension, or a history of prematurity should receive the vaccine for respiratory syncytial virus (RSV) according to the American Academy of Pediatrics recommendations, which are updated annually. Use of the RSV vaccine palivizumab has been shown to reduce hospitalization due to RSV infection in infants and young children with hemodynamically significant CHD (Feltes, Cabalka, Meissner, et al., 2003) (see Chapter 6).

Infants and children who have serious heart disease are at risk for developmental delays (Majnemer, Limperopoulous, Shevell, et al., 2009). There is growing interest in characterizing and mitigating these outcomes through early identification and initiation of integrated developmental services. Multiple factors can influence neurodevelopmental outcomes, including genetics (e.g., chromosomal abnormalities and microdeletions), family background (e.g., parental intelligence quotient [IQ] and socioeconomic status), preoperative factors (including prematurity, cyanosis, shock), intraoperative factors (e.g., use of cardiopulmonary bypass, deep hypothermic circulatory arrest), and postoperative factors (e.g., hemodynamic instability, hypoxia, acidosis, cardiac arrest, stroke, ischemic events). In 2012 the American Heart Association published guidelines for the evaluation and management of neurodevelopmental outcomes in children with CHD (Marino, Lipkin, Newburger, et al., 2012). The guidelines outline an algorithm for surveillance, screening, evaluation, reevaluation, and management of developmental disorder or disability to supplement the 2006 American Academy of Pediatrics statement on developmental surveillance and screening.

PREPARE THE CHILD AND FAMILY FOR INVASIVE PROCEDURES

Chapter 20 provides an extensive discussion of the principles for preparing children for invasive procedures. In 2003 the American Heart Association published a scientific statement, "Recommendations for Preparing Children and Adolescents for Invasive Cardiac Procedures" (LeRoy, Elixson, O'Brien, et al., 2003), that addresses issues specific to the child with heart disease. The reader is referred to these resources for a complete review of the topic. The following discussion highlights some important aspects of preparation for cardiac catheterization and cardiac surgery.

The expected outcomes for preprocedure preparation include reducing anxiety, improving patient cooperation with procedures, enhancing recovery, developing trust with caregivers, and improving long-term emotional and behavioral adjustments following procedures (LeRoy et al., 2003). Important factors to consider in planning preparation strategies are the child's cognitive development, previous hospital experiences, the child's temperament and coping style, the timing of preparation, and the involvement of parents. The most beneficial preparation strategies usually combine information giving and coping skills training, such as conscious breathing exercises, distraction techniques, guided imagery, and other behavioral interventions.

Outpatient preoperative and precatheterization workups are common for most elective procedures. Children are then admitted on the morning of the procedure. Preprocedure teaching is often done in the clinic setting or at home and may include a tour of the ICU and inpatient facilities. Children of different ages and developmental levels require different amounts of information and different approaches. Whereas young children should be prepared close in time to the event, older children and adolescents may benefit from teaching several weeks in advance. Parents should be included in the preparation session to support their child and learn about upcoming events.

Topics to include in preoperative or precatheterization preparation include information on the environment, equipment, and procedures that the child will encounter during and after the procedure. Many information-giving techniques can be used, such as verbal and written information, hospital tours, preoperative classes, picture books, or videos. Information about what the child will see, hear, and feel should be included, especially for older children and adolescents. Some of the sensory experiences of being in an ICU or catheterization laboratory include sights (monitors, many people, a lot of equipment), sounds (beeping noises, alarms, voices), and sensations (lines and dressings, tape, discomfort, thirst). Familiar aspects of the environment, such as BP cuffs, stethoscopes, or oximeter probes, are reviewed, and new equipment, such as monitors, IV lines, and oxygen masks, are described. Comforting aspects of the environment, such as play areas, chairs for parents, and televisions, are emphasized. Many patients who will be sedated during catheterization or receive narcotic pain relievers after surgery will have minimal recall of that period and will not need detailed information about the equipment or procedures used. Information should be specific to the planned procedure for each patient.

A discussion of ways the child can cope with the experience should be included. For a young child, bringing a familiar stuffed animal or comfort object will help relieve anxiety, and advising an older child to bring headphones and favorite music to the catheterization laboratory will help distract him or her during the procedure. Recovery topics after catheterization include lying still to prevent bleeding at the catheter site, advancing diet, controlling pain, and monitoring. After surgery, the nurse reviews the importance of ambulation, coughing, deep breathing, drinking, and eating, and describes pain management and monitoring routines. Simple coping strategies for use during painful procedures should be reviewed; these include distraction techniques such as counting, blowing, singing, and telling stories.

Children and their families should have a choice about an ICU tour. Exposure to the ICU environment can increase anxiety in some children, particularly young children, those with previous hospital experiences, and those who are highly anxious (LeRoy et al., 2003). Usually the day before the procedure is ample time to allow the child to ask questions and to prevent undue fantasizing about the experience. The child should be protected from the frightening sights in the unit; equipment not in view postoperatively, such as equipment located behind or below the bed, needs less attention. The child and parents are encouraged to ask questions or to explore further any equipment in the room, but they should not be pushed to assimilate more information than they are able.

Preoperative physical care differs little, if any, from that for any other surgery and is discussed in Chapter 20. The child should be assured that the parents will be there when the child wakes up; parents should be allowed to accompany their child as far as possible to the operating suite (see Chapter 20, Surgical Procedures). After all of the equipment and procedures have been explained, it is important to talk about "getting well" and going home.

PROVIDE POSTOPERATIVE CARE

Immediate postoperative care is usually provided by specially trained nurses in ICUs. Many of the procedures, such as arterial pressure and central venous pressure (CVP) monitoring, and the observations related to vital functions require advanced educational training (readers should refer to critical care texts for further information). However, nurses caring for the child before surgery and during the convalescent period need to be familiar with the major principles of care. Selected complications that may occur postoperatively are described in Box 23.7.

Observe Vital Signs

Vital signs and BP are recorded frequently until the child's condition is stable. Heart rate and respirations are counted for 1 full minute, compared with the ECG monitor, and recorded with activity. The heart rate is normally increased after surgery. The nurse observes cardiac rhythm and notifies the practitioner of any changes in regularity. Dysrhythmias may occur postoperatively secondary to anesthetics, acid-base and electrolyte imbalance, hypoxia, surgical intervention,

BOX 23.7 Selected Complications After Cardiac Surgery and Treatment Approaches

Cardiac

Heart failure: Digoxin, diuretics
Low cardiac output: Intravenous (IV) inotropes
Dysrhythmias: Identification, drug treatment, possible pacing, cardioversion
Tamponade (blood or fluid in the pericardial space constricting the heart): Prompt removal of fluid by pericardiocentesis

Respiratory

Atelectasis: Chest physical therapy, coughing, deep breathing, ambulation
Pulmonary edema: Diuretics
Pleural effusions: Diuretics, possible chest tube drainage
Pneumothorax: Possible chest tube drainage

Neurologic

Seizures: Assessment, antiepileptic drugs
Cerebrovascular accident (CVA; stroke), cerebral edema, neurologic deficits: Assessment and treatment

Infectious Disease

Infections (especially wound, pneumonia, otitis media, and sepsis): Antibiotics

Hematologic

Anemia: Iron supplementation, possible transfusion
Postoperative bleeding: Initially, clotting factors, blood products; may need repeat surgery to locate and ligate source of bleeding

Other

Postpericardiotomy syndrome (syndrome of fever, leukocytosis, friction rub, pericardial and pleural effusions, and lethargy seen about 7 to 21 days after cardiac surgery; possible viral or autoimmune etiologies): Antipyretics, diuretics, antiinflammatory medications

or trauma to conduction pathways. Cardiac arrest occurs at a higher rate in children with heart disease than in healthy children (Marino, Tabbutt, MacLaren, et al., 2018). Close monitoring in this postoperative period is essential to promote early recognition and treatment of decompensation to prevent cardiac arrest and support surgical recovery.

At least hourly, the lungs are auscultated for breath sounds. Diminished or absent sounds may indicate an area of atelectasis or a pleural effusion or pneumothorax, which necessitates further medical assessment. Temperature changes are typical during the early postoperative period. Hypothermia is expected immediately after surgery due to hypothermic procedures, effects of anesthesia, and loss of body heat to the cool environment. During this period, the child is kept warm to prevent additional heat loss. Infants may be placed under radiant heat warmers. During the next 24 to 48 hours the body temperature may rise to 37.7°C (100°F) or slightly higher as part of the inflammatory response to tissue trauma. After this period, an elevated temperature is most likely a sign of infection and warrants immediate investigation for probable cause.

Intra-arterial monitoring of BP is commonly done after open-heart surgery. A catheter is passed into the radial artery or other artery, and the other end is attached to an electronic monitoring system, which provides a continuous recording of the BP. The intra-arterial line is maintained with a low-rate, constant infusion of heparinized saline to prevent clotting.

Several IV lines are inserted preoperatively, including a peripheral IV to give fluids and medications and a central venous line, usually in a large vessel in the neck, to measure CVP. Additional, intracardiac monitoring lines are sometimes placed intraoperatively in the right atrium, left atrium, or pulmonary artery. Intracardiac lines allow assessment of pressures inside the cardiac chambers, providing vital information about volume status, cardiac output, and ventricular function. All lines must be cared for using strict aseptic technique, and patients must be carefully assessed for bleeding at the time of line removal.

Maintain Respiratory Status

Infants usually require mechanical ventilation in the immediate postoperative period. Early extubation in the operating room or early postoperative period is becoming more common. Children, especially those not requiring cardiopulmonary bypass, may be extubated in the operating room or in the first few postoperative hours. Suctioning is performed only as needed and performed carefully to avoid vagal stimulation (which can trigger cardiac dysrhythmias) and laryngospasm, especially in infants. Suctioning is intermittent and maintained for no more than 5 seconds at a time to avoid depleting the oxygen supply. Supplemental oxygen is administered with a manual resuscitation bag before and after the procedure to prevent hypoxia. The heart rate is monitored after suctioning to detect changes in rhythm or rate, especially bradycardia.

When ventilator weaning and extubation are completed, humidified oxygen is delivered by mask, hood, or nasal cannula to prevent drying of mucosa. The child is encouraged to turn and deep breathe at least hourly. Incentive spirometer use should be encouraged. Measures are used to enhance ventilation and decrease pain, such as splinting of the operative site and use of analgesics. Chest tubes are inserted into the pleural or mediastinal space during surgery or in the immediate postoperative period to remove drainage. This drainage is checked hourly for color and quantity. Immediately after surgery the drainage may be bright red, but afterwards it should be serous. The largest volume of drainage occurs in the first 12 to 24 hours and is greater in extensive heart surgery.

! NURSING ALERT

Chest tube drainage greater than 3 ml/kg/h for more than 3 consecutive hours or 5 to 10 ml/kg in any 1 hour is excessive and may indicate postoperative hemorrhage. The surgeon should be notified immediately because cardiac tamponade can develop rapidly and is life threatening.

Chest tubes are usually removed on the first to third postoperative day. Removal of chest tubes is an uncomfortable, frightening experience. Analgesics such as morphine sulfate, often combined with midazolam (Versed), should be given before the procedure. Older children are forewarned that they will feel a sharp, momentary pain. After the suture is cut, the tubes are quickly pulled out at the end of full inspiration in the extubated patient to prevent intake of air into the pleural cavity. (In the intubated patient, the tubes are pulled out on inspiration because the lungs are stented open with the positive pressure ventilation.) A purse-string suture (placed when the tubes were inserted) is pulled tight to close the opening. A petrolatum-covered gauze dressing is immediately applied over the wound and securely taped on all four sides to the skin so that an airtight seal is formed. It is left on for 1 or 2 days. Breath sounds are checked to assess for a pneumothorax, a possible complication of chest tube removal. A chest radiograph is usually obtained after removal to evaluate for possible pneumothorax or pleural effusion.

Monitor Fluids

Intake and output of all fluids must be accurately calculated. Intake is primarily IV fluids; however, a record of fluid used to flush the arterial and CVP lines or to dilute medications is also kept. Output includes

hourly recordings of urine (usually a Foley catheter is inserted and attached to a closed collecting device), drainage from chest and nasogastric tubes, and blood drawn for analysis. Renal failure is a potential risk from a transient period of low cardiac output.

! NURSING ALERT

The signs of renal failure are decreased urinary output (<1 ml/kg/h) and elevated levels of blood urea nitrogen and serum creatinine.

Fluids are restricted during the immediate postoperative period to prevent hypervolemia, which places additional demands on the myocardium, predisposing the patient to cardiac failure. If the child is to be extubated within the first 24 to 48 hours, fluids are provided primarily intravenously. If the child is to be intubated longer, fluids may be given via a nasogastric or nasojejunal tube to optimize nutrition and gut motility. Approximately 4 hours after extubation, enteral fluids may be reinitiated in the setting of a stable hemodynamic and respiratory status. To monitor fluid retention, the child is weighed daily, and the same scale is used at approximately the same time each day to avoid errors in measurement. Fluid restriction may be imposed even when oral fluids are given. The nurse calculates the distribution over a 24-hour period based on the child's preoperative weight and drinking habits. The distribution should allow for most fluid to be given during the child's most wakeful and active periods.

Provide Rest and Progressive Activity

After heart surgery, rest should be provided to decrease the workload of the heart and promote healing. The simplest way to ensure individualized, efficient, high-quality care is to plan at the beginning of the shift the nursing procedures to be done, with periods of rest identified. The schedule should be shared with parents to allow them to visit at the most advantageous times, such as after a rest period when no special treatments are anticipated.

A progressive schedule of ambulation and activity is planned, based on the child's preoperative activity patterns and postoperative cardiovascular and pulmonary function. Ambulation is initiated early once the child is extubated. Activity progresses from sitting on the edge of the bed and dangling the legs to standing up and sitting in a chair. Heart rate and respirations are carefully monitored to assess the degree of cardiac demand imposed by each activity. Tachycardia, dyspnea, cyanosis, desaturation, progressive fatigue, and dysrhythmias indicate the need to limit further energy expenditure.

Provide Comfort and Emotional Support

Heart surgery is both painful and frightening for children, and comfort is a primary nursing concern. Several types of incisions are used by the cardiac surgeon. A median sternotomy is most common, following the sternum down the center of the chest. A mini-sternotomy opens the lower sternum. A thoracotomy incision is most uncomfortable because it goes through muscle tissue. It allows access to the side of the chest through an incision from under the arm around the back to the scapula.

Most patients need IV analgesics for pain control during the immediate postoperative period. Patient-controlled analgesia may be used with children old enough to understand the concept. Nonsteroidal antiinflammatory drugs (NSAIDs) such as ketorolac (Toradol) may be used intravenously. For patients with a thoracotomy, a nerve block placed at the time of surgery is helpful.

After extubation and removal of lines and tubes, pain can be satisfactorily controlled with oral medications such as ibuprofen, oxycodone, and acetaminophen. Acetaminophen alone provides adequate pain relief for most children at discharge. Sternotomy incisions are usually well tolerated, with some discomfort when walking and coughing. Thoracotomy incisions may require a more aggressive pain management plan with around-the-clock medications for several days to allow for adequate rest, ambulation, and pulmonary hygiene.

In addition to pharmacologic pain control, every effort is made to minimize the discomfort of procedures, such as using a firm pillow or favorite stuffed animal placed against the chest incision during movement and performing treatments after pain medication is given, preferably at a time that coincides with the drug's peak effect. Nonpharmacologic measures are used to lessen the perception of pain, and parents are encouraged to comfort their child as much as possible. (See also Chapter 5, Pain Assessment; Pain Management.)

Children may become depressed after surgery. This is thought to be caused by preoperative anxiety, postoperative psychologic and physiologic stress, and sensory overstimulation. Typically, the child's disposition improves on leaving the ICU.

Children may also be angry and uncooperative after surgery as a response to the physical pain and to the loss of control imposed by the surgery and treatments. They need an opportunity to express feelings, either verbally or through activity. Children often regress in their behavior during the stress of surgery and hospitalization. They also may express feelings of anger or rejection toward their parents. The nurse can support the parents by being available for information and explaining all procedures to them. The first few postoperative days are particularly difficult because parents see their child in pain and realize the potential risks from surgery. They often are overwhelmed by the physical environment of the ICU and feel useless because they can do so little for their child. The nurse can minimize such feelings by including parents in caregiving activities and comfort and play activities, providing information about the child's condition, and being sensitive to their emotional and physical needs. The importance of their presence in making the child feel more secure is stressed even if they do not provide physical care.

QUALITY PATIENT OUTCOMES: Congenital Heart Disease

- Improved cardiac function
- Prevention of fluid and sodium overload
- Decreased cardiac demands
- Improved oxygenation
- Reduced respiratory distress

PLAN FOR DISCHARGE AND HOME CARE

Ideally, discharge planning begins on admission for cardiac surgery and includes an assessment of the parents' adjustment to the child's altered state of health. Neonates need additional screening tests (e.g., newborn metabolic screen and hearing) and may need immunizations, as well as a car seat test before discharge. The family will need both verbal and written instructions on medication, nutrition, activity restrictions, return to school, wound care, and signs and symptoms of infection or complications (see Family-Centered Care box). Referrals to community agencies may be necessary to assist parents in the transition from the hospital to home and to reinforce the teaching.

FAMILY-CENTERED CARE

Topics to Include in Discharge Teaching After Cardiac Surgery

- Medication teaching
- Activity restrictions
- Diet and nutrition
- Wound care (including dressings, if any; suture removal; bathing)
- Bacterial (infective) endocarditis prophylaxis (see Box 23.9)
- Follow-up appointments (cardiologist, primary care provider)
- Community agencies as needed (visiting nurse service, early developmental intervention)
- When to call practitioner; signs and symptoms of postoperative problems
- Review of cardiac defect and surgical repair

The parents also need clear instructions on when to seek medical care for complications and how to contact the health care provider. Follow-up with the cardiologist and primary care provider is also arranged before discharge. Parents should have a summary, including their child's medical condition, medications, and health care providers available for emergencies. Appropriate identification, such as a MedicAlert device, is indicated for children with a pacemaker or a heart transplant and for those receiving anticoagulation therapy or antidysrhythmic medication.

Although surgical correction of heart defects has improved dramatically, it is still not possible to completely repair many of the complex anomalies. For many children, repeat procedures are required to replace conduits or grafts or to manage complications, such as re-stenosis. Consequently, the long-term prognosis is uncertain, and full recovery is not always possible. For these families, medical follow-up and continued emotional support are essential. The nurse can often serve as an important primary health professional and as a resource for referrals when needed.

ACQUIRED CARDIOVASCULAR DISORDERS

INFECTIVE ENDOCARDITIS

Infective endocarditis (IE) (also called bacterial endocarditis or subacute bacterial endocarditis [SBE] in the past) is an infection of the inner lining of the heart (endocardium), generally involving the valves. The incidence of IE is much less in children than adults but increasing in both groups (Gupta, Sakhuja, McGrath, et al., 2016). In the past, it was most often a result of bacteremia in children with acquired or congenital anomalies of the heart or great vessels. Now, the increased incidence is likely related to the increased use of indwelling lines in infants and children with many other illnesses.

Pathophysiology

Organisms may enter the bloodstream from any site of localized infection. Endocarditis may occur from routine exposure to bacteremia associated with usual daily activities such as brushing teeth, although it can also occur after procedures such as dental work; invasive procedures involving the gastrointestinal and genitourinary tracts; cardiac surgery, especially if synthetic material is used (valves, patches, conduits); or from long-term indwelling catheters. The most common causative agents are Staphylococcus aureus and viridans streptococci; other causative agents include gram-negative bacteria and fungi such as Candida albicans. The microorganisms grow on the endocardium, forming vegetations (verrucae), deposits of fibrin, and platelet thrombi. The lesion may invade adjacent tissues, such as the aortic and mitral valves, and may break off and embolize elsewhere, especially in the spleen, kidney, and CNS.

BOX 23.8 Clinical Manifestations of Infective Endocarditis

Onset usually insidious
Unexplained fever (low grade and intermittent)
Anorexia
Malaise
Weight loss
Characteristic findings caused by extracardiac emboli formation:
- Splinter hemorrhages (thin black lines) under the nails
- Osler nodes (red, painful intradermal nodes found on pads of phalanges)
- Janeway lesions (painless hemorrhagic areas on palms and soles)
- Petechiae on oral mucous membranes

May be present:
- Heart failure
- Cardiac dysrhythmias
- New murmur or change in previously existing one

Diagnostic Evaluation

The diagnosis of IE is suspected based on clinical manifestations (Box 23.8). The most commonly used diagnostic guidelines are the revised Duke criteria, which outline major and minor criteria consistent with IE (Li, Sexton, Mick, et al., 2000). Definitive diagnosis rests on growth and identification of the causative agent in the blood. At least three blood cultures are drawn at different times to aid in diagnosis. Vegetations on the valve and abnormal valve function can often be visualized by echocardiography. A diagnosis of culture-negative IE is made when the patient has echocardiographic or clinical evidence of IE but no organism can be cultured. Several laboratory findings, including anemia, elevated erythrocyte sedimentation rate [ESR], leukocytosis, and microscopic hematuria, may suggest IE.

Therapeutic Management

Treatment should be instituted immediately and consists of administration of high doses of appropriate antibiotics intravenously for 2 to 8 weeks. Blood cultures are taken periodically to evaluate the response to antibiotic therapy. Frequent echocardiograms are done to monitor for vegetations, valve function, and ventricular function. Heart surgery to repair or replace the affected valve may be necessary.

Prevention involves administration of prophylactic antibiotic therapy to high-risk patients prior to dental procedures that are associated with the risk of entry of organisms (Box 23.9). Drugs of choice for prophylaxis, given 1 hour prior to the procedure, include amoxicillin, ampicillin, and clindamycin in penicillin-allergic patients (Wilson, Taubert, Gewitz, et al., 2007).

QUALITY PATIENT OUTCOMES: Infective Endocarditis
- Prevention in high-risk patients with antibiotic prophylaxis
- Early recognition and treatment

Nursing Care Management

Nurses counsel parents of high-risk children concerning the signs and symptoms of endocarditis and the need for prophylactic antibiotic therapy before dental work. The family's dentist should be advised of the child's cardiac diagnosis as an added precaution to ensure preventive treatment. It is important that all children with congenital or acquired heart disease maintain the highest level of oral health to reduce the chance of bacteremia from oral infections.

BOX 23.9 Cardiac Conditions Associated With the Highest Risk of Adverse Outcome From Endocarditis

Prophylaxis with dental procedures recommended for[a]:
- Previous episode of infective endocarditis (IE)
- Prosthetic cardiac valve

Congenital heart disease (CHD), including only:
- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure

Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibits endothelialization)

Cardiac transplantation recipients who develop cardiac valvulopathy

[a]Except for the conditions listed, antibiotic prophylaxis is no longer recommended for any other form of CHD.

Adapted from Wilson, W., Taubert, K. A., Gewitz, M., et al. (2007). Prevention of infective endocarditis: Guidelines from the American Heart Association. *Circulation, 116*(15), 1736–1754.

Parents should also have a high index of suspicion regarding potential infections. Without unduly alarming them, the nurse stresses that any unexplained fever, weight loss, or change in behavior (lethargy, malaise, anorexia) must be brought to the practitioner's attention. Children at risk (e.g., those with CHD) should have blood drawn for culture if they have a fever without an obvious source. Early diagnosis and treatment are important in preventing further cardiac damage, embolic complications, and growth of resistant organisms.

Treatment of endocarditis requires long-term parenteral drug therapy. In many cases, IV antibiotics may be administered at home with nursing supervision. Nursing goals during this period are (1) preparation of the child for IV infusion, usually with an intermittent infusion device and several venipunctures for blood cultures; (2) observation for side effects of antibiotics, especially inflammation along venipuncture sites; (3) observation for complications, including embolism and HF; and (4) education on the importance of follow-up visits for cardiac evaluation, echocardiographic monitoring, and blood cultures. Some children may need preparation for surgery and, later, postoperative care.

ACUTE RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Acute rheumatic fever (ARF) is a result of an abnormal immune response to a group A strep (GAS) infection, usually pharyngitis, in a genetically susceptible host (Marijon, Mirabel, Celermajer, et al., 2012). It occurs most often in late school-age children and adolescents and is rare in adults. ARF is a self-limited illness that involves the joints, skin, brain, and heart, but cardiac valve damage, which is referred to as **rheumatic heart disease (RHD)**, the most significant complication of ARF, occurs in more than half of the cases. The mitral valve is most often affected. In developed countries, ARF and RHD have become uncommon. However, in developing countries, because of overcrowded living conditions and poor access to medical care, ARF and resulting RHD is the leading cause of HF in young people (Remenyi, Carapetis, Wyber, et al., 2013).

Etiology

Strong evidence supports a relationship between upper respiratory tract infection with GAS and subsequent development of ARF (usually within 2 to 6 weeks). Prevention or treatment of GAS infection prevents ARF. If the GAS infection is untreated, antibodies are produced to fight the infection, which can also act against the heart valves causing damage. If children have one strep infection, they are at greater risk for repeated infections, and recurrent infections cause the cumulative valve damage of RHD.

BOX 23.10 Clinical Manifestations of Acute Rheumatic Fever (Jones Criteria, 2015 Revision)

Major Manifestations

Carditis (seen in 50% to 70% of cases)
- New murmur of valve regurgitation (mitral valve most common)
- Echo Doppler evidence of cardiac involvement
- Tachycardia out of proportion to fever
- Pericardial friction rub
- Chest pain
- Muffled heart sounds
- Cardiomegaly on chest x-ray
- Prolonged PR interval on ECG

Polyarthritis (seen in 35% to 66%)
- Swollen, hot, red, very painful joint pain
- Migratory: affects one joint for 1 to 2 days, then another is affected
- Large joints: knees, elbows, hips, shoulders, wrists, chorea (seen in 10% to 30%) (also called Sydenham chorea or St. Vitus' dance)
- Sudden aimless, irregular movements of extremities, exacerbated by stress
- Profound muscle weakness
- Emotional lability
- Facial grimaces and speech disturbances
- More common in females

Subcutaneous nodules (0% to 10%)
- Nontender swelling over bony prominences
- May persist for many weeks and then resolve

Erythema marginatum (less than 6%)
- Pink rash with pale center and wavy, well-demarcated borders
- Seen on trunk and extremities
- More prominent with heat, blanches with pressure
- Nonpruritic

Minor Manifestations

Arthralgias

Fever (greater than 38.5°C)

ESR above 60 mm and/or CRP greater than 3 mg/dL

Prolonged PR interval

CRP, C-reactive protein; *ECG,* electrocardiogram; *ESR,* erythrocyte sedimentation rate.

Adapted from Gewitz, M. H., Baltimore, R. S., Tani, L. Y., et al. (2015). Revision of the Jones criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography: A scientific statement from the American Heart Association. *Circulation, 131*, 1806–1818.

Diagnostic Evaluation

The diagnosis is based on a set of diagnostic criteria first described by Dr. T. Duckett Jones in 1944 and known as the Jones criteria. Endorsed by the American Heart Association and the World Heart Federation, the most recent revision was completed in 2015 and added evidence supporting the use of Doppler echocardiogram in the diagnosis of carditis (Gewitz, Baltimore, Tani, et al., 2015). The revised Jones criteria are outlined in Box 23.10. The updated Jones criteria suggest that the presence of two major manifestations or one major and two minor manifestations, with supportive evidence of recent GAS infection, indicates a high probability of ARF (see Nursing Care Guidelines box). The most significant manifestation of ARF is carditis. Carditis is the only manifestation of ARF that leads to permanent damage.

Children suspected of having ARF are tested for streptococcal antibodies. The most reliable and best standardized test is an elevated or rising

NURSING CARE GUIDELINES

Diagnosis of Initial Attack of Rheumatic Fever (Jones Criteria, 1992 Update)[a]

Major Manifestations

Carditis

Tachycardia out of proportion to degree of fever
Cardiomegaly
New murmurs or change in preexisting murmurs
Muffled heart sounds
Pericardial friction rub
Chest pain
Changes in ECG (especially prolonged PR interval)

Polyarthritis

Swollen, hot, red, painful joint(s)
After 1 to 2 days, different joint(s) affected
Favors large joints: Knees, elbows, hips, shoulders, wrists

Erythema Marginatum

Erythematous macules with clear center and wavy, well-demarcated border
Transitory
Nonpruritic
Primarily affects trunk and extremities (inner surfaces)

Chorea (St. Vitus' Dance, Sydenham Chorea)

Sudden aimless, irregular movements of extremities
Involuntary facial grimaces
Speech disturbances
Emotional lability
Muscle weakness (can be profound)
Muscle movements exaggerated by anxiety and attempts at fine motor activity; relieved by rest

Subcutaneous Nodes

Nontender swelling
Located over bony prominences
May persist for some time and then gradually resolve

Minor Manifestations

Clinical Findings

Arthralgia
Fever

Laboratory Findings

Elevated acute-phase reactants
- ESR
- CRP
- Prolonged PR interval

Supporting Evidence of Antecedent Group A Streptococcal Infection

Positive throat culture or rapid streptococcal antigen test result
Elevated or rising streptococcal antibody titer

[a] If supported by evidence of preceding group A streptococcal infection, the presence of two major manifestations or of one major and two minor manifestations indicates a high probability of acute rheumatic fever.
CRP, C-reactive protein; *ECG,* electrocardiogram; *ESR,* erythrocyte sedimentation rate.
From Guidelines for the diagnosis of rheumatic fever, Jones criteria, 1992 update, Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young of the American Heart Association. (1992). *JAMA, 268*(15), 2069–2073.

antistreptolysin O (ASO or ASLO) titer, which occurs in 80% of children with ARF. Additional antistreptococcal antibody titers may be sent if ASO titers are negative. Acute-phase reactants, ESR, and C-reactive protein (CRP) are usually elevated as well. Echocardiograms play an important role in diagnosing RHD and monitoring deteriorating valve function.

Therapeutic Management

Primary prevention involves prompt diagnosis and treatment of strep throat infections so that ARF does not occur. Penicillin is the drug of choice or an alternative in penicillin-sensitive children (Gerber, Baltimore, Eaton, et al., 2009).

For children with ARF, treatment includes antibiotics, antiinflammatory therapy, and supportive care and management of HF in some. Antibiotics are given to treat the GAS infection and begin long-term prophylactic treatment to prevent future infections. Penicillin is the drug of choice. Salicylates are used to control the inflammatory process, especially in the joints, and reduce the fever and discomfort. The diagnosis must be confirmed before aspirin therapy is started so that clinical signs are not masked by the therapy. Aspirin up to 80-100 mg/kg/day has traditionally been given in four or five divided doses as initial therapy (Steer & Gibofsky, 2019). Newer nonsteroidal antiinflammatory agents such as Naproxen are now being used. Treatment continues until symptoms resolve which is usually within 2 weeks. Naproxen is dosed at 10 to 20 mg/kg/day in divided doses every 12 hours to a maximum of 1000 mg per day in children aged over two years (Steer & Gibofsky, 2019). Administration of prednisone may be indicated in patients with pericarditis or heart failure and in patients who do not respond to aspirin therapy. Neither salicylates nor prednisone has been shown to affect cardiac sequelae.

Supportive care involves initial bed rest during the acute illness and then quiet activities as symptoms subside. Good nutrition is important. Care for children with significant carditis includes HF therapies such as supplemental oxygen, diuretics, fluid and salt restriction, digoxin, or ACE inhibitors. Children with chorea with motor impairment must be protected from injury and eliminate physical and emotional stress, which can exacerbate their symptoms.

Children who have had ARF are susceptible to recurrent infections that are likely to result in RHD and further damage to the heart valves. Prophylactic treatment against recurrence of ARF (secondary prevention) is started after the acute therapy. The treatment of choice is intramuscular injections of benzathine penicillin G every 28 days because it is most effective. The duration of secondary prophylaxis is based on the presence of residual heart disease. If ARF occurs without carditis, prophylaxis is recommended for 5 years or until age 21 years, whichever is longer. In patients with carditis, 10 years is recommended or until 21 years old. Patients with RHD may need longer therapy (Steer & Gibofsky, 2019; Gerber et al., 2009).

Management of RHD may require surgical valve repair or replacement. Valve replacement with a mechanical valve requires lifelong anticoagulation with warfarin.

QUALITY PATIENT OUTCOMES: Acute Rheumatic Fever
- Group A strep (GAS) tonsillopharyngitis identified and treated
- Early recognition and treatment to prevent cardiac valve damage
- Recurrence prevented with prophylaxis compliance

Nursing Care Management

The objective of nursing care is, first, prevention. For the child with ARF, nursing care (1) encourages compliance with drug regimens, (2) facilitates recovery from the illness, and (3) provides emotional support. Nurses play an important role in prevention by educating parents about the complications of strep infections and working with patients and families to ensure follow-up with antibiotic prophylaxis. Because compliance is a major concern in long-term drug therapy, every effort is made to encourage adherence to the therapeutic plan (see Chapter 20, Compliance). When compliance is poor, monthly injections may be substituted for daily oral administration of antibiotics, and children need preparation for this often-dreaded procedure.

Interventions for ARF are primarily concerned with providing rest, adequate nutrition, and management of cardiac symptoms or chorea. One of the most disturbing manifestations of ARF is **chorea**. The onset is gradual and may occur weeks to months after the illness. Sometimes mistaken for nervousness, clumsiness, or inattentiveness, it is usually a source of great frustration to the child because the movements, incoordination, and weakness severely limit physical ability. It is important that parents and teachers are aware of the involuntary, sudden nature of the movements and that the movements are transitory and will eventually disappear.

Children with RHD will need lifelong follow-up, education, and management of HF, and monitoring for progressive valve disease. If surgery is required, preparation for the procedure is provided. An important aspect of postoperative care is education about anticoagulation medications and follow-up.

HYPERLIPIDEMIA (HYPERCHOLESTEROLEMIA)

Hyperlipidemia is a general term for excessive lipids (fat and fatlike substances); **hypercholesterolemia** refers to excessive cholesterol in the blood. **Dyslipidemia** is a term used to describe all abnormalities in lipid metabolism, including low levels of high-density lipoprotein (HDL) or "healthy" cholesterol, high low-density lipoprotein (LDL) or "lousy" cholesterol, or high triglycerides. Abnormal lipid or cholesterol levels play an important role in producing atherosclerosis (fatty plaque on the arteries), which eventually can lead to coronary artery disease, which is a primary cause of morbidity and mortality in the adult population. A presymptomatic phase of atherosclerosis begins in childhood or adolescence, providing the template for later clinical disease. Preventive cardiology focuses on the identification of high-risk patients and management of lipid levels in childhood or adolescence.

Cholesterol is part of the lipoprotein complex in plasma that is essential for cellular metabolism. Triglycerides, natural fats synthesized from carbohydrates, are used for energy. Both are major lipids transported on **lipoproteins**, a combination of lipids and proteins, which include:

Low-density lipoproteins (LDLs): LDL is the major carrier of cholesterol to the cells. Cells use cholesterol for synthesis of membranes and steroid production. Elevated circulating LDL is a strong risk factor in cardiovascular disease. In addition, particle size and density of LDL may affect overall risk, with small, dense particles associated with increased atherosclerosis.

High-density lipoproteins (HDLs): HDL cholesterol contains very low concentrations of triglycerides, relatively little cholesterol, and high levels of protein. They transport free cholesterol to the liver for excretion in the bile. High levels of HDL are thought to be protective against cardiovascular disease.

Very-low-density lipoproteins (VLDLs): VLDLs contain high concentration of triglycerides, some cholesterol, and a little protein. Triglycerides are the main storage form of fuel or energy for the body.

TABLE 23.5 Classification of Cholesterol Levels in Children

Category	Normal (mg/dl)	Borderline High (mg/dl)	Elevated (g/dl)
Total cholesterol	<170	170-199	≥200
Low-density lipoprotein (LDL)	<110	110-129	≥130
Non–high-density lipoprotein (HDL)	<120	120-144	≥145
High-density lipoprotein (HDL)[a]	>45	N/A	N/A

[a]Borderline low HDL, 40–45; low HDL, <40.
N/A, Not applicable.
Adapted from Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents & National Heart, Lung, and Blood Institute. (2011). Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents: Summary report. *Pediatrics, 128*(Suppl 5), S213–S256.

Diagnostic Evaluation

Hyperlipidemia can have a genetic basis (familial homozygous or heterozygous hypercholesterolemia causing significantly elevated LDL and total cholesterol) and/or a lifestyle component or can be caused by secondary problems, such as hypothyroidism. Hyperlipidemia is diagnosed based on analysis of blood. A complete lipid profile should be drawn, ideally after a 12-hour fast. In children with elevated cholesterol levels, a screening thyroid-stimulating hormone is measured at diagnosis in order to rule out hypothyroidism as a cause of secondary hypercholesterolemia. Additional blood work is individualized based on other risk factors. Lipid values may be affected by recent high fevers, and therefore cholesterol values should not be drawn if a child has had a fever within the past 3 weeks. Diagnostic values for acceptable, borderline, and high total cholesterol and LDL cholesterol levels are listed in Table 23.5.

The National Heart, Lung, and Blood Institute published comprehensive guidelines for cardiovascular health and risk reduction in children and adolescents in 2011, recommending universal screening for all children between the ages of 9 and 11 years, and again between the ages of 17 and 21 years. In addition, earlier lipid screening continues to be recommended for children older than 2 years of age who have a family history of dyslipidemia or early heart disease in a first- or second-degree relative, as well as for those children who have individual coronary risk factors (Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents & National Heart, Lung, and Blood Institute, 2011) (see Translating Evidence Into Practice box). The goal of this approach is to identify children at risk, with the goal of decreasing coronary risk factors (Daniels, 2012; de Ferranti, Daniels, Gillman, et al., 2012; McCrindle, Kwiterovich, McBride, et al., 2012). In addition to abnormal cholesterol levels, known risk factors that correlate with the development of cardiovascular disease include:

- Positive family history of elevated cholesterol and/or early heart disease
- Cigarette smoking
- Obesity
- Sedentary lifestyle
- Nutritional factors
- Older age
- Male gender
- Hypertension
- Type 1 or type 2 diabetes

Search Strategies

The literature was searched to locate clinical research studies related to this issue. Selection criteria included English-language publications within the past 10 years, research-based articles (level 3 or lower), and infant and child populations.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, Joanna Briggs Institute, National Guidelines Clearinghouse (Agency for Healthcare Research and Quality), TRIP Database Plus, PedsCCM, BestBETs.

Critically Analyze the Evidence

- In late 2011, an expert panel of the National Heart, Lung, and Blood Institute made a recommendation that lipid screening be performed on all children 9 to 11 years old; this recommendation was based on evidence that as many as 30% to 60% of children with dyslipidemia might be missed when screening is performed by family history alone (Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents & National Heart, Lung, and Blood Institute, 2011). The expert panel's guidelines also include comprehensive screening and treatment guidelines for children with cardiovascular disease risk factors.
- Diagnosis of obesity is paramount in enhancing care of pediatric patients who are obese. Current laboratory (cholesterol or glucose) screening rates (10%) are inadequate in the outpatient setting (Patel, Madsen, Maselli, et al., 2010).
- Testing for cardiovascular risk factors: HDL cholesterol, LDL cholesterol, fasting glucose, HgbA1c, BP, thyroid-stimulating hormone, and ALT should be considered in pediatric patients with increased waist circumference and even normal BMI (l'Allemand-Jander, 2010).
- In children who are obese, LDL cholesterol, HDL cholesterol, total cholesterol, and triglycerides are significantly different from those in subjects who are not obese (Simsek, Balta, Balta, et al., 2010).
- Serum triglyceride levels are a predictive risk factor of carotid intima-media thickness (Simsek et al., 2010).
- In children and adolescents (12 to 19 years old), fasting non-HDL cholesterol levels were strongly associated with metabolic syndrome. A non-HDL cholesterol threshold of 120 mg/dl indicated borderline risk for metabolic syndrome, and a threshold of 145 mg/dl indicated high metabolic syndrome risk (Li, Ford, McBride, et al., 2011).
- Cholesterol levels in childhood are a major population predictor for adult cholesterol levels (Daniels, Greer, & Committee on Nutrition, 2008).
- Precursors of atherosclerosis are present in young people. The atherosclerotic process begins early in life with early phases characterized by the development of fatty streaks in the vessels (PDAY study) (Enos, Holmes, & Beyer, 1953; Strong, Malcom, McMahan, et al., 1999).
- Atherosclerosis is related to the presence and degree of cardiovascular risk factors in adults (Berenson, Srinivasan, Bao, et al., 1998).
- Most severely affected children come from families with a high incidence of early heart disease. Children whose genetic family history is unknown should also be screened (Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents & National Heart, Lung, and Blood Institute, 2011).
- Universal cholesterol screening in children would identify all individuals with dyslipidemia. Using solely the family history to identify subjects for cholesterol screening missed individuals with moderate dyslipidemia and those with potentially genetic dyslipidemia (Ritchie, Murphy, Ice, et al., 2010).

Apply the Evidence: Nursing Implications

There are strong recommendations (Guyatt, Oxman, Vist, et al., 2008) that lipid screening should be performed on all children 9 to 11 years old and again between 17 and 21 years old. Selective screening is still recommended over the age of 2 years in children with affected first- or second-degree relatives or those with individual cardiac risk factors. The National Heart, Lung, and Blood Institute guidelines have been endorsed by the American Academy of Pediatrics (Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents & National Heart, Lung, and Blood Institute, 2011).

Quality and Safety Competencies: Evidence-Based Practice[a]

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe use of cholesterol screening in children.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by using cholesterol screening in children.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate strengths and weakness of evidence for using cholesterol screening in children.

Updated by Olga A. Taylor

In addition to the risk factors noted earlier, the American Heart Association and National Heart, Lung, and Blood Institute have identified pediatric patients who are considered at higher risk for atherosclerosis because of coexisting health problems, including:

- Heterozygous or homozygous familial hyperlipidemia
- Chronic inflammatory diseases
  - Type 1 or 2 diabetes
  - Chronic kidney disease
- Cancer survivors
- Transplant patients
- CHD
- Kawasaki disease with current or history of coronary artery aneurysms (de Ferranti, Steinberger, Amerduri, et al., 2019)

Therapeutic Management

The first step in the treatment of high cholesterol is focused on lifestyle modification. The National Heart, Lung, and Blood Institute guidelines advocate the benefits of a heart-healthy diet for all children (Box 23.11). Children and adolescents with known dyslipidemia should have individual nutritional counseling, ideally by a dietitian with expertise in pediatric lipids.

BOX 23.11 Recommendations for Dietary and Lifestyle Management of Dyslipidemia for Children and Adolescents Older Than 2 Years of Age

For All Children and Adolescents

- Obtain 1 hour of moderate or vigorous physical activity at least 5 days a week
- Less than 2 hours per day of sedentary screen time
- Avoid firsthand and secondhand smoke exposure
- Eat a diverse diet rich in fruits, vegetables, whole grains, lean meats, and fish
- Refer to registered dietitian for individual nutritional counselling

Elevated Low-Density Lipoprotein Cholesterol

- 25% to 30% of calories from fat
- Less than 7% of calories from saturated fats (approximately 12 to 15 g/day)
- Avoid trans fats
- Favor monounsaturated fats
- Less than 200 mg/day of dietary cholesterol

Elevated Triglycerides or Non–High-Density Lipoprotein Cholesterol

- Decrease intake of simple sugars
  - Avoid white bread, white pasta, white potatoes, white rice, sugary cereals, cookies, cakes, candy
  - No sugar-sweetened beverages
  - Replace simple sugars with complex carbohydrates
- 25% to 30% of calories from fat
- Less than 7% of calories from saturated fat
- Favor monounsaturated fats (beneficial effects on high-density lipoprotein cholesterol)
  - Use olive oil, canola oil, avocados, nuts, and fish
- Avoid trans fats
- Increase dietary fish intake for omega-3 fatty acids

Adapted from Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents & National Heart, Lung, and Blood Institute. (2011). Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents: Summary report. *Pediatrics, 128*(Suppl 5), S213–S256.

Research continues to support the benefit of diets low in saturated fats for patients with elevated LDL cholesterol. Current thinking favors a "Mediterranean"-type diet. Whole grains, fruits, and vegetables form the foundation of this diet. Patients who have elevated triglycerides, particularly those with an elevated body mass index (BMI), should also receive targeted counseling aimed at a low-glycemic diet. In both situations, monounsaturated fats are favored, as they have beneficial effects on HDL cholesterol. These fats include olive oil, canola oil, nuts, avocados, and fish. Regular aerobic exercise, at least 60 minutes a day 5 days a week, is recommended for all children and adolescents. In addition, patients and parents should be counseled regarding the negative effects of smoking (both firsthand and secondhand).

For some children, drug therapy may be necessary in addition to lifestyle modification, in order to achieve acceptable lipid values. After 6 months of lifestyle counselling, pharmacologic therapy is recommended for children older than 10 years of age who have LDL cholesterol values that are greater than 190 mg/dl without other risk factors or those with LDL values greater than 160 mg/dl in patients with additional risk factors and/or with a family history of early heart disease in a first-degree relative. In young people who are considered to have individual high-risk conditions (such as homozygous familial hypercholesterolemia, type 1 diabetes, chronic kidney disease, Kawasaki disease with aneurysms, or heart transplant recipients), the threshold for initiation of medication is lower and is considered when LDL values are greater than 130 mg/dl.

The use of medication in a child or adolescent needs to be a cooperative decision made with the patient and parents. Parents and patients should understand the available data related to statin use in young people, particularly because prospective, long-term evidence-based practice is not practical or available for this population. Options for lipid-lowering medications include bile acid–binding resins, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins), ezetimibe, and fibrates (for patients with severely elevated triglycerides). Nicotinic acid is generally not used in children and adolescents.

The most recent guidelines on lipid abnormalities in children recommend treatment with statins if pharmacologic therapy is indicated after lifestyle modification has been attempted (Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents & National Heart, Lung, and Blood Institute, 2011).

Statins are effective in lowering LDL cholesterol. To a lesser degree, they also help lower triglycerides levels and can raise HDL cholesterol somewhat. Statins work by inhibiting the enzyme necessary for cholesterol synthesis. Statins are started at the lowest possible dose in young people. Blood work should be followed closely in children and adolescents and usually includes a fasting lipid profile and an alanine aminotransferase (ALT) test repeated approximately 1 month after initiation and then monitored every 6 months to once a year as well as with any dosage changes.

Muscle symptoms should be assessed. Patients beginning therapy with a statin should be counseled regarding rare but potentially serious side effects (such as rhabdomyolysis) as well as more minor potential side effects. Patients should discontinue their medication and contact their practitioner if they develop dark urine or new muscle aches. Statin medications are not safe during pregnancy; therefore sexually active adolescents need to take adequate birth control measures. Very long–term studies are unlikely to be available over decades; however, in the shorter term studies that have been completed, statins seem to have a similar safety profile for children as they do for adults (McCrindle, Urbina, Dennison, et al., 2007). Ezetimibe is sometimes given in combination with statins to further reduce LDL cholesterol, which it accomplishes by decreasing reabsorption of cholesterol from the gut. Another

class of lipid-lowering drugs is bile acid–binding resins. Bile acid–binding resins act by binding bile acids in the intestinal lumen. Because the intestine does not absorb them, resin binders do not produce systemic toxicity and are safe for children. Cholestyramine (Questran) and colestipol (Colestid) are both powders that are mixed with water or juice just before ingestion. Unfortunately, the vast majority of patients do not get adequate reduction in LDL cholesterol from bile acid–binding resins alone. Many cannot tolerate the medication because of the taste; gritty texture; and side effects, the most significant being constipation, abdominal pain, gastrointestinal bloating, flatulence, and nausea. Lastly, it is not common to use medications to lower triglyceride values unless they are significantly elevated (>500 mg/dl), in which case fibrates, which decrease the production of triglycerides, may be considered.

Nursing Care Management

Nurses play an important role in the screening, education, and support of children with lipid abnormalities and their families. When a child is referred to a preventive cardiology clinic, it is essential that the family be adequately prepared for the first visit. Generally, the parents will be asked to keep a dietary history of the child before this visit. Some clinics use questionnaires regarding the child's normal dietary habits. Families should be instructed to bring their child to the lab in the morning after fasting for at least 12 hours before blood work. In addition, parents should be aware that lipids should not be drawn within 3 weeks of a febrile illness because doing so can affect cholesterol values. It is important to schedule the blood test early in the morning and to arrange for nourishment immediately thereafter. At the visit, a full family history should be taken, including the health of both parents and all first- and second-degree relatives. Specific questions should be asked regarding early heart disease, hypertension, strokes (CVAs), sudden death, hyperlipidemia, diabetes, and endocrine abnormalities.

Patients and parents should be educated about cholesterol and lipid abnormalities. This should include a brief introduction of the different lipoprotein categories, including an explanation of the components of the lipid profile. In addition, lifestyle risk factors for heart disease, such as smoking, screen and sedentary time, exercise, and diet, should be reviewed in depth. For management to be effective, parents and patients need to understand the rationale for screening and treatment.

Ideally, a heart-healthy diet is reviewed by an experienced dietitian and should reflect national guidelines for healthy eating. Stringent dietary guidelines may become an issue of control and a source of great stress for many families. Rather, the positive aspects of healthy eating, regularly exercising, and avoiding smoking should be emphasized. Basic dietary changes should be encouraged for the whole family so that the affected child is not singled out. Cultural differences must be considered and recommendations individualized. Substitution rather than elimination needs to be emphasized. Visual aids (e.g., test tubes depicting the amount of fat in a hot dog or the number or packs of sugar in a glass of juice) are often helpful, especially for younger children. Diets should be flexible and individually tailored by a dietitian who is experienced in lipid disorders. Dietary recommendations need to meet the nutritional demands of growing children while providing benefit to the overall profile. Parents and patients are encouraged to participate in dietary and educational sessions, ask questions, and share ideas and experiences.

Parents often feel guilty about the hereditary component of hyperlipidemia. Many also believe that they have failed if the diet alone is not making a significant difference in their child's lipid profile. They need to be reassured that a dietary approach alone is often insufficient, especially for children with genetically elevated values.

Parents of children who require pharmacologic therapy need to understand the purpose, dosage, and possible side effects of the various drugs. Medication schedules should remain flexible and should not interfere with the child's daily activities. Follow-up phone calls by the nurse between visits allow parents to discuss their concerns and ask any questions that have arisen.

CARDIAC DYSRHYTHMIAS

Dysrhythmias, or abnormal heart rhythms, can occur in children with structurally normal hearts, as features of some congenital heart defects, and in patients following surgical repair of congenital heart defects. They are also seen in patients with cardiomyopathy and with cardiac tumors. They can occur secondary to metabolic and electrolyte imbalances. Childhood dysrhythmias can have a genetic or familial etiology. Dysrhythmias can be classified in several ways, such as by heart rate characteristics (bradycardia and tachycardia) or by the origin of the dysrhythmia in the atria or ventricles. Some dysrhythmias are well tolerated and self-limiting. Others may cause decreased cardiac output with associated symptoms. Some dysrhythmias can cause sudden death. Treatment depends on the cause of the dysrhythmia and its severity.

Many advances have been made in the diagnosis and treatment of pediatric dysrhythmias in the past decade. Improvements in technology have allowed better diagnosis, the development of ablation techniques, and the expansion of pacemaker capabilities. New antidysrhythmic medications have proven safe and effective in children. Radiofrequency ablation has offered a cure for some dysrhythmias. Pediatric electrophysiology has become a highly specialized field, and students should consult more detailed sources for an in-depth discussion. The following sections describe diagnostic studies and provide a general discussion of the most common tachycardia (supraventricular tachycardia) and the most common bradycardia (complete heart block) that require treatment in the pediatric population.

Diagnostic Evaluation

Nurses must be familiar with the standards of normal heart rate for the age-group. An initial nursing responsibility is recognition of an abnormal heartbeat, either in rate or in rhythm. When a dysrhythmia is suspected, the apical rate is counted for 1 full minute and compared with the radial rate, which may be lower because not all apical beats are felt. Consistently high or low heart rates should be regarded as suspicious. The patient should be placed on a cardiac monitor with recording capabilities. A 12-lead ECG yields more information than the monitor recording and should be done as soon as possible.

The basic diagnostic procedure is the ECG, including 24-hour Holter monitoring. **Electrophysiologic cardiac catheterization** allows for identification of the conduction disturbance and immediate investigation of drugs that may control the dysrhythmia. Another procedure that may be used is **transesophageal recording**. An electrode catheter is passed to the lower esophagus and, when in position at a point proximal to the heart, is used to stimulate and record dysrhythmias.

Dysrhythmias can be classified according to various criteria, such as effect on heart rate and rhythm, as follows:

Bradydysrhythmias: Abnormally slow rate
Tachydysrhythmias: Abnormally rapid rate
Conduction disturbances: Irregular heart rate

Bradydysrhythmias

Sinus bradycardia (slower than normal rate) in children can be attributed to the influence of the autonomic nervous system, as with hypervagal tone, or in response to hypoxia and hypotension. Sinus bradycardias are also known to develop after atrial repairs involving atrial suture lines, such as in the Fontan procedure.

Complete atrioventricular (AV) block is also referred to as **complete heart block**. This can be either congenital (occurring in children with structurally normal hearts) or acquired after surgery to repair cardiac defects. AV blocks are most often related to edema around the conduction system and resolve without treatment. Temporary epicardial wires are placed in most patients at surgery; if a rhythm disturbance occurs, temporary pacing can be used. Several days after surgery, the health practitioner removes the wires by pulling slowly and deliberately down on them from the site of insertion.

Some children may need a permanent pacemaker. The pacemaker takes over or assists in the heart's conduction function. Pacemaker functions have become more sophisticated, and some models can adjust the heart rate to activity demands or be programmed for overdrive pacing or cardioversion.

The implantation of a pacemaker, in the operating room or possibly the catheterization laboratory, is usually a low-risk procedure. The pacemaker is made up of two basic parts: the pulse generator and the lead. The pulse generator is composed of the battery and the electronic circuitry. The lead is an insulated, flexible wire that conducts the electrical impulse from the pulse generator to the heart. Two types of leads, transvenous and epicardial, are available. After the lead has been attached to the heart, a small incision is made, and a pocket is formed under the muscle to house and protect the generator. Continuous ECG monitoring is necessary during the recovery phase to assess pacemaker function. The nurse should be aware of the programmed rate and expected individual generator variations. The pacemaker insertion site is monitored for signs of infection. Analgesics are given for pain.

Discharge teaching includes information about the signs and symptoms of infection, general wound care, and activity restrictions. Parents, and patients if they are old enough, should be taught to take a pulse and know the settings of the pacemaker. If the patient's low rate is set at 80 beats/min and the heart rate is only 68 beats/min, there is a possible problem with the pacemaker that needs to be investigated. Instructions for telephone transmission of ECG readings are also given. Telephone transmission can be used to transmit ECG strips and to monitor battery life and pacemaker function. The pacemaker generator will have to be replaced periodically because of battery depletion. Children with pacemakers should wear a MedicAlert device, and their parents should have a paper identification card with specific pacer data in case of an emergency. Cardiopulmonary resuscitation (CPR) instruction is suggested for parents.

Tachydysrhythmias

Sinus tachycardia (an abnormally fast heart rate) secondary to fever, anxiety, pain, anemia, dehydration, or any other etiologic factor requiring increased cardiac output should be ruled out before diagnosing an increased heart rate as pathologic. Supraventricular tachycardia (SVT) is the most common tachydysrhythmia found in children and refers to a rapid regular heart rate of 200 to 300 beats/min. As many as 1 in 250 children experience SVT (Schlechte, Boramanand, & Funk, 2008). The onset of SVT is often sudden, the duration is variable, and the rhythm may end abruptly and convert back to a normal sinus rhythm. Clinical signs in infants and young children are poor feeding, extreme irritability, and pallor. Children may experience palpitations, dizziness, chest pain, and diaphoresis. If SVT is sustained, signs of HF may be seen.

The treatment of SVT depends on the degree of compromise imposed by the dysrhythmia. In some cases, vagal maneuvers, such as applying ice to the face, massaging the carotid artery (on one side of the neck only), or having an older child perform a Valsalva maneuver (e.g., exhaling against a closed glottis, blowing on a thumb as if it were a trumpet for 30 to 60 seconds), can terminate SVT. If vagal maneuvers fail or the child is hemodynamically unstable, adenosine (a drug that impairs AV conduction) may be used. Adenosine is given by rapid IV push with a saline bolus immediately after the drug because of its very short half-life. If this is unsuccessful or cardiac output is compromised, esophageal overdrive pacing or synchronized cardioversion (delivering an electrical shock to the heart) can be used in the intensive care setting. Sedation is needed for both procedures. Cardioversion should never be done in a conscious patient. Traditional first-line medical management of chronic SVT is a beta-blocker or digoxin. A primary focus of nursing care is education of the family regarding the symptoms of SVT and its treatment. If medication is prescribed, instructions on accurate dosage and the importance of administering the correct dose at specified intervals are stressed. SVT may occur again despite therapy. Parents should be taught to take a radial pulse for a full minute.

Radiofrequency ablation has become first-line therapy for some types of SVT. The procedure is done in the cardiac catheterization laboratory and begins with mapping of the conduction system to identify the dysrhythmia focus. A catheter delivering radiofrequency current is directed at the site, and the area is heated to destroy the tissue in the area. These are lengthy procedures, often lasting 6 to 8 hours, and sedation or general anesthesia is required. Preparation is similar to that for cardiac catheterization. Another procedure, cryoablation, is also used in treatment of SVT. For this kind of ablation, liquid nitrous oxide is used to cool a catheter to subfreezing temperatures, which then destroys the tissue of target by freezing.

PULMONARY HYPERTENSION

Pulmonary hypertension (PH) is a pulmonary vascular disease associated with diverse cardiac, lung, and systemic diseases as well as familial and idiopathic etiologies. The pulmonary arteries are described as having vascular narrowing due to decreased vascular growth and surface area and intraluminal obstruction, and they undergo structural remodeling of the vessel wall (Abman & Ivy, 2011). Pulmonary hypertension is defined by a mean pulmonary arterial pressure (mPAP) of 25 mm Hg or greater in children older than 3 months of age and is categorized based on a classification system created by the World Health Organization (Simonneau, Gatzoulis, Adatia, et al., 2013). In the pediatric population, there are three causes of PH: (1) increased pulmonary venous pressures (e.g., mitral stenosis, left ventricle noncompliance); (2) post-tricuspid cardiac shunts (e.g., large VSD, large patent ductus arteriosus [PDA]); and (3) small pulmonary arteries, that is, arteries that are too few or too narrow (e.g., idiopathic pulmonary arterial hypertension [IPAH], persistent pulmonary hypertension of the newborn [PPHN], connective tissue disorders, hypoxia, drugs, toxins). There is no cure for PH, and there is significant morbidity and mortality. However, advancements in therapeutic management in the last 10 to 15 years are helping to slow the progression of the disease and improve quality of life.

Clinical Manifestations

The clinical manifestations include dyspnea with exercise, chest pain, and syncope. Dyspnea is the most common symptom and is caused by impaired oxygen delivery. Chest pain is the result of coronary ischemia in the right ventricle from severe hypertrophy. Syncope reflects a limited cardiac output leading to decreased cerebral blood flow. Right-sided heart dysfunction is steadily progressive, and when symptoms of venous congestion and edema are present, the prognosis is poor.

Therapeutic Management

Pediatric PH guidelines from the American Heart Association and American Thoracic Society outline treatment recommendations for conditions specific to the pediatric population, including PPHN,

congenital diaphragmatic hernia (CDH), bronchopulmonary dysplasia, and CHD (Abman, Hansmann, Archer, et al., 2015). The discussion here focuses on pharmacotherapy, supportive therapy, and, briefly, invasive interventions.

Three classes of drugs are used extensively in the treatment of pediatric PH: phosphodiesterase-5 (PDE5) inhibitors (sildenafil, tadalafil), endothelin receptor antagonists (ERAs; bosentan, ambrisentan), and prostanoids or prostacyclin (PGI_2) analogs (epoprostenol, treprostinil). Vasoconstriction is a primary component of PH, and these drugs work on different aspects to promote vasodilation and smooth muscle relaxation. For patients who are responsive to inhaled nitric oxide or vasodilator drug testing during cardiac catheterization, oral calcium channel blockers (nifedipine and diltiazem) have been successful and are the treatment of choice. Table 23.6 reviews the common PH drugs, dose form availability, adverse side effects, and comments on important aspects in the administration of these medications. Choice of treatment is determined by the severity of the disease, and all of these medications carry adverse effects.

In general, situations that may exacerbate the disease and cause hypoxia are avoided. Exercise prescriptions are specific to each patient. Patients should avoid high altitudes because of the relative hypoxia, and some patients have moved to sea level to slow the progress of the disease. Supplemental oxygen is commonly used to relieve hypoxia, especially at night while sleeping. Patients with pulmonary artery hypertension (PAH) are at risk for thromboembolic events. Anticoagulation therapy has been shown to increase survival in adults. Many patients are treated with warfarin to prevent pulmonary embolism, which can be fatal. Digoxin and diuretics are often used to treat right-sided heart failure.

Some patients fail to respond to medical management, and disease progression leads to severe right ventricle dysfunction. In these cases, two potential options are available. Creation of an atrial septostomy or communication between the two atria can be done in the catheterization lab. This often increases cardiac output and thus results in some improvement in function and quality of life. Lung transplantation may be another treatment option for children, primarily those with severe disease.

Nursing Care Management

The diagnosis of PH is devastating for the child and family. There is no known cure, and the treatments require significant lifestyle changes and commitment on the part of the patient and family to make them successful. Anxiety, depression, and fear of the future are common. Patients and families require extensive education about the disease and its management. They need emotional support to cope with a poor prognosis and make decisions about treatment options.

The medical treatment is complex and involves different medications and therapies. Families are often referred to a specialized center that has experience in the management of PH. This may involve travel far from home with associated emotional and financial hardships. The patient and family must cope with the symptoms of the disease and the side effects of the treatment. Dealing with a continuous IV infusion or continuous oxygen administration requires a major adjustment in lifestyle to accommodate the therapy. The prostacyclin infusion cannot be interrupted at any time, since symptoms can worsen and cause acute pulmonary hypertensive crisis, which can be fatal. Backup systems must be in place at all times. The patient and family must make a commitment to adhere to a complex regimen of preparing the infusion, maintaining the equipment, and maintaining sterility of the central line. Treatments are expensive, so insurance coverage and financial issues are critical. Nurses have an important role in educating and preparing families to perform these complex therapies. Discharge planning involves many team members and outside agencies. The nurse has a pivotal role in coordinating the child's care in the hospital and the transition to home.

CARDIOMYOPATHY

Cardiomyopathy refers to abnormalities of the myocardium in which the cardiac muscles' ability to contract is impaired. Cardiomyopathies are relatively rare in children. Possible etiologic factors include familial or genetic causes, infection, deficiency states, metabolic abnormalities, and collagen vascular diseases. Most cardiomyopathies in children are considered primary or idiopathic, in which the cause is unknown

TABLE 23.6 Pharmacologic Therapy for Pediatric Pulmonary Hypertension

Drug Class	Agent	Dose Form	Adverse Effects	Comments
Calcium channel blocker	Nifedipine, diltiazem	Oral	Bradycardia, decreased cardiac output, peripheral edema, rash, gum hyperplasia, constipation	Only effective for PH if patient is responsive to vasodilator testing in the catheterization lab. Requires high (maximal) dosing to achieve desired vasodilation.
PDE5 inhibitor	Sildenafil, tadalafil	Oral	Flushing, hypotension, headache, priapism	
Endothelin receptor antagonist (ERA)	Bosentan, ambrisentan	Oral	Hepatotoxic, peripheral edema, teratogenic	Requires monthly LFTs; birth control important for adolescent and young women
Prostacyclin	Epoprostenol (Flolan), treprostinil (Remodulin)	IV/SC	Headache, flushing, hypotension, site pain (SC form), cellulitis, central line complications, jaw pain, nausea, or diarrhea	Flolan has an extremely short half-life (2-5 min), and PH crises occurs rapidly if infusion is stopped. Dosing is complex, and there is a high risk of error.
Prostacyclin	Treprostinil (Remodulin)	Oral	Headache, flushing, pain in extremities, jaw pain, nausea, or diarrhea (GI side effects can be greater than other dose forms)	Transition from IV/SC form occurs over days in the hospital. Timing of dosing is critical; if two doses are missed, need IV/SC form. Cannot be crushed, chewed, or compounded.
Prostacyclin	Treprostinil (Remodulin)	Inhaled	Headache, flushing, pain in extremities, jaw pain, nausea, or diarrhea	Must be inhaled 1-9 times every 6 hours. Can worsen reactive airway symptoms

GI, Gastrointestinal; *IV,* intravenous; *LFT,* liver function test; *PDE5,* phosphodiesterase-5; *PH,* pulmonary hypertension; *SC,* subcutaneous.
Adapted from Abman, S. H., Hansmann, G., Archer, S. L., et al. (2015). Pediatric pulmonary hypertension: Guidelines from the American Heart Association and American Thoracic Society. *Circulation, 132*(21), 2037–2099.

and the cardiac dysfunction is not associated with systemic disease. Some of the known causes of **secondary cardiomyopathy** are anthracycline toxicity (the antineoplastic agents, doxorubicin [Adriamycin] and daunomycin), hemochromatosis (from excessive iron storage), Duchenne muscular dystrophy, Kawasaki disease, collagen diseases, and thyroid dysfunction.

Cardiomyopathies can be divided into three broad clinical categories according to the type of abnormal structure and dysfunction present: (1) dilated cardiomyopathy, (2) hypertrophic cardiomyopathy, and (3) restrictive cardiomyopathy.

Dilated cardiomyopathy is characterized by ventricular dilation and greatly decreased contractility, resulting in symptoms of HF. This is the most common type of cardiomyopathy in children. Its cause is often unknown. The clinical findings are of HF with tachycardia, dyspnea, hepatosplenomegaly, fatigue, and poor growth. Dysrhythmias may be present and may be more difficult to control with worsening HF.

Hypertrophic cardiomyopathy is characterized by an increase in heart muscle mass without an increase in cavity size, usually occurring in the left ventricle and associated with abnormal diastolic filling. It is a familial autosomal dominant genetic abnormality in most cases and is probably the most common genetically transmitted cardiovascular disease (Gajarski, Naftel, Pahl, et al., 2009). The expression of clinical disease varies greatly among patients. Clinical symptoms usually appear in the school-age period or adolescence and may include anginal chest pain, dysrhythmias, and syncope. One recent study confirmed that unexplained syncope in the childhood age-group (younger than 18 years old) with known hypertrophic cardiomyopathy had a 60% cumulative risk of sudden death within 5 years of the syncopal event (Spirito, Autore, Rapezzi, et al., 2009). Presentation in infancy includes signs of HF and has a poor prognosis. The ECG demonstrates left ventricular hypertrophy, often with ST-T changes. The echocardiogram is most helpful and demonstrates asymmetric septal hypertrophy and an increase in left ventricular wall thickness, with a small left ventricle cavity.

Restrictive cardiomyopathy, which is rare in children, describes a restriction to ventricular filling caused by endocardial or myocardial disease or both. It is characterized by diastolic dysfunction and absence of ventricular dilation or hypertrophy. Symptoms are similar to those of HF (see discussion earlier in the chapter).

Therapeutic Management

Treatment is directed toward correcting the underlying cause whenever feasible. However, in most affected children, this is not possible, and treatment is aimed at managing HF (see discussion earlier in the chapter) and dysrhythmias. Digoxin, diuretics, and aggressive use of afterload reduction agents have been found to be helpful in managing symptoms in those with dilated cardiomyopathy. Practice guidelines for the management of HF in children have been outlined and provide an in-depth review of available therapies (Kirk, Dipchand, Rosenthal, et al., 2014; Rossano & Shaddy, 2014). Digoxin and inotropic agents usually are not helpful in the other forms of cardiomyopathy because increasing the force of contraction may exacerbate the muscular obstruction and actually impair ventricular ejection. Beta-blockers (such as carvedilol) and calcium channel blockers (such as verapamil) have been used to reduce left ventricular outflow obstruction and improve diastolic filling in those with hypertrophic cardiomyopathy.

Careful monitoring and treatment of dysrhythmias are essential. The placement of an AICD should be considered for patients at high risk of sudden death because of ventricular dysrhythmias. Anticoagulants may be given to reduce the risk of thromboemboli, a complication of the sluggish circulation through the heart. For worsening HF and signs of poor perfusion, IV inotropic or vasodilating drugs may be needed. Severely ill children may require mechanical ventilation, oxygen administration, IV medications, and placement of ventricular assist devices. Heart transplantation may be a treatment option for patients who have worsening symptoms despite maximum medical therapy.

Nursing Care Management

Because of the poor prognosis in many children with cardiomyopathy, nursing care is consistent with that for any child with a life-threatening disorder (see Chapter 17). One of the most difficult adjustments for the child may be the realization of failing health and the need for restricted activity. The child should be included in decisions regarding activity and allowed to discuss feelings, particularly if the disease follows a progressively fatal course. After symptoms of HF or dysrhythmias develop, the same nursing interventions discussed earlier in the chapter are implemented. If heart transplantation is considered, the needs of the child and family are great in terms of psychologic preparation and postoperative care. The nurse plays an important role in assessing the family's understanding of the procedure and long-term consequences. Children of school age and older should be fully informed to give their assent to the procedure (see Chapter 20, Informed Consent).

HEART TRANSPLANTATION

Heart transplantation has become a treatment option for infants and children with worsening HF and a limited life expectancy despite maximum medical and surgical management. Indications for heart transplantation in children are cardiomyopathy and end-stage CHD. It is also an option for patients with some forms of complex congenital cardiac defects, such as hypoplastic left heart syndrome (HLHS), for whom conventional surgical approaches have a high mortality rate.

The heart transplant procedure may be orthotopic or heterotopic. **Orthotopic heart transplantation** refers to removing the recipient's own heart and implanting a new heart from a donor who has had brain death but a healthy heart. The donor and recipient are matched by weight and blood type. **Heterotopic heart transplantation** refers to leaving the recipient's own heart in place and implanting a new heart to act as an additional pump, or "piggyback" heart; this type of transplant is rarely done in children.

Before transplantation, potential recipients undergo a careful cardiac evaluation to determine if there are any other medical or surgical options to improve the patient's cardiac status. Other organ systems are assessed to identify problems that might increase the risk of or preclude transplantation. A psychosocial evaluation of the patient and family is done to assess family function, support systems, and ability to comply with the complex medical regimen after the transplant. Support services to help the family successfully care for their child are provided when possible. Parents and older adolescents need extensive education about the risks and benefits of transplantation so that they can make an informed decision. Patients are listed on a national computer network organized by the United Network for Organ Sharing to match donors and recipients (see also Chapter 17, Organ or Tissue Donation and Autopsy).

The annual number of pediatric heart transplants has increased from 274 in 1998 to 684 in 2015 (Dipchand, Rossano, Edwards, et al., 2015). Primary diagnosis for most candidates older than 1 year of age at listing continues to be cardiomyopathy, and most (>85%) candidates are status 1A at the time of transplant (Scientific Registry of Transplant Recipients, 2015). The 1-year graft survival rate for pediatric heart transplants in the current era is 90% (Scientific Registry of Transplant Recipients, 2015).

Waiting list mortality remains high, particularly in the smallest children. Recent progress in suitable ventricular assist devices for use in children as a bridge to transplantation has made outcomes to survival for cardiac transplantation more successful (Blume, Naftel, Bastardi, et al., 2006). A multicenter study using the US Scientific Registry of Transplant Recipients to identify the vulnerable population was conducted (Almond, Thiagarajian, Piercy, et al., 2009). Among 3098 children listed for a heart transplant between 1999 and 2006, the median age was 2 years. Sixty percent of patients were listed as a top status (30% ventilated and 18% on supportive measures), and of those children, 17% died, 63% received transplants, 8% recovered, and 12% remained listed. These numbers concluded that US waiting time remains high in the current era, and high-risk groups in these categories could benefit from emerging cardiac assist devices, such as extracorporeal membrane oxygenation and ventricular assist devices. In response, donor centers and transplant centers are identifying strategies to increase donor supply, optimize donor management, and facilitate changes in the organ allocation system (Zafar, Castleberry, Khan, et al., 2015).

The posttransplant course is complex. Although heart function is greatly improved or normal after transplantation, the risk of rejection is serious. The leading cause of death in the first 3 years after heart transplantation is rejection, with the greatest risk in the first 6 months (Everitt, Pahl, Schechtman, et al., 2011). Rejection of the heart is diagnosed primarily by endomyocardial biopsy in older children. Serial echocardiograms are often used in infants and young children to reduce the need for invasive biopsies. Immunosuppressants must be taken for life and have many systemic side effects. Triple-drug therapy for immunosuppression with a calcineurin inhibitor (cyclosporine or tacrolimus), steroids, and mycophenolate mofetil or azathioprine is most commonly used in pediatric patients. Steroids are weaned in the first year and may be discontinued in some patients; many pediatric centers are avoiding long-term steroids by using induction therapy protocols of high-dose steroids and thymoglobulin at the time of transplant (Thrush & Hoffman, 2014).

Infection is always a risk. Potential long-term problems that may limit survival include chronic rejection, causing coronary artery disease; renal dysfunction and hypertension resulting from cyclosporine administration; lymphoma; and infection. Coronary artery disease is the leading cause of death among late survivors of heart transplantation (Boucek, Aurora, Edwards, et al., 2007). In the short term, after successful transplantation, children can return to full participation in age-appropriate activities and appear to adapt well to their new lifestyle. Transplantation is not a cure because patients must live with the lifetime consequences of chronic immunosuppression.

NURSING CARE MANAGEMENT

Successfully caring for a child after a heart transplant requires the expertise and dedication of many members of the health care team. Nurses play vital roles in assessment, coordination of care, psychosocial support, and patient and family education. The heart transplant recipient must be carefully monitored for signs of rejection, infection, and the side effects of the immunosuppressant medications. The patient's and family's psychosocial well-being also needs to be assessed to identify issues such as increased family stress, depression, substance abuse, and school problems. Noncompliance with an intense medication regimen, especially during adolescence, can lead to serious medical problems and can be fatal. Immunosuppressants and nursing implications are discussed in Chapter 26 in relation to renal transplantation. Care of the immunosuppressed child is reviewed in Chapter 25. Psychosocial concerns and appropriate interventions for the child with a life-threatening disorder are presented in Chapter 17.

The first 6 months to 1 year after the transplant are most intense because the risk of complications is greatest and the patient and family are adjusting to a new lifestyle. Patients are monitored closely by the health care team, with frequent visits and laboratory tests. Care is usually shared between local health care providers and the transplant center. Many patients can return to school and other age-appropriate activities within 2 to 3 months after the transplant.

VASCULAR DYSFUNCTION

SYSTEMIC HYPERTENSION

Hypertension is defined as the consistent elevation of BP beyond values considered to be the upper limits of normal. The two major categories of hypertension are **essential hypertension** (no identifiable cause) and **secondary hypertension** (subsequent to an identifiable cause). Whether essential or attributable to a secondary cause, hypertension is a major contributor to cardiovascular disease in the adult population. Recently published Clinical Practice Guidelines streamline the recommendations for the evaluation of BP and outline the parameters for testing and treatment of young people with high BP (Flynn, Kaelber, Baker-Smith, et al., 2017). These guidelines are endorsed in another American Heart Association Scientific Statement that is aimed at risk reduction in patients considered to be at high risk (de Ferranti et al., 2019). It is important to note that new normative BP tables are based only on children of normal weight, those below the 95th percentile BMI (as opposed to all children). The new guidelines rely on percentiles (based on age, sex, and height) to define norms only for children younger than 13 years old, whereas the definition of abnormal BP in adolescents older than 13 years of age is now defined using numeric cut points, designed to interface with adult hypertension guidelines (Whelton, Carey, Aranow, et al., 2018). The previous category of prehypertension has been relabeled as elevated blood pressure.

Abnormal BP categories are now defined as follows: (1) elevated blood pressure, (2) stage 1 hypertension, or (3) stage 2 hypertension (see https://pediatrics.aappublications.org/content/140/3/e20171904 for additional information). All BP normal values are based on auscultated blood pressures, the preferred method of measurement. The goal of treatment is decreasing systolic and diastolic BP values to below the 90th percentile in children younger than 13 years old and less than 130/80 mm Hg in adolescents older than 13 years of age (Flynn et al., 2017).

ETIOLOGY

Most instances of hypertension in very young children occur secondary to a structural abnormality or an underlying pathologic process, although this is being challenged by screening programs of relatively healthy children. The most common cause of secondary hypertension is renal disease followed by cardiovascular, endocrine, and some neurologic disorders. As a rule, the younger the child and the more severe the hypertension, the more likely it is to be secondary (Mattoo, 2019).

The causes of essential hypertension are undetermined, but evidence indicates that both genetic and environmental factors may play a role. The incidence of hypertension has been shown to be higher in children whose parents are hypertensive. African Americans have a higher incidence of hypertension than whites, and in African Americans hypertension develops earlier, is frequently more severe, and results in death at an earlier age. Environmental factors that contribute to the risk of developing hypertension include obesity, salt ingestion, smoking, and stress.

DIAGNOSTIC EVALUATION

BP assessment is recommended as a routine part of annual assessment in healthy children older than 3 years of age. BP readings should be taken in children younger than 3 years old if they have individual risk factors, including CHD, kidney disease, malignancy, transplant, certain neurologic problems, or systemic illnesses known to cause hypertension, or high-risk family history. Assessing for symptoms of BP elevation such as frequent headaches, dizziness, and visual changes should be part of the health history. In infants and very young children who cannot communicate symptoms, observation of behaviors such as head banging/rubbing or irritability may provide clues, although many behavioral changes are nonspecific.

Before a diagnosis of hypertension is made, BP should be measured on at least three separate occasions at healthy visits only. An ambulatory BP monitor may be helpful to assess for "white-coat hypertension" or for those patients who have had elevated BPs for a year or more as well as patients whose BPs fall in the range of stage 1 hypertension over three clinic visits. Appropriate cuff size should be specified. These monitors are useful in that they provide BP readings over a 24-hour period. There are different normative values for ambulatory BP readings (Flynn, Daniels, Hayman, et al., 2014).

A careful medical history and family history should be obtained to screen for other relatives with hypertension and other cardiovascular risk factors. In children with suspected hypertension, initial laboratory data include a urinalysis, renal function studies (such as creatinine and blood urea nitrogen), a lipid profile, and electrolytes. For obese patients, hemoglobin A1c (HgbA1c), aspartate aminotransferase (AST), ALT and fasting lipid values are recommended. Additional testing is determined based on the individual's age, history, degree of BP elevation, and physical examination and may include additional laboratory work (thyroid-stimulating hormone [TSH], complete blood count [CBC], drug screen, retinal examination, sleep study). Renal ultrasonography is now recommended only in children younger than 6 years old unless there are laboratory abnormalities or clinical reasons to prompt kidney imaging. If a renal ultrasound is indicated, it should include Doppler flow as well as kidney size. ECGs are no longer recommended as a routine part of the workup in children and adolescents. Echocardiograms are not recommended as part of the initial screening but should be obtained prior to initiating pharmacologic therapy in order to help evaluate the presence of end-organ involvement, such as left ventricular hypertrophy and effects on ejection fraction. The frequency of repeat surveillance echocardiograms depends on the presence or absence of left ventricular hypertrophy as well as the individual response to BP treatment. A more extensive workup for a secondary cause of hypertension may be indicated in children with significant hypertension in the setting of normal initial screening results (Flynn et al., 2017).

Therapeutic Management

Therapy for secondary hypertension involves the diagnosis and treatment of the underlying cause. Children and adolescents with consistently elevated BP readings from no known cause or those with secondary hypertension not amenable to surgical correction are treated with a combination of lifestyle and pharmacologic interventions. Dietary practices and lifestyle changes are important in the control of hypertension both for children and for adults. Nonpharmacologic measures, such as weight control in overweight patients, increased exercise, limited salt intake (such as recommended in the Dietary Approaches to Stop Hypertension [DASH] diet), and avoidance of stress and smoking, carry no risk and should be instituted as first-line therapy except in severe cases in which pharmacologic therapy may be indicated as well.

Drug therapy is instituted with caution in children but may be necessary to treat significant elevations of BP despite lifestyle modification. Pharmacologic treatment begins with one drug, with other drugs added if adequate control is not obtained. The classes of oral antihypertensive drugs now recommended for use in young people include ACE inhibitors, angiotensin-receptor blockers, long-acting calcium channel blockers, and thiazide diuretics. Beta-blockers are no longer recommended in children due to their side effects and the availability of other medications. The goal of treatment is to achieve a normotensive state without accompanying drug side effects.

Nursing Care Management

BP measurement should be a part of the routine assessment of children older than 3 years of age and patients younger than 3 years old who are considered to be at high risk for hypertension. To obtain an accurate reading, care is taken to quiet the child or relax the adolescent while the measurement is recorded to avoid false readings caused by excitement. BP should be measured in the sitting position with the arm at the level of the heart. Initial evaluation should also include four extremity pressures (in the supine position) to rule out COA. The chief cause of falsely elevated BP readings is the use of improperly fitting, narrow cuffs. Therefore attention to correct measurement technique is essential (see Chapter 4, Blood Pressure).

Education aimed at understanding hypertension and its implication over the life span is essential in promoting patient and family compliance with both nonpharmacologic and pharmacologic therapies (see Chapter 20, Compliance).

Ambulatory or home BP measurements can facilitate surveillance in youngsters being assessed for hypertension or can document the effectiveness of therapy for those being treated for chronic hypertension. In addition, a family member can be instructed on how to take and record accurate BP measurements, thus decreasing the number of trips to a health care facility. This individual needs to have parameters, above which they should contact the practitioner. In addition, the school nurse can often be a valuable resource in monitoring BP. The nurse plays an important role in assessing individual families and providing targeted information regarding nonpharmacologic modes of intervention, such as diet, weight loss, smoking cessation, and exercise programs. A DASH diet—low in sodium, red meats, and sugar and high in fruits, vegetables, whole grains, beans, nuts, low-fat dairy, fish, and poultry—is recommended for children and adolescents with elevated BP or hypertension. The child should be referred to a registered dietitian with expertise in working with children and adolescents with hypertension. Exercise regimens should be individualized but should emphasize the benefits of regular aerobic exercise (ideally 300 minutes of aerobic exercise weekly). School-age children and young adolescents generally prefer team sports to individual training, which they may view as a burden rather than an enjoyable activity. If peers and family members can be encouraged to participate in any of the management strategies, the child's compliance is likely to be greater.

If drug therapy is prescribed, the nurse needs to provide information to the family on the reasons for it, how the drug works, and possible side effects. General instructions for antihypertensive drugs include:

- Rise slowly from a horizontal position and avoid sudden position changes.
- Take drugs as prescribed.
- Maintain adequate hydration.
- Notify the practitioner if side effects occur but do not discontinue the drug.

- Avoid alcohol and stay on the prescribed diet (generally the DASH diet).

The need for regular follow-up is stressed, especially because antihypertensive therapy can sometimes be safely discontinued if BP remains under control over time.

KAWASAKI DISEASE

Kawasaki disease is an acute systemic vasculitis of unknown cause. It is seen in every racial group, with 76% of the cases occurring in children younger than 5 years old. The peak incidence is in the toddler age-group. The acute disease is self-limited; however, without treatment approximately 20% to 25% of children develop coronary artery dilation or aneurysm formation (coronary artery anomaly [CAA]). Infants younger than 1 year old are at the greatest risk for heart involvement, although an increased incidence has also been reported in older children, perhaps because of later diagnosis in many.

The etiology of Kawasaki disease is unknown. The illness is not spread by person-to-person contact; however, several factors support an infectious etiologic trigger, possibly in a genetically susceptible host. This theory is supported by a higher prevalence in Asian children and in siblings and children of patients with Kawasaki disease. Kawasaki disease is often seen in geographic and seasonal outbreaks, with an increased incidence reported in late winter and early spring (McCrindle, Rowley, Newburger, et al., 2017; Newburger, de Ferranti, & Fulton, 2017).

Pathophysiology

The principal area of concern in Kawasaki disease is the cardiovascular system. During the initial stage of the illness, extensive inflammation of the arterioles, venules, and capillaries is evident, resulting in many of the clinical symptoms. In addition, segmental damage to the medium-size muscular arteries, mainly the coronary arteries, can occur, resulting in the formation of coronary artery aneurysms in some children. Death is very rare in Kawasaki disease (<0.1% of cases) and is usually the result of myocardial ischemia from coronary thrombosis during the first few months of illness or years later from severe scar formation and stenosis in coronary aneurysms (Wilder, Palinkas, Kao, et al., 2007).

Clinical Manifestations

Because no specific diagnostic test exists for Kawasaki disease, the diagnosis is established based on clinical findings and associated laboratory results (Box 23.12). These criteria should be used as guidelines. It is important to note that many children with Kawasaki disease do not fulfill standard diagnostic criteria, and infants in particular often have an incomplete presentation. It is therefore important to consider Kawasaki disease as a possible diagnosis in any infant or child with prolonged fever that is unresponsive to antibiotics and is not attributable to another cause.

Kawasaki disease manifests in three phases: acute, subacute, and convalescent. The **acute phase** begins with abrupt onset of a high fever that is unresponsive to antibiotics and antipyretics. The remaining diagnostic symptoms evolve over the next week or so. Symptoms may come and go and do not need to be present simultaneously for diagnosis, although the fever is generally persistent throughout. During this stage, the child is typically very irritable. Laboratory tests may demonstrate an elevated white blood cell count, elevated liver function tests, and elevated markers of inflammation (ESR and CRP). Of note, the platelet count is initially normal, rising in the second week of illness. Patients may also present with sterile pyuria, hydrops of the gallbladder, and/or aseptic meningitis. The **subacute phase** begins with resolution of the fever and lasts until all clinical signs of Kawasaki disease have disappeared. During this phase, coronary artery aneurysms may become evident, and previously dilated vessels may continue to increase in size. Irritability persists during this phase. Lab work shows a normochromic, normocytic anemia as well as thrombocytosis. Inflammatory markers start to resolve (after intravenous immunoglobulin [IVIG] treatment, ESR is no longer an accurate marker of inflammation, as it is raised by IVIG, and therefore CRP is favored). In the **convalescent phase**, all clinical signs of Kawasaki disease have resolved, and laboratory values are returning to normal. The entire illness lasts 6 to 8 weeks until the child has regained his or her usual temperament, energy, and appetite and all blood tests are back to normal.

BOX 23.12 Diagnostic Criteria for Kawasaki Disease

Classic Kawasaki disease criteria include fever for 5 calendar days along with four of five clinical criteria[a] (diagnosis may be made on day 4 of fever by an experienced clinician in children with fever and more than four clinical criteria):

1. Changes in the extremities: In the acute phase, edema or erythema of the palms and soles; in the subacute phase, periungual desquamation (peeling) of the hands and feet
2. Bilateral conjunctival injection (inflammation) without exudation
3. Changes in the oral mucous membranes, such as erythema, cracking of the lips, oropharyngeal reddening; or "strawberry tongue" (large papillae are exposed)
4. Rash: Maculopapular, diffuse erythroderma, or erythema multiforme-like
5. Cervical lymphadenopathy (typically unilateral >1.5 cm)

[a]Incomplete Kawasaki disease should be considered in situations of prolonged fever (see algorithm for incomplete Kawasaki disease from American Heart Association guidelines). Kawasaki disease can be diagnosed with fewer clinical criteria when coronary artery changes are noted.

Adapted from McCrindle, B. W., Rowley, A. H., Newburger, J. W., et al. (2017). Diagnosis, treatment, and long-term management of Kawasaki disease: A scientific statement for health professionals from the American Heart Association. *Circulation, 135*(17), e927–e999.

Cardiac Involvement

Long-term complications of Kawasaki disease include the development of coronary artery aneurysms, potentially disrupting blood flow to the heart. Children with large (giant) aneurysms have a risk of myocardial infarction, resulting from thrombotic occlusion of a coronary aneurysm or late-stenosis and occlusion of the affected vessel.

Affected coronary arteries may dilate progressively over the initial few weeks of illness, reaching their maximal diameter approximately 4 to 6 weeks from the onset of fever. Over years, as the damaged vessel tries to heal, stenosis of the aneurysm may develop and may lead to myocardial ischemia. The vast majority of the morbidity in Kawasaki disease occurs in children affected with the largest aneurysms (giant aneurysms >8 mm or z-score >10). The actual mortality is low (<0.1% in Japan). Symptoms of acute myocardial infarction in young children can be confusing and may include abdominal pain, vomiting, restlessness, inconsolable crying, pallor, and shock, as well as chest pain or pressure (noted more often in older children). Cardiac involvement in the initial phase of the illness may also include effects related to inflammation of the myocardium, including myocarditis, valvulitis, or arrhythmias.

Echocardiograms are used to assess coronary artery dilation, monitoring coronary artery dimensions during the initial illness as well as myocardial and valvar function. A baseline echocardiogram should be obtained at the time of diagnosis and is then used for comparison with future studies. Follow-up echocardiograms should be obtained

approximately 1 week after the initial diagnosis and again 4 to 6 weeks later in uncomplicated patients. Additional echocardiograms should be done (often as frequently as twice a week) in situations where a child has coronary artery dilation or obvious aneurysm formation or when response to treatment is incomplete.

Therapeutic Management

The current treatment of children with Kawasaki disease includes the administration of high-dose IVIG along with salicylate therapy. IVIG has been demonstrated to be effective at reducing the incidence of coronary artery abnormalities when given within the first 10 days of the illness and ideally in the first 7 days of illness. A single infusion of IVIG, 2 g/kg over 10 to 12 hours, is recommended. Retreatment with IVIG and/or other antiinflammatory drugs should be given to patients who have an incomplete response to the initial IVIG (those with continued or recrudescent fever 36 hours after the end of the initial IVIG infusion) or those with coronary artery dilation (McCrindle et al., 2017).

Aspirin has been used historically to control fever and symptoms of inflammation. Initial doses of aspirin have ranged from moderate to high dose (30 to 50 mg/kg/day in divided doses every 6 hours up to 80 to 100 mg/kg/day in divided doses every 6 hours). The use of aspirin is not associated with a decrease in the incidence of coronary aneurysms. After the patient is afebrile for 48 to 72 hours, aspirin can be reduced to an antiplatelet dose (3 to 5 mg/kg/day). Low-dose aspirin is continued in patients without echocardiographic evidence of coronary abnormalities until the platelet count has returned to normal (6 to 8 weeks) (McCrindle et al., 2017). If the child develops coronary abnormalities, salicylate therapy is continued indefinitely. Additional antithrombotic medications (e.g., clopidogrel [Plavix], enoxaparin [Lovenox], or warfarin) are added for children with coronary artery aneurysms depending on the size of the CAA.

Prognosis

Most children with Kawasaki disease recover fully after treatment. However, when cardiovascular complications occur, serious morbidity may result. The prognosis for patients is strongly related to the extent of coronary damage, with patients who have giant aneurysms being at the highest risk for complications and those with normal coronary dimensions having an excellent long-term prognosis.

QUALITY PATIENT OUTCOMES: Kawasaki Disease

- Early diagnosis and treatment
- Prevention of cardiovascular complications

Nursing Care Management

In the initial phase, the nurse must monitor the child's cardiac status carefully. Intake and output and daily weight measurements are recorded. Fluids are administered with care because of the usual finding of myocarditis. The child should be assessed frequently for signs of HF, including decreased urinary output, gallop rhythm (an additional heart sound), tachycardia, and respiratory distress.

Administration of IVIG should follow the same guidelines as for any blood product, with frequent monitoring of vital signs. Generally, IVIG rates are titrated up per individual hospital protocols. During the infusion and in the few days after, patients must be watched for reactions to this medication, which may include fever, headache, and nausea. Cardiac status must be monitored because of the large volume being administered to patients who may have diminished left ventricular function.

The majority of nursing care in the hospital focuses on symptomatic relief. To minimize skin discomfort, cool cloths; unscented lotions; and soft, loose clothing are helpful. During the acute phase, mouth care, including lubricating ointment to the lips, is important for mucosal inflammation. Clear liquids and soft foods can be offered.

Patient irritability and mood swings are pervasive in KD. During hospitalization, these children need a quiet environment that promotes adequate rest. Their parents need to be supported in their efforts to comfort an often inconsolable child. They may need time away from their child, and nurses can often provide respite care for the family. Parents need to understand that irritability is a hallmark of Kawasaki disease and that it will resolve. They need not feel guilty or embarrassed about their child's behavior.

Discharge Teaching

Parents need accurate information about the course of the illness, including the importance of follow-up monitoring and when they should contact their practitioner. Irritability may persist for up to 2 months after the onset of symptoms. Periungual desquamation (peeling of the hands and feet) begins in the second and third weeks. Usually the fingertips peel first, followed by the toes and feet. The peeling is painless, but the new skin may be tender. A temporary arthritis may occur in Kawasaki disease, involving the small joints initially but possibly also affecting the larger weight-bearing joints. Affected children are typically most stiff in the mornings, during cold weather, and after naps. Passive range-of-motion exercises in the bathtub are often helpful in increasing flexibility. Any live immunizations (e.g., measles, mumps, and rubella; varicella) should be deferred for 11 months after the administration of IVIG because the body might not produce the appropriate amount of antibodies to provide lifelong immunity. Daily temperatures should be recorded in the first week or two after discharge, and the occurrence of fever should be communicated to the health care provider, as continuing fever warrants evaluation and further treatment.

Parents of children with large or giant aneurysms should be educated on the unlikely but real possibility of myocardial infarction, as well as the signs and symptoms of cardiac ischemia in a child. CPR should be taught to parents of children with coronary artery aneurysms.

Long-Term Follow-Up

The frequency and type of follow-up are based on the presence or absence of coronary damage. The long-term outlook for children without aneurysms is excellent, and therefore long-term cardiology follow-up is no longer indicated in this group of patients (McCrindle et al., 2017). These patients should have a cholesterol screen performed at routine physical examinations as per the general population; routine BP monitoring; and education recommending a heart-healthy lifestyle, including exercise, a heart-healthy diet, and avoidance of smoking.

In patients with aneurysms, cardiology follow-up is necessary. The frequency of cardiology follow-up as well as the use of long-term antithrombotic therapy is based on the largest abnormal coronary dimension with patients classified according to the American Heart Association risk levels (McCrindle et al., 2017). Noninvasive coronary imaging (e.g., echocardiography, ECGs, and stress testing to assess for reversible ischemia) is used as much as possible, with other forms of imaging, such as low-radiation cardiac computed tomography, cardiac MRI, and cardiac angiography, recommended based on individual symptoms as well as the classification of risk according to the American Heart Association (McCrindle et al., 2017).

In addition to regular monitoring, patients with coronary aneurysms may require long-term antiplatelet or anticoagulation and possibly beta-blocker therapy or other therapies, depending on the severity of coronary involvement.

MULTISYSTEM INFLAMMATORY SYNDROME

Multisystem Inflammatory Syndrome in children (MIS-C) is associated with coronavirus disease (COVID-19) and causes different body systems to become inflamed, including the heart, lungs, kidneys, brain, skin, eyes, or gastrointestinal organs (Dufort, Koumans, Chow, et al., 2020). Many children have fever and mucocutaneous lesions similar to Kawasaki's disease; however, MIS-C is associated with more cardiovascular involvement.

Pathophysiology

Little is known about the pathophysiology of MIS-C. It is felt that MIS-C is a consequence of immune-mediated injury triggered by COVID-19 (Feldstein, Rose, Horwitz, et al., 2020).

Clinical Manifestations

The Centers for Disease Control (2020) describes MIS-C in children less than 21 years of age using the following criteria:

- Fever ≥38.0° C for ≥24 hours or report of subjective fever lasting ≥24 hours
- Laboratory evidence of inflammation including, but not limited to, one or more of the following: an elevated C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), fibrinogen, procalcitonin, d-dimer, ferritin, lactic acid dehydrogenase (LDH), or interleukin 6 (IL-6), elevated neutrophils, reduced lymphocytes and low albumin
- Evidence of clinically severe illness requiring hospitalization, with multisystem (≥2) organ involvement (cardiac, renal, respiratory, hematologic, gastrointestinal, dermatologic or neurological)
- No alternative plausible diagnoses
- Positive for current or recent COVID-19 infection documented by reverse-transcriptase polymerase chain reaction (RT-PCR), serology, or antigen test; or COVID-19 exposure within the 4 weeks prior to the onset of symptoms

Therapeutic Management

Since MIS-C is a new syndrome in children numerous treatment options are being investigated. Some aspects of MIS-C management are similar to the therapeutic management of Kawasaki disease (see p….). Intravenous immune globulin and systemic glucocorticoids are given (Whittaker, Bamford, Kenny, et al., 2020). Antiviral agents are being explored during the acute stage of the illness. Many children with MIS-C require mechanical ventilation and some receive extracorporeal membrane oxygenation (ECMO) support (Feldstein, Rose, Horwitz, et al., 2020).

Until more is known about long-term cardiac sequelae of MIS-C, providers should consider following Kawasaki's disease guidelines for follow-up. Long-term monitoring for other potential sequelae of MIS-C will also be critical (Whittaker, Bamford, Kenny, et al., 2020).

Nursing Care Management

Caring for a child with MIS-C is similar to the care of a critically ill child with Kawasaki's disease (see p. 764).

SHOCK

Shock, or **circulatory failure**, is a complex clinical syndrome characterized by inadequate tissue perfusion to meet the metabolic demands of the body, resulting in cellular dysfunction and eventual organ failure. Although the causes are different, the physiologic consequences are the same and include hypotension, tissue hypoxia, and metabolic acidosis. Circulatory failure in children is a result of hypovolemia, altered peripheral vascular resistance, or pump failure. Types of shock and their clinical signs are listed in Table 23.7.

Pathophysiology

A healthy child's circulatory system is able to transport oxygen and metabolic substrates to body tissues, which require a constant source for these essential needs. The cardiac output and distribution to the various body tissues can change rapidly in response to intrinsic (myocardial and intravascular) or extrinsic (neuronal) control mechanisms. In shock states, these mechanisms are altered or challenged.

Reduced blood flow, as in hypovolemic shock, causes diminished venous return to the heart, low CVP, low cardiac output, and hypotension. Vasomotor centers in the medulla are signaled, causing a compensatory increase in the force and rate of cardiac contraction and constriction of arterioles and veins, thereby increasing peripheral vascular resistance. Simultaneously, the lowered blood volume leads to the release of large amounts of catecholamines, antidiuretic hormone, adrenocorticosteroids, and aldosterone in an effort to conserve body fluids. This causes reduced blood flow to the skin, kidneys, muscles, and viscera to shunt the available blood to the brain and heart. Consequently, the skin feels cold and clammy, there is poor capillary filling, and glomerular filtration rate and urinary output are significantly reduced.

As a result of impaired perfusion, oxygen is depleted in the tissue cells, causing them to revert to anaerobic metabolism, producing lactic acidosis. The acidosis places an extra burden on the lungs as

TABLE 23.7 Clinical Signs of Shock

Clinical Signs	Hypovolemic Shock	Distributive Shock	Cardiogenic Shock	Obstructive Shock
Respiratory rate	Normal to increased	Normal to increased	Labored	Labored
Breath sounds	Normal	Normal (crackles may or may not be present)	Crackles, grunting	Crackles, grunting
Systolic blood pressure	Compensated-normal	Compensated-normal	Hypotensive-low	Hypotensive-low
Pulse pressure	Narrow	Variable	Narrow	Narrow
Heart rate	Tachycardia	Tachycardia	Tachycardia	
Peripheral pulses	Weak	Bounding or weak	Weak	
Skin	Pale, cool	Warm or cool	Pale, cool	
Capillary refill	Delayed (>2 sec)	Variable	Delayed (>2 sec)	
Urine output	Decreased (<1 ml/kg/h [<30 kg; 66 pounds); <30-50 ml/kg/h [>30 kg, 66 pounds])			
Level of consciousness	Irritable early	Late, lethargic		

Adapted from American Heart Association. (2016). Pediatric advanced life support (PALS) provider manual. Dallas, TX: American Heart Association.

they attempt to compensate for the metabolic acidosis by increasing the respiratory rate to remove excess carbon dioxide. Prolonged vasoconstriction results in fatigue and atony of the peripheral arterioles, which leads to vessel dilation. Venules, which are less sensitive to vasodilator substances, remain constricted for a time, causing massive pooling in the capillary and venular beds, which further depletes blood volume.

Complications of shock create further hazards. CNS hypoperfusion eventually may lead to cerebral edema, cortical infarction, or intraventricular hemorrhage. Renal hypoperfusion causes renal ischemia with possible tubular or glomerular necrosis and renal vein thrombosis. Reduced blood flow to the lungs can interfere with surfactant secretion and result in acute respiratory distress syndrome, which is characterized by sudden pulmonary congestion and atelectasis with formation of a hyaline membrane. Gastrointestinal tract bleeding and perforation are always possibilities after splanchnic ischemia and necrosis of intestinal mucosa. Metabolic complications of shock may include hypoglycemia, hypocalcemia, and other electrolyte disturbances.

Clinical Manifestations

Shock can be regarded as a form of compensation for circulatory failure and, because of its progressive nature, can be divided into two stages or phases: **compensated** and **hypotensive** (previously referred to as decompensated). Cardiac arrest represents irreversible shock. At all stages the principal differentiating signs are the degree of tachycardia and perfusion to extremities, the level of consciousness, and BP. Additional signs or modifications of these more universal signs may be present, depending on the type and cause of the shock. Initially, the child's ability to compensate is effective; therefore early signs are subtle. As the shock state advances, signs are more obvious and indicate early decompensation (Box 23.13).

BOX 23.13 Clinical Manifestations of Shock

Compensated
Apprehensiveness
Irritability
Unexplained tachycardia
Normal blood pressure (BP)
Narrowing pulse pressure
Thirst
Pallor
Diminished urinary output
Reduced perfusion of extremities

Hypotensive
Confusion and somnolence
Tachypnea
Moderate metabolic acidosis
Oliguria
Cool, pale extremities
Decreased skin turgor
Poor capillary filling

Irreversible
Thready, weak pulse
Hypotension
Periodic breathing or apnea
Anuria
Stupor or coma

Compensated Shock

When vital organ function is maintained by intrinsic mechanisms and the child's ability to compensate is effective, cardiac output and systemic arterial BP are usually normal or increased. However, blood flow is generally uneven or maldistributed in the microcirculation. Early clinical signs are subtle and include apprehension, irritability, normal BP, narrowing pulse pressure, thirst, pallor, and diminished urinary output.

! NURSING ALERT

Unexplained mild tachycardia and a decrease in perfusion of the hands and feet are differentiating features of compensated shock.

Hypotensive (Decompensated) Shock

As shock progresses, perfusion in the microcirculation becomes marginal despite compensatory adjustments, and the signs are more obvious and indicate early decompensation. These signs are tachypnea; moderate metabolic acidosis; oliguria; and cool, pale extremities with decreased skin turgor and poor capillary filling. Hypotensive shock may be differentiated from compensated shock by evaluating BP; the child in hypotensive shock will have a low BP, but hypotension is a late finding. Another clinical sign of hypotensive shock is a change in level of consciousness as brain perfusion declines. The outcomes of circulatory failure that progress beyond the limits of compensation are tissue hypoxia, metabolic acidosis, and eventual dysfunction of all organ systems

! NURSING ALERT

In hypotensive shock, tachycardia is pronounced and pulse pressure (difference between systolic and diastolic blood pressure) becomes narrowed. There is poor capillary filling, and the child exhibits confusion, sleepiness, and decreased responsiveness.

As hypotensive shock progresses along a physiologic continuum, clinical signs indicate a progression of circulatory damage. With the progression of shock, there is damage to vital organs (e.g., the heart or brain) of such magnitude that the entire system is disrupted regardless of therapeutic intervention. There is pronounced systemic vasoconstriction and hypoxia of visceral and cutaneous circulations with hypotension, acidosis, lethargy or coma, and oliguria or anuria. The child is totally obtunded. A thready and weak pulse, hypotension, periodic breathing or apnea, anuria, and stupor or coma are signs of impending cardiac arrest. Death occurs even if cardiovascular measurements return to normal levels with therapy.

! NURSING ALERT

Hypotension is a late and poor prognostic sign of shock, so signs of shock must be recognized and appropriate interventions implemented before hypotension is evident.

At all stages, the principal differentiating signs are observed in the (1) degree of tachycardia and perfusion to the extremities, (2) level of consciousness, and (3) BP. Additional signs or modifications of these more universal signs may be present depending on the type and cause of the shock. Initially, the child's ability to compensate is effective; therefore early signs are subtle. As the shock state advances, signs are more obvious and indicate early decompensation.

Additional signs may be present, depending on the type and cause of the shock. In early septic shock, there are chills, fever, and vasodilation, with increased cardiac output that results in warm, flushed skin

(hyperdynamic, or "warm" shock). A later and ominous development is disseminated intravascular coagulation (DIC) (see Chapter 24), the major hematologic complication of septic shock. Anaphylactic shock is frequently accompanied by urticaria and angioneurotic edema, which is life threatening when it involves the respiratory passages (see Anaphylaxis later in the chapter).

Laboratory tests that assist in assessment are blood gas measurements, pH, and sometimes liver function tests. Coagulation tests are evaluated when there is evidence of bleeding, such as oozing from a venipuncture site, bleeding from any orifice, or petechiae. Cultures of blood and other sites are indicated when there is a high suspicion of sepsis. Renal function tests are performed when impaired renal function is evident.

Therapeutic Management

Treatment of shock consists of three major interventions: (1) oxygenation and ventilation, (2) fluid administration, and (3) improvement of the pumping action of the heart (vasopressor support). The priority is to establish an airway and administer oxygen. After the airway is ensured, circulatory stabilization is the major concern. Establishment of adequate IV access, ideally with multilumen central lines, is essential to deliver fluids and medications.

Oxygenation and Ventilatory Support

The lung is the organ most sensitive to shock. Decreased distribution or redistribution of blood flow to respiratory muscles plus the increased work of breathing can rapidly lead to respiratory failure. Supplemental oxygen is always given as soon as possible. Critically ill patients are unable to maintain an adequate airway. To place the lung at rest and improve ventilation, endotracheal intubation is initiated early with positive-pressure ventilation and oxygen. Blood gases, oxygen saturation (using pulse oximetry), and pH are monitored frequently.

Increased extravascular lung water caused by edema contributes to the development of respiratory complications. Therapy is directed toward maintaining normal arterial blood gas measurements, normal acid-base balance, and circulation. Efforts are made to remove fluid and prevent its accumulation with the use of diuretics.

Cardiovascular Support

In many cases, rapid restoration of blood volume is the main therapy needed in the resuscitation of the child in shock. An isotonic crystalloid solution (0.9% normal saline or lactated Ringer solution) is usually the first choice for fluid replacement. Crystalloid is given in IV boluses of 20 ml/kg over 5 to 20 minutes and repeated as necessary. Blood products may also be given if acute blood loss is the cause of hypovolemia. The child's response is assessed after each bolus. An increase in BP and a decrease in heart rate indicate successful resuscitation. An increased cardiac output results in improved capillary circulation and skin color. Colloids (protein-containing fluids) are often administered to children in shock; albumin is the most common. Because albumin is a protein solution, it remains in the vascular space much longer than crystalloid fluids.

For the critically ill child with shock and multisystem organ dysfunction, more aggressive monitoring is necessary. CVP measurements of right atrial pressure help guide fluid therapy, and urinary output measurement is an important indicator of adequacy of circulation. Correction of acidosis, hypoxemia, hypoglycemia, hypothermia, and any metabolic derangements is mandatory.

Temporary pharmacologic support may be required to enhance myocardial contractility, reverse metabolic or respiratory acidosis, and maintain arterial pressure. The principal agents used to improve cardiac output and circulation are catecholamines, such as dopamine (Intropin) and epinephrine (Adrenalin). Dopamine is the preferred drug in most situations because it also improves renal perfusion. Metabolic acidosis is usually corrected with adequate tissue perfusion and improved renal function. This is accomplished with adequate ventilatory support, including oxygen, and restoration of blood volume and peripheral circulation

QUALITY PATIENT OUTCOMES: Shock

- Oxygen content of blood optimized
- Cardiac output improved
- Oxygen demand reduced
- Metabolic abnormalities corrected
- Type of shock identified and treated

Nursing Care Management

The child who is in shock requires intensive observation and care. The initial action is to ensure adequate tissue oxygenation. The nurse should be prepared to administer oxygen by the appropriate route and to assist with any intubation and ventilatory procedures indicated. Other procedures and activities that require immediate attention are establishing an IV line, weighing the child, obtaining baseline vital signs, placing an indwelling catheter, obtaining blood gases and other measurements, and administering fluids and medications as indicated. The child is best positioned flat with the legs elevated.

! NURSING ALERT

Early clinical signs of shock include apprehension, irritability, normal blood pressure (BP), narrowing pulse pressure (difference between diastolic and systolic BP), thirst, pallor, diminished urinary output, unexplained mild tachycardia, and decreased perfusion of the hands and feet.

The nurse's responsibilities are to monitor the IV infusion, intake and output, vital signs (including CVP), and general systems assessments on a routine basis. IV medications are titrated according to patient responses, and vital signs are taken every 15 minutes during the critical periods and thereafter as needed. Urinary output is measured hourly; blood gases, hematocrit, pH, and electrolytes are monitored frequently to assess the child's status and the efficacy of therapy. An apnea and cardiac monitor and pulse oximeter is attached and monitored continuously. In the initial stages of acute shock, more than one nurse is often needed to manage the necessary activities that must be carried out simultaneously (see Emergency Treatment box).

EMERGENCY TREATMENT

Shock

Ventilation
Establish airway; be prepared for intubation.
Administer 100% oxygen.

Fluid Administration
Restore fluid volume as ordered via intravenous (IV) lines.

Cardiovascular Support
Administer inotropes and vasopressors as ordered.

General Support
Keep child flat with legs raised above level of heart.
Keep child warm and calm.

Throughout the intense activity, support for the family must not be overlooked. Someone should contact family members at frequent intervals to inform them of what is being done and whether there is any progress. Ideally, someone should remain with the parents to serve as a liaison between them and the intensive care team. However, this is not always feasible in such a critical situation. As soon as possible, the family should be allowed to see the child. A member of the clergy or a social worker may be called to help provide comfort and support.

ANAPHYLAXIS

Anaphylaxis is the acute clinical syndrome resulting from the interaction of an allergen and a patient who is hypersensitive to that allergen. When the antigen enters the circulatory system, a generalized reaction rapidly takes place, and chemical substances, primarily histamine, are released from mast cells and cause vasodilation, bronchoconstriction, and increased capillary permeability.

Severe reactions are immediate in onset; are often life threatening; and frequently involve multiple systems, primarily the cardiovascular, respiratory, gastrointestinal, and integumentary systems. Exposure to the antigen can be by ingestion, inhalation, skin contact, or injection. Examples of common allergens associated with anaphylaxis include drugs (e.g., antibiotics, chemotherapeutic agents, radiologic contrast media), latex, foods, venom from bees or snakes, and biologic agents (antisera, enzymes, hormones, blood products).

NURSING ALERT

Penicillin allergy is associated with immediate onset (within 1 hour of administration) or accelerated onset (1 to 72 hours after administration) of skin eruption, especially an urticarial rash, or more serious symptoms such as laryngeal edema or anaphylactic shock.

Clinical Manifestations

The onset of clinical symptoms usually occurs within seconds or minutes of exposure to the antigen, and the rapidity of the reaction is directly related to its intensity: the sooner the onset, the more severe the reaction. The reaction may be preceded by symptoms of uneasiness, restlessness, irritability, severe anxiety, headache, dizziness, paresthesia, and disorientation. The patient may lose consciousness. Cutaneous signs of flushing and urticaria are common early signs followed by angioedema, most notable in the eyelids, lips, tongue, hands, feet, and genitalia.

Bronchiolar constriction may follow, causing narrowing of the airway; pulmonary edema and hemorrhage also may occur. Laryngeal edema with severe acute upper airway obstruction may be life threatening and requires rapid intervention. Shock occurs as a result of mediator-induced vasodilation, which causes capillary permeability and loss of intravascular fluid into the interstitial space. Sudden hypotension and impaired cardiac output with poor perfusion are seen.

Therapeutic Management

Successful outcome of anaphylactic reactions depends on rapid recognition and institution of treatment. The goals of treatment are to provide ventilation, restore adequate circulation, and prevent further exposure by identifying and removing the cause when possible.

A mild reaction with no evidence of respiratory distress or cardiovascular compromise can be managed with subcutaneous administration of antihistamines, such as diphenhydramine (Benadryl) and epinephrine.

Moderate or severe distress presents a potentially life-threatening emergency. Establishing an airway is the first concern, as with all shock states. Epinephrine is given subcutaneously or intravenously as an antihistamine and to support the cardiovascular system and increase BP. Other routes for giving epinephrine are intramuscular and via the airway, either nebulized or injected through an endotracheal tube. In severe anaphylaxis, epinephrine by any route is better than none. Fluids are given to restore blood volume. Additional vasopressors may be given to improve cardiac output. A **biphasic reaction** may occur within 4 hours after symptoms have originally subsided, so it is important to monitor the child closely for this reaction (Sampson, Wang, & Sicherer, 2020).

Prevention of a reaction is preferable. Preventing exposure is more easily accomplished in children known to be at risk, including those with (1) a history of previous allergic reaction to a specific antigen; (2) a history of atopy; (3) a history of severe reactions in immediate family members; and (4) a reaction to a skin test, although skin tests are not available for all allergens. Desensitization may be recommended in certain cases.

QUALITY PATIENT OUTCOMES: Anaphylaxis

- Early recognition of symptoms
- Airway patency maintained
- Adequate circulation restored and maintained
- Further exposure to allergic agent prevented

Nursing Care Management

Major nursing responsibilities in anaphylaxis include anticipating which children are likely to develop a reaction, recognizing the early signs, and intervening appropriately. When an anaphylactic reaction is suspected, nursing responsibilities include immediate intervention and preparation for medical therapy. If emergency supplies such as epinephrine are not immediately available, emergency medical services should be accessed. Ventilation is ensured by placing the child in a head-elevated position, unless contraindicated by hypotension, to facilitate breathing and administer oxygen. If the child is not breathing, CPR is initiated and emergency medical services are summoned.

If the cause can be determined, measures are implemented to slow the spread of the offending substance. An IV infusion is established immediately. Emergency medications are given intravenously whenever possible; however, epinephrine may be given intramuscularly (see Drug Alert box). Vital signs and urinary output are monitored frequently. Medications are administered as prescribed, with regular assessment to monitor effectiveness and to detect signs of side effects of medication and fluid overload.

DRUG ALERT

Epinephrine

Intramuscular administration of epinephrine (0.01 mg/kg up to 0.3 mg) is the first line of therapy, and administration should never be delayed. Two premixed preparations are available: EpiPen Jr (0.15 mg) for children 8 to 25 kg (3.5 to 11.25 pounds) and EpiPen (0.3 mg) for children over 25 kg (11.25 pounds). As in any shock state, the airway is the first concern, followed by assessment of breathing and then circulation (ABCs).

To prevent an anaphylactic reaction, parents are always asked about possible allergic responses to foods, latex, medications, and environmental conditions. These are displayed prominently on

the patient's chart. The specific allergen is noted, as are the type and severity of the reaction. Parents are excellent historians, especially when the child has displayed a pronounced reaction to a substance. Drugs, including related drugs (e.g., penicillin, nafcillin), and other items, such as latex, that have produced a reaction previously are never used. If the child is allergic to insect venom, the family is instructed to purchase an emergency kit to keep with the child at all times. Both the family and the child, if the child is old enough, are taught how to use the equipment. The patient should carry medical identification at all times.

SEPTIC SHOCK

Sepsis and septic shock are caused by infectious organisms. Normally, an infection triggers an inflammatory response in a local area, which results in vasodilation, increased capillary permeability, and eventually elimination of the infectious agent. The widespread activation and systemic release of inflammatory mediators is called the **systemic inflammatory response syndrome (SIRS)**. Box 23.14 provides the exact definitions for SIRS, infection, sepsis, and severe sepsis (Weiss, Peters, Alhazzani, et al., 2020). SIRS can occur in response to both infectious and noninfectious (e.g., trauma, burns) causes. When caused by infection, it is called **sepsis**. Septic shock is defined as sepsis with organ dysfunction and hypotension.

Most of the physiologic effects of shock occur because the exaggerated immune response triggers more than 30 different mediators that result in diffuse vasodilation, increased capillary permeability, and maldistribution of blood flow. This impairs oxygen and nutrient delivery to the cells, resulting in cellular dysfunction. If the process continues, multiple-organ dysfunction occurs and may result in death. Although the incidence of shock continues to be on the increase, survival rate due to early detection and treatment improves (Martin, 2012).

Three stages have been identified in septic shock. In early septic shock, the patient has chills, fever, and vasodilation with increased cardiac output, which results in warm, flushed skin that reflects vascular tone abnormalities and hyperdynamic, warm, or hyperdynamic-compensated responses. BP and urinary output are normal. The patient has the best chance for survival in this stage. The second stage—the normodynamic, cool, or hyperdynamic-decompensated stage—lasts only a few hours. The skin is cool, but pulses and BP are still normal. Urinary output diminishes, and the mental state becomes depressed. With advancing disease, certain signs of circulatory decompensation that deteriorate to signs of circulatory collapse are indistinguishable from late shock of any cause. In the hypodynamic, or cold, stage of shock, cardiovascular function progressively deteriorates even with aggressive therapy. The patient has hypothermia, cold extremities, weak pulses, hypotension, and oliguria or anuria. Patients are severely lethargic or comatose. Multiorgan failure is common. This is the most dangerous stage of shock.

Management of septic shock involves measures to provide hemodynamic stability and adequate oxygenation to the tissues and the use of antimicrobials to treat the infectious organism. As with other forms of shock, hemodynamic stability is achieved with fluid volume resuscitation and inotropic agents as needed. Providing adequate oxygenation often requires intubation and mechanical ventilation, supplemental oxygen, sedation, and paralysis to decrease the work of breathing. Septic shock involves activation of complement proteins that promote clumping of the granulocytes in the lung. The granulocytes can release chemicals that can cause direct lung injury to the pulmonary capillary endothelium. This causes a fluid leak into the alveoli, which causes stiff, noncompliant lungs. DIC and multiorgan dysfunction may also occur and require prompt assessment and management.

BOX 23.14 Definitions of Systemic Inflammatory Response Syndrome, Infection, and Septic Shock

Systemic inflammatory response syndrome (SIRS): The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count:

1. Core temperature of more than 38.5°C (101.3°F) or less than 36°C (96.8°F)
2. Tachycardia, defined as a mean heart rate more than two standard deviations above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5- to 4-hour period; or, for children younger than 1 year old, bradycardia, defined as a mean heart rate below the 10th percentile for age in the absence of external vagal stimulus, beta-blocker drugs, or CHD; or otherwise unexplained persistent depression over a 0.5-hour period
3. Mean respiratory rate more than two standard deviations above normal for age or mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia
4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or more than 10% immature neutrophils

Infection: A suspected or proven (by positive culture, tissue stain, or PCR test) infection caused by any pathogen; or a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (e.g., white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans).

Septic Shock: Severe infection leading to cardiovascular dysfunction (including hypotension, need for treatment with a vasoactive medication, or impaired perfusion) and organ dysfunction in children as severe infection leading to cardiovascular and/or noncardiovascular organ dysfunction.

CHD, Congenital heart disease; *PCR,* polymerase chain reaction.
Adapted from Weiss, S.L., Peters, M.J., Alhazzani, W., et al. (2020). Surviving Sepsis Campaign International Guidelines for the Management of Septic Shock and Sepsis-Associated Organ Dysfunction in Children. *Pediatric Critical Care Medicine, 21*(2); e53-e106; Goldstein, B., Giroir, B., Randolph, A., et al. (2005). International Pediatric Sepsis Consensus Conference: Definitions for sepsis and organ dysfunction in pediatrics. *Pediatric Critical Care Medicine, 6*(1), 2–8.

Newer therapies are being developed to modify the host immune response by attempting to block various mediators, thereby interrupting the inflammatory cascade. Evidence-based management protocols for the management of adult and pediatric septic shock have recently been published (de Caen, Berg, Chameides, et al., 2015; Weiss, Peters, Alhazzani, et al., 2020).

Early identification of the symptoms of septic shock and starting antimicrobial therapy as soon as possible (within 1 hour of recognition) is critical to patient survival (Weiss, Peters, Alhazzani, et al., 2020). A high index of suspicion is required in all critically ill patients who are at greater risk for sepsis because of multiple invasive lines and devices, poor nutrition, and impaired immune function. Subtle alterations in tissue perfusion and unexplained tachypnea and tachycardia often are early warning signs. Identification of the infectious agent and prompt treatment are also critical to patient survival. Broad-spectrum antibiotics should be given, and the site of infection should be removed if possible (e.g., drain abscesses, remove indwelling lines). Patients should be managed in an ICU in which continuous monitoring and sophisticated cardiac and respiratory support are available. Multidisciplinary collaboration is essential in managing these critically ill patients.

BOX 23.15 Criteria for Definition of *Staphylococcus aureus* Toxic Shock Syndrome

Fever of 38.9°C (102°F) or higher
Presence of diffuse macular erythroderma
Desquamation, particularly of palms and soles, 1 to 2 weeks after onset of illness
Hypotension, defined as a systolic blood pressure of 90 mm Hg or less for adults, and below the 5th percentile for children younger than 16 years old; or an orthostatic drop in diastolic blood pressure of 15 mm Hg or more with a change from lying to sitting; or orthostatic syncope; or orthostatic dizziness
Involvement of three or more of the following organ systems: GI, muscular, mucous membrane, renal, hepatic, hematologic, or CNS
Toxic shock syndrome is probable when four of the five major criteria are fulfilled. In addition, if blood and cerebrospinal fluid cultures are obtained, they must be negative for any organisms other than *S. aureus.* Serologic tests for Rocky Mountain spotted fever, leptospirosis, and measles also must be negative.

CNS, Central nervous system; *GI,* gastrointestinal.
Adapted from Wharton, M., Chorba, T. L., Vogt, R. L., et al. (1990). Case definitions for public health surveillance. *MMWR Recommendations and Reports, 39*(RR-13), 1–43.

TOXIC SHOCK SYNDROME

Toxic shock syndrome (TSS) is a relatively rare condition caused by the toxins produced by the Staphylococcus bacteria. First described in 1978, TSS can cause acute multisystem organ failure and a clinical picture that resembles septic shock. TSS became well known in 1980 because of the striking relationship between the disease and tampon use. An aggressive health education campaign about the dangers of prolonged tampon use and a change in the chemical composition of tampons have markedly reduced the incidence of TSS in menstruating women. Cases of TSS have also been reported in men, older women, and children.

Diagnostic Evaluation

Diagnosis is made based on the criteria established by the Centers for Disease Control and Prevention's toxic case definition (Box 23.15). A history of tampon use contributes to the diagnosis. Additional laboratory tests include cultures from blood, the vagina, the cervix, and any discharge. Other laboratory tests are those that facilitate the management of shock.

Therapeutic Management

The management of patients with TSS is the same as management of shock of any cause and may range from supportive care in mild cases to hospitalization and intensive care in severe cases. Appropriate parenteral antibiotics are usually administered after cultures are obtained.

Nursing Care Management

Because the disease is relatively rare, the major efforts of nursing are directed toward prevention. The association between the disease and the use of tampons provides some direction for education. Avoiding the use of tampons offers the most certain preventive measure, although this approach is probably unacceptable to most adolescent girls, who prefer the freedom, comfort, and inconspicuousness that tampons afford.

Adolescent girls who use tampons can be taught general hygiene measures, such as good hand washing and careful insertion to avoid vaginal abrasion. It is wise to modify their use, alternating with sanitary napkins—perhaps using the napkins during the night, when at home during the day, and when flow is slight. Young girls are advised not to use super-absorbent tampons and not to leave any tampon in the body for more than 4 to 6 hours.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A nurse is working with a new graduate on the pediatric unit, and the patient is returning from the cardiac catheterization lab. The patient is a 3-year-old with a congenital heart disease who is having more symptoms related to heart failure. The nurse determines that the graduate understands the important nursing interventions when she makes which statements? **Select all that apply.**
   - **A.** "Check pulses, especially below the catheterization site, for equality and symmetry."
   - **B.** "Check vital signs, which may be taken as frequently as every 30 to 45 minutes, with special emphasis on the heart rate, which is counted for 1 full minute for evidence of dysrhythmias or bradycardia."
   - **C.** "Special attention needs to be given to the BP, especially for hypertension, which may indicate hemorrhage or bleeding from the catheterization site."
   - **D.** "Check the dressing for evidence of bleeding or hematoma formation in the femoral or antecubital area."
   - **E.** "Allow the child to ambulate because this will prevent skin breakdown from lying so long in one place."

2. A nurse recently accepted a position in the congenital heart disease clinic at a major children's hospital. It is important for her to understand the different types of heart defects in children. In the table below, which heart defect and hemodynamic change pairing is correct? **Choose the most likely options for the information missing from the table below by selecting from the lists of options provided.**

Diagnosis	Hemodynamic change	Defect
Ventricular Septal Defect (VSD)	Higher pressure in the left ventricle pumps more blood into the lungs causing increased pulmonary vascular resistance	3
Aortic Stenosis	2	Narrowing of the aortic valve
Tricuspid Atresia	Increased pulmonary blood flow	4
1	Structures on the left side of the heart (the side which receives oxygen-rich blood from the lungs and pumps it out to the body) are severely underdeveloped	Underdeveloped left side of the heart.

Select from these options.

1	2	3 and 4
Atrial Septal Defect (ASD)	Decreased pulmonary blood flow	Abnormal opening between right and left ventricles = 3
Coarctation of the Aorta	Resistance of blood flow in the left ventricle causing decreased cardiac output	Four defects of the heart disrupt blood flow
Heart Failure	Increased pressure proximal to the defect and decreased pressure distal to the obstruction	Valve fails to develop leaving no communication from the right atrium to the right ventricle = 4
Hypoplastic Left Heart Syndrome	Blood flows from the left to right atrium causing increased flow of blood to the right side of the heart	Local narrowing near the insertion of the ductus arteriosus

3. A nurse is discharging a 5-week-old infant male with a congenital heart defect who will be going home on digoxin. The child was born prematurely, and the medication has shown beneficial effects in increasing cardiac output. The nurse is preparing the family for discharge and has spent time teaching both parents how to give digoxin to the infant. Which of the following answers by the father indicate the need for more teaching? **Select all that apply.**
   - **A.** "If more than two doses have been missed, I should call the doctor."
   - **B.** "If I miss a dose, I don't give an extra dose, but I give the next dose as ordered."
   - **C.** "If the baby vomits, I should give a second dose of 10mg of the medication."
   - **D.** I know I should give the drug carefully by slowly directing it to the side and back of the mouth."
   - **E.** "I give the medication every 8 hours, and I can place it in a bit of formula so that I know the baby will take it."

4. A 5-year-old boy presents with symptoms that are suspicious of the acute phase of Kawasaki disease. He was playing last week with a cousin who was staying with the family. The nurse completes a history and physical assessment, and the findings are listed below. Which history and assessment findings reflect the diagnosis of Kawasaki disease? **Select all that apply.**
   - **A.** Irritability
   - **B.** Loud pansystolic murmur
   - **C.** Tender, swollen abdomen
   - **D.** Cervical lymphadenopathy
   - **E.** Erythema of the palms and soles
   - **F.** Bilateral conjunctival inflammation
   - **G.** Loss of ambulation and weakened muscles
   - **H.** Temperature over 100° F (37.8° C) for the last 5 days
   - **I.** Inflammation of the pharynx with red, cracked lips and a "strawberry tongue"

The Child With Hematologic or Immunologic Dysfunction

Rosalind Bryant

http://evolve.elsevier.com/wong/essentials

CONCEPTS

- Perfusion
- Clotting

HEMATOLOGIC AND IMMUNOLOGIC DYSFUNCTION

Several tests can be performed to assess hematologic function, including additional procedures to identify the cause of the dysfunction. The following discussion is limited to a description of the most common and one of the most valuable tests, the **complete blood count (CBC)**. Other procedures, such as those related to iron, coagulation, and immune status, are discussed throughout the chapter as appropriate. The nurse should be familiar with the significance of the findings from the CBC (Table 24.1).

As with any disorder, the history and physical examination are essential to identify hematologic dysfunction, and the nurse is often the first person to suspect a problem based on information from these sources. Comments by the parent regarding the child's lack of energy, food diary of poor sources of iron, frequent infections, and bleeding that is difficult to control offer clues to the more common disorders affecting the blood. A careful physical appraisal, especially of the skin, can reveal findings (e.g., pallor, petechiae, bruising) that may indicate minor or serious hematologic conditions. Nurses need to be aware of the clinical manifestations of blood diseases to assist in recognizing symptoms and establishing a diagnosis.

NURSING TIP: A common term used in describing an abnormal complete blood count (CBC) is **shift to the left**, which refers to the presence of immature neutrophils in the peripheral blood from hyperfunction of the bone marrow, as seen during a bacterial infection.

RED BLOOD CELL DISORDERS

ANEMIA

Anemia is a reduction in red blood cell (RBC) mass per volume and/or hemoglobin (Hgb or Hb) concentration compared with normal values for age (Brugnara, Oski, & Nathan, 2015; Thornburg, 2020). This diminishes the oxygen-carrying capacity of the blood, causing a reduction in the oxygen available to the tissues. The anemias are the most common hematologic disorder of infancy and childhood and are not diseases but an indication or manifestation of an underlying pathologic process.

Classification

Anemias can be classified using two basic approaches: **etiology** or **physiology**, manifested by erythrocyte or Hgb depletion, and **morphology**, the characteristic changes in RBC size, shape, or color (Box 24.1). Although the morphologic classification is useful in terms of laboratory evaluation of anemia, the etiology provides direction for planning nursing care. For example, anemia with reduced Hgb concentration may be caused by a dietary depletion of iron, and the principal intervention is replenishing iron stores. The classification of anemias is found in Fig. 24.1.

Consequences of Anemia

The basic physiologic defect caused by anemia is a decrease in the oxygen-carrying capacity of blood and consequently a reduction in the amount of oxygen available to the body cells. When the anemia has developed slowly, the child usually adapts to the declining Hgb level.

The effects of anemia on the circulatory system can be profound. Because the viscosity of blood depends almost entirely on the concentration of RBCs, the resulting hemodilution of severe anemia decreases peripheral resistance, causing greater quantities of blood to return to the heart. The increased circulation and turbulence within the heart may produce a murmur. Because the cardiac workload is greatly increased, especially during exercise, infection, or emotional stress, cardiac failure may ensue.

Children seem to have a remarkable ability to function well despite low levels of Hgb. **Cyanosis**, which results from an increased quantity of deoxygenated Hgb in arterial blood, is typically not evident. Growth retardation, resulting from decreased cellular metabolism, and coexisting anorexia is a common finding in chronic severe anemia. It is frequently accompanied by delayed sexual maturation in the older child.

Diagnostic Evaluation

In general, anemia may be suspected based on history and physical examination findings, such as a lack of energy, easy fatigability, and pallor. Laboratory tests are another clue to the disorder, with possible alterations in the CBC, such as decreased RBCs, and decreased Hgb and hematocrit (Hct) levels (see Fig. 24.1). Although anemia is sometimes defined as decreased Hgb level, it important to be aware that normal Hgb levels vary with age (see Table 24.1).

Other tests specific to a particular type of anemia are used to determine the underlying cause of anemia. These are discussed in relation to the particular disorder.

TABLE 24.1 Tests Performed as Part of a Complete Blood Count

Test (Average Value)	Description, Comments
RBC count (4.5-5.5 million/mm^3)	Number of RBCs/mm^3 of blood Indirectly estimates Hgb content of blood Reflects function of bone marrow
Hgb determination (11.5-15.5 g/dl)	Amount of Hgb (g)/dl of whole blood Total blood Hgb primarily depends on number of circulating RBCs but also on amount of Hgb in each cell
Hct (35%-45%)	Percent volume of packed RBCs in whole blood Indirectly measures Hgb content Is approximately three times Hgb content
RBC indices	
MCV (77-95 fl)	Average or mean volume (size) of a single RBC MCV value is expressed as femtoliter (fl) or cubic micron (mm^3)
MCH (25 to 33 pg/cell)	Average or mean quantity (weight) of Hgb in a single RBC MCH value is expressed as picogram (pg) or micromicrogram (mmcg) Whereas MCV and MCH depend on accurate counts of RBCs, MCHC does not; therefore MCHC is often more reliable All indices depend on average cell measurements and do not show individual RBC variations (anisocytosis)
MCHC (31%-37% Hgb [g]/dl RBC)	Average concentration of Hgb in a single RBC MCHC values are expressed as percent Hgb (g)/cell or Hgb (g)/dl RBC
RBC volume distribution width (13.4% ± 1.2%)	Average size of RBCs Differentiates some types of anemia
Reticulocyte count (0.5%-1.5% erythrocytes)	Percent reticulocytes in RBCs Index of production of mature RBCs by bone marrow Decreased count indicates depressed bone marrow function Increased count indicates erythrogenesis in response to some stimulus When reticulocyte count is extremely high, other forms of immature RBCs (normoblasts, even erythroblasts) may be present Indirectly estimates hypochromic anemia Usually elevated in patients with chronic hemolytic anemia
WBC count (4.5-13.5 × 10^3 cells/mm^3)	Number of WBCs/mm^3 of blood Total number of WBCs less important than differential count
Differential WBC count	Inspection and quantification of WBC types present in peripheral blood Values are expressed as percentages; to obtain absolute number of any type of WBC, multiply its respective percentage by total number of WBCs
Neutrophils (polys) (54%-62%) (3-5.8 × 10^3 cells/mm^3)	Primary defense in bacterial infection; capable of phagocytizing and killing bacteria
Bands (3%-5%) (0.15-0.4 × 10^3 cells/mm^3)	Immature neutrophil Increased numbers in bacterial infection Also capable of phagocytosis and killing
Eosinophils (1%-3%) (0.05-0.25 × 10^3 cells/mm^3)	Named for their staining characteristics with eosin dye Increased in allergic disorders, parasitic diseases, certain neoplasms, and other diseases
Basophils (0.075%) (0.015-0.030 × 10^3 cells/mm^3)	Named for their characteristic basophilic stippling Contain histamine, heparin, and serotonin; believed to cause increased blood flow to injured tissues while preventing excessive clotting
Lymphocytes (25%-33%) (1.5-3.0 × 10^3 cells/mm^3)	Involved in development of antibody and delayed hypersensitivity
Monocytes (3%-7%)	Large phagocytic cells that are involved in early stage of inflammatory reaction
ANC (>1000/mm^3)	Percent neutrophils/bands times WBC count Indicates body's capability to handle bacterial infections
Platelet count (150-400 × 10^3/mm^3)	Number of platelets/mm^3 of blood Cellular fragments that are necessary for clotting to occur
Stained peripheral blood smear	Visual estimation of amount of Hgb in RBCs and overall size, shape, and structure of RBCs Various staining properties of RBC structures may be evidence of immature forms of erythrocytes Shows variation in size and shape of RBCs: microcytic, macrocytic, poikilocytic (variable shapes)

ANC, Absolute neutrophil count; *Hct,* hematocrit; *Hgb,* hemoglobin; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *RBC,* red blood cell; *WBC,* white blood cell.

Therapeutic Management

The objective of medical management is to reverse the anemia by treating the underlying cause. In nutritional anemias, the specific deficiency is replaced. In blood loss from acute hemorrhage, RBC transfusion may be given. In patients with severe anemia, supportive medical care may include oxygen therapy, bed rest, and replacement of intravascular volume with intravenous (IV) fluids. In addition to these general measures, the nurse may implement more specific interventions, depending on the cause. The next sections will discuss these interventions.

Nursing Care Management

The assessment of anemia includes the basic techniques that are applicable to any condition. The age of the infant or child provides some clues regarding the possible etiology of the anemia. For example, iron-deficiency anemia occurs more frequently in toddlers between 12 and 36 months old and during the growth spurt of adolescence.

BOX 24.1 Red Blood Cell Morphology

Size (Cell Size)

Variation in red blood cell (RBC) sizes (anisocytosis)

- Normocytes (normal cell size)
- Microcytes (smaller than normal cell size)
- Macrocytes (larger than normal cell size)

Shape (Cell Shape)

Variation in RBC shapes (poikilocytosis)

- Spherocytes (globular cells)
- Drepanocytes (sickle-shaped cells)
- Numerous other irregularly shaped cells

Color (Cell Staining Characteristics)

Variation in hemoglobin concentration in the RBC

- Normochromic (sufficient or normal amount of hemoglobin per RBC)
- Hypochromic (reduced amount of hemoglobin per RBC)
- Hyperchromic (increased amount of hemoglobin per RBC)

In interviewing the family, the nurse assesses the following areas: (1) nutrition, especially if the child is lactose intolerant or has inadequate intake of iron; (2) history of chronic, recurrent infection; (3) eating habits, particularly pica (consumption of nonnutritive substances such as dirt, starch, lead-based paint chips, paper); (4) bowel habits and presence of frank blood in stools or black, tarry stools as a result of chronic blood loss; and (5) familial history of hereditary diseases, such as sickle cell disease (SCD) or thalassemia.

The nurse should also obtain pertinent information that may aid in identifying the cause of the anemia. For example, a statement such as "My child drinks a lot of milk" is a frequent finding in toddlers with iron-deficiency anemia.

The stool examination using the Hemoccult test for occult (microscopic) blood can identify chronic intestinal bleeding that results from a primary or secondary lactase deficiency. It is also important to understand the significance of various blood tests (see Table 24.1).

Prepare the Child and Family for Laboratory Tests

Several blood tests are generally ordered sequentially. Therefore the child may undergo multiple finger or heel punctures or venipunctures. These invasive procedures may be better tolerated (see Chapter 20, Blood Specimens) with the topical anesthetic known as eutectic mixture of lidocaine and prilocaine (EMLA) or lidocaine (ELA-Max or LMX) cream applied prior to needle punctures (see Chapter 5, Pain Management). Therefore the nurse is responsible for preparing the child and family for the tests by:

- Explaining the significance of each test, particularly why the tests are not all done at one time
- Encouraging parents or another supportive person to be with the child during the procedure
- Allowing the child to play with the equipment on a doll or participate in the actual procedure (e.g., by holding the Band-Aid)

Older children may appreciate the opportunity to observe the blood cells under a microscope or in photographs. This experience is especially important if a serious blood disorder, such as aplastic anemia, is suspected because it serves as a foundation for explaining the pathophysiology of the disorder.

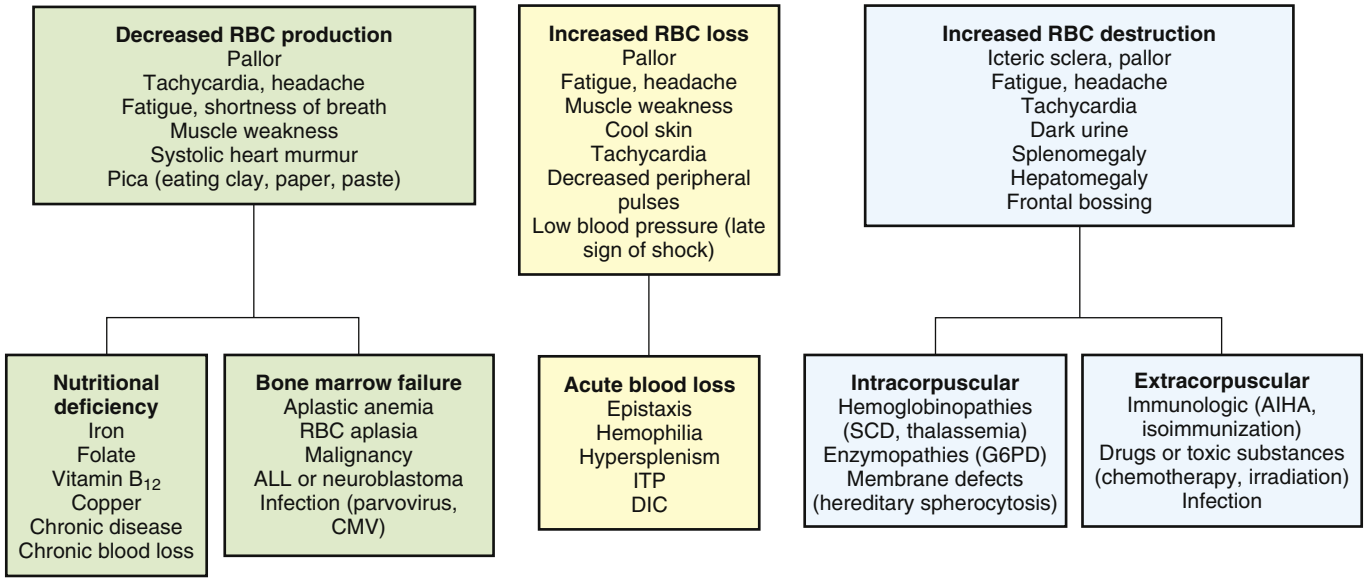

Fig. 24.1 Classifications of anemias. *AIHA,* Autoimmune hemolytic anemia; *ALL,* acute lymphoblastic leukemia; *CMV,* cytomegalovirus; *DIC,* disseminated intravascular coagulation; *G6PD,* glucose-6-phosphate dehydrogenase; *ITP,* idiopathic thrombocytopenic purpura; *RBC,* red blood cell; *SCD,* sickle cell disease.

Bone marrow aspiration is not a routine hematologic test but is essential for definitive diagnosis of certain anemias, such as severe aplastic anemia.

NURSING TIP: Suggested explanations for teaching children about blood components are:

Red blood cells: Carry the oxygen you breathe from your lungs to all parts of your body

White blood cells: Help keep germs from causing infection

Platelets: Small parts of cells that help make bleeding stop by forming a clot (scab) over the hurt area

Plasma: The liquid portion of blood; has clotting factors that help make bleeding stop

Decrease Tissue Oxygen Needs

Because the basic pathologic process in anemia is a decrease in oxygen-carrying capacity of the RBCs, an important nursing responsibility is to minimize tissue oxygen needs by continual assessment of the child's energy level. Assess the child's level of tolerance for activities of daily living and play, and make adjustments to allow as much self-care as possible without undue exertion. During periods of rest, the nurse measures vital signs and observes behavior to establish a baseline of nonexertion energy expenditure. During periods of activity, the nurse repeats these measurements and observations to compare them with resting values.

NURSING TIP: Signs of exertion include tachycardia, palpitations, tachypnea, dyspnea, shortness of breath, hyperpnea, dizziness, lightheadedness, diaphoresis, and change in skin color. The child looks fatigued (e.g., sagging, limp posture; slow, strained movements; inability to tolerate additional activity; difficulty sucking in infants).

Prevent Complications

Children with anemia are prone to infection because tissue hypoxia causes cellular dysfunction, and the disturbed metabolic processes weaken the host's defenses against foreign agents. Take all of the usual precautions to prevent infection, such as practicing thorough hand washing, selecting an appropriate room in a noninfectious area, restricting visitors or hospital personnel with active infection, and maintaining adequate nutrition. The nurse also observes for signs of infection, particularly temperature elevation and leukocytosis. However, an elevated white blood cell (WBC) count sometimes occurs in anemia without the presence of systemic or local infection.

IRON-DEFICIENCY ANEMIA

Anemia caused by an inadequate supply or loss of iron is the most prevalent and preventable nutritional disorder in the United States and globally. The prevalence of iron-deficiency anemia during infancy has declined in the United States (Mahoney, 2017). The reduced prevalence of iron-deficiency anemia in infants has been partly attributed to the American Academy of Pediatrics' promotion of iron-fortified formula instead of cow's milk during the first year of life in conjunction with the Special Supplementation Food Program for Women, Infants, and Children (WIC) that provides iron-fortified formula and routine screening of Hgb levels during early childhood (Fleming, 2015; Powers & Buchanan, 2014). The promotion of iron supplement in the exclusively breastfed infant, introduction of iron-fortified infant formula and cereal, weaning from the bottle by 1 year of age, limiting intake of cow's milk to 16 to 24 oz/day, and delayed introduction of cow's milk into the diet have also contributed to the decreased incidence of iron-deficiency anemia in infants and young children (Fleming, 2015). Preterm infants are especially at risk because of their reduced fetal iron supply. Children 12 to 36 months old are at risk for anemia as a result of excessive cow's milk consumption, not eating an adequate amount of iron-containing food, and possible blood loss from milk protein colitis (Eussen, Alles, Uijterschout, et al., 2015; Paoletti, Bogen, & Ritchey, 2014; Rothman, 2020). Adolescents are also at risk for iron deficiency because of their rapid growth rate combined with poor eating habits, menses, obesity, or strenuous activities. However, iron deficiency both with and without anemia remains a relatively common health problem, especially among at-risk children and pregnant women (Fleming, 2015; Juul, Derman, & Auerbach, 2019; Mahoney, 2017; Miller, 2013).

Pathophysiology

Iron-deficiency anemia can be caused by any number of factors that decrease the supply of iron, impair its absorption, increase the body's need for iron, or affect the synthesis of Hgb. Although the clinical manifestations and diagnostic evaluation are similar regardless of the cause, the therapeutic and nursing care management depends on the specific reason for the iron deficiency. The following discussion is limited to iron-deficiency anemia resulting from inadequate iron in the diet.

During the last trimester of pregnancy, iron is transferred from the mother to the fetus at the rate of 4 mg/day. Most of the iron is stored in the circulating erythrocytes of the fetus, with the remainder stored in the fetal liver, spleen, and bone marrow. When iron stores are deficient, the production of hemoglobin is reduced. Consequently, the main effect of iron deficiency is decreased Hgb level and reduced oxygen-carrying capacity of the blood.

Along with maternal iron supplements, delayed umbilical clamping for 1 to 3 minutes can improve iron status and reduce the risk of iron deficiency in the newborn (Anderson, Domeliof, Anderson, et al., 2014; Mercer, Erickson-Owens, Collins, et al., 2017; Miller, 2013; Rothman, 2020). Maternally derived iron stores are usually adequate for the first 5 to 6 months in a full-term infant but for only 2 to 3 months in preterm infants and multiple births. If dietary sources of iron are not supplied to meet the infant's growth demands after the depletion of fetal iron stores, iron-deficiency anemia results. Physiologic anemia should not be confused with iron-deficiency anemia resulting from nutritional causes.

Although infants with iron-deficiency anemia are underweight, many are overweight because of excessive milk ingestion (known as **milk babies**). These children become anemic for two reasons: (1) milk, a poor source of iron, is given almost to the exclusion of solid foods; and (2) increased fecal loss of blood occurs in 50% of iron-deficient infants fed cow's milk.

Therapeutic Management

After the diagnosis of iron-deficiency anemia is made, therapeutic management focuses on increasing the amount of supplemental iron the child receives. This is usually done through dietary counseling and the administration of oral iron supplements.

If the addition of iron-rich foods to the diet does not provide sufficient supplemental quantities of the mineral, oral iron supplements are prescribed. Ferrous iron is more readily absorbed than ferric iron and results in higher Hgb levels. Ingested iron is absorbed largely from the duodenum, and absorption is facilitated by an acid environment. Children normally absorb an average of 10% to 20% of the iron in oral supplements, but during periods of iron deficiency they absorb an additional 5% to 10%. Oral iron supplementation is prescribed as

3 to 6 mg of elemental iron per kilogram per day. Side effects of oral iron therapy may include nausea, gastric irritation, diarrhea or constipation, and anorexia. If the iron produces vomiting and diarrhea, it should be administered with meals. Lower dosages of iron are associated with fewer side effects.

Ideally, the daily dose of iron should be given in two or three divided doses between meals. Ascorbic acid (vitamin C) appears to facilitate absorption of iron and may be given as vitamin C–enriched foods and juices with the iron preparation. The administration of oral iron with vitamin C supplementation was supported in a recent cohort study. The oral iron with vitamin C was given over a period of 10 weeks and had a complete response in majority (6/7 = 86%) with greater than 2 g/dl rise in Hgb along with significant improvement of other iron-related indices (Sourabh, Bhatia, & Jain, 2019).

The response to oral iron therapy is reflected in a peak increase in the reticulocyte count by the fifth to tenth day of administration. Following the reticulocyte rise, the Hgb and Hct levels and RBC count increase. The Hgb level rises from 0.1 to 0.4 g/dl/24 h depending on anemia severity; therefore a substantial increase should occur by the end of 1 month (Rothman, 2020).

If the Hgb level fails to rise after 1 month of oral therapy, it is important to assess for persistent bleeding, iron malabsorption, noncompliance, improper iron administration, or other causes of the anemia. Parenteral (IV or intramuscular [IM]) iron administration is safe and effective but is expensive, and occasionally is associated with regional lymphadenopathy, transient arthralgias, or serious allergic reaction (Bregman & Goodnough, 2014; Fleming, 2015). Therefore parenteral iron is reserved for children who have iron malabsorption, chronic hemoglobinuria, or intolerance to oral preparations. The deep IM injection route for iron administration is discouraged because it is painful; requires multiple injections; may leak into the subcutaneous tissue, causing skin discoloration at the injection site; and is associated with gluteal sarcoma (Juul, Derman, & Auerbach, 2019). Careful observation with IV iron administration is required because of the risk of anaphylaxis, so a test dose is recommended before use. Several IV iron preparations (e.g., ferumoxytol, ferric carboxymaltose, iron sucrose complex, iron isomaltoside) show promise in complete replacement of iron with little toxicity (Auerbach, James, Nicoletti, et al., 2017; DeLoughery, 2014; Mantadakis, 2018; Smith, 2012). Transfusions are indicated for the most severe anemia and in cases of serious infection, cardiac dysfunction, or surgical emergency when anesthesia is required. Packed RBCs (2 to 3 ml/kg), not whole blood, are used to minimize the chance of circulatory overload. Supplemental oxygen is administered when tissue hypoxia is severe.

Prognosis

The prognosis for a child with iron-deficiency anemia is very good. There is evidence that if the anemia is severe and long-standing, then diminished cognitive function, behavioral changes, delayed infant growth and development, decreased exercise tolerance, and impaired immune function may develop (Angulo-Barroso, Li, Santos, et al., 2016; Fleming, 2015; Jauregui-Lobera, 2014; Pivina, Semenova, Dosa, et al., 2019). However, there is lack of convincing evidence that iron treatment of young children with iron-deficiency anemia or nonanemic iron deficiency has an effect on psychomotor development or cognitive function (Abdullah, Thorpe, Mamak, et al., 2015; McDonagh, Blazina, Dana, et al., 2015; Thompson, Biggs, & Pasricha, 2013; Wang, Zhan, Gong, et al., 2013). Therefore there is a need for further large, long-term follow-up, randomized interventional studies.

QUALITY PATIENT OUTCOMES: Iron-Deficiency Anemia

- Early recognition of signs and symptoms of iron-deficiency anemia
- Appropriate quantity of milk, use of iron-fortified infant formula, and introduction of solid foods
- Adherence to oral iron supplement with appropriate administration
- Hemoglobin increase within 1 month and anemia resolved within 6 months

Nursing Care Management

An essential nursing responsibility is instructing parents in the administration of iron. Oral iron should be given as prescribed in two divided doses between meals, when the presence of free hydrochloric acid is greatest, because more iron is absorbed in the acidic environment of the upper gastrointestinal (GI) tract. A citrus fruit or juice taken with the medication aids in absorption.

DRUG ALERT

Cow's milk contains substances that bind the iron and interfere with absorption. Iron supplements should not be administered with milk or milk products (Powers & Buchanan, 2014; Walczyk, Muthayya, Wegmuller, et al., 2014).

An adequate dosage of oral iron turns the stools a tarry green or black color. The nurse advises parents of this normally expected change and inquires about its occurrence on follow-up visits. Absence of the greenish black stool may be a clue to poor compliance (e.g., in schedule, in dosage, in administration, in side effects). If compliance is an issue, make every effort to institute strategies to improve adherence to the medication regimen, such as changing the schedule to more convenient times.

DRUG ALERT

Liquid preparations of iron may temporarily stain the teeth. If possible, the medication should be taken through a straw or given through a syringe or medicine dropper placed toward the back of the mouth. Brushing the teeth after administration of the drug lessens the discoloration.

NURSING ALERT

Because iron ingestion in excessive quantities is toxic or even fatal, parents should be instructed to keep no more than a month's supply in the home and store it safely away from the reach of children.

Diet

A primary nursing objective is to prevent nutritional anemia through family education. The nurse must reinforce the importance of administering iron supplementation to exclusively breastfed infants by 4 months of age because breast milk is a low iron source (American Academy of Pediatrics, 2016; Centers for Disease Control and Prevention, 2018a; Lokeshwar, Mehta, Mehta, et al., 2011; Ziegler, Nelson, & Jeter, 2011). The American Academy of Pediatrics recommends that preterm infants, marginally low– and low-birth-weight infants, or infants with inadequate iron stores at birth receive iron supplements at approximately 2 months old (Berglund, Westrup, & Domellof, 2010).

In formula-fed infants, the most convenient and best sources of supplemental iron are iron-fortified commercial formula and iron-fortified infant cereal (National Institutes of Health, Office of Dietary Supplements, 2018). Iron-fortified formula provides a relatively constant and predictable amount of iron and is not associated with an increased incidence of GI symptoms, such as colic, diarrhea, or constipation. Infants younger than 12 months old should *not* be given fresh cow's milk because it may increase the risk of GI blood loss occurring from exposure to a heat-labile protein in cow's milk or cow's milk–induced GI mucosal damage resulting from a lack of cytochrome iron (heme protein) (Subramaniam & Girish, 2015). If GI bleeding is suspected, several stool analyses for occult blood known as *guaiac tests* are performed to identify any intermittent blood loss.

Since the best first solid-food source of iron is commercial iron-fortified cereals, it may be difficult initially to teach the infant to accept foods other than milk. Predominantly milk-fed infants tend to rebel against solid foods, and parents are cautioned about this and the need to be firm in not relinquishing control to the child. It may require intense problem solving on the part of both the family and the nurse to overcome the child's resistance.

A difficulty encountered in discouraging the parents from feeding milk to the exclusion of other foods is dispelling the popular myth that milk is a "perfect food." Many parents believe that milk is best for infants and equate weight gain with "healthiness." Although milk is an excellent food, it is deficient in iron, vitamin C, zinc, and fluoride. Sources of each of these nutrients and the role they play in preventing deficiencies need to be discussed with the family, especially the persons responsible for feeding the infant. Also stress that overweight is not synonymous with good health. The same principles are applied as those for introducing new foods (see Chapter 7, Provide Optimal Nutrition), especially feeding the solid food prior to milk intake.

Counseling families whose children are anemic is often a difficult and challenging task. Meal planning must be based on the family's budget, cultural pattern, and food preferences. Diet education of teenagers is difficult, especially because teenage girls are particularly prone to following weight-reduction diets. Stressing the physical and behavioral improvements and effect that the improved diet will have on all family members may encourage parents and teens to adhere to the treatment plan.

SICKLE CELL ANEMIA

Sickle cell anemia (SCA) is one of a group of diseases collectively called **hemoglobinopathies** in which normal adult Hgb (Hgb A or HbA) is partly or completely replaced by abnormal sickle Hgb (HbS). **Sickle cell disease (SCD)** refers to a group of hereditary disorders, all of which are related to the presence of HbS. Although the term *SCD* is sometimes used to refer to SCA, this use is incorrect. The correct terms for SCA are homozygous sickle cell disease (HgbSS) and **homozygous SCD**.

The following are the most common forms of SCD in the United States:

- **SCA,** the homozygous form of the disease (HbgSS), in which valine, an amino acid, is substituted for glutamic acid at the sixth position of the beta chain
- **Sickle cell–C disease,** a heterozygous variant of SCD (HgbSC), is characterized by the presence of both HgbS and HgbC, in which lysine is substituted for glutamic acid at the sixth position of the beta chain
- **Sickle thalassemia disease,** a combination of sickle cell trait and beta thalassemia trait (Sβthal). In the β^+ (beta plus) form, some normal HbA can be produced. In the β^0 (beta zero) form, there is no ability to produce HbA.

Of the SCDs, SCA is the most common form in African Americans, followed by sickle cell–C disease and sickle thalassemia disease. Numerous other sickle syndromes exist in which HbS is paired with other mutant globin.

SCD is one of the most common genetic diseases worldwide, affecting approximately 100,000 Americans and including other nationalities, such as Africans, Hispanics, Italians, Greeks, Iranians, Turks, and individuals of Arab, Caribbean, Asian Indian descent, and other ethnic groups. The incidence of the disease varies in different geographic locations. Among African Americans, the incidence of sickle cell trait is about 8%, whereas among inhabitants of West Africa, the incidence is reported to be as high as 40%. The high incidence of sickle cell trait in West Africans is believed to be the result of selective protection afforded trait carriers against malaria caused by endemic *Plasmodium falciparum* infection (Nussbaum, McInnes, & Willard, 2016).

The gene that determines the production of HbS is situated on an autosome and, when present, is always detectable. Heterozygous persons who have both normal HbA and abnormal HbS are said to have **sickle cell trait**. Persons who are homozygous have predominantly HbS and have SCA. The inheritance pattern is essentially that of an autosomal recessive disorder. Therefore when both parents have sickle cell trait, there is a 25% chance with each pregnancy of producing an offspring with SCA.

Although the defect is inherited, the sickling phenomenon is usually not apparent until later in infancy because of the presence of fetal Hgb (HbF). As long as the child has predominantly HbF, sickling does not occur because there is less HbS. Newborns with SCA are generally asymptomatic because of the protective effect of HbF (60% to 80% HbF), but this rapidly decreases during the first year, so these children are at risk for sickle cell–related complications (Heeney & Ware, 2015; Piel, Steinberg, & Rees, 2017).

Pathophysiology

The clinical manifestations of SCA are primarily the result of (1) obstruction caused by the sickled RBCs with other cells, (2) vascular inflammation, and (3) increased RBC destruction (Fig. 24.2). The abnormal adhesion, entanglement, and enmeshing of rigid sickle-shaped cells accompanied by the inflammatory process intermittently blocks the microcirculation causing vasoocclusion (Fig. 24.3). The resultant absence of blood flow to adjacent tissues causes local hypoxia, leading to tissue ischemia and infarction (cellular death). Most of the complications seen in SCA can be traced to this process and its impact on various organs of the body (Box 24.2).

The clinical manifestations of SCA vary greatly in severity and frequency. The most acute symptoms of the disease occur during periods of exacerbation called **crises**. There are several types of episodic crises, including vasoocclusive, acute splenic sequestration, aplastic, hyperhemolytic, cerebrovascular accident (CVA), acute chest syndrome, and infection. The crises may occur individually or concomitantly with one or more other crises. The **vasoocclusive crisis (VOC)**, preferably called a "painful episode," is characterized by ischemia causing mild to severe pain that may last from minutes to days or longer. Dactylitis (swelling in hands and feet) is often the first painful manifestation of VOC in children, usually occurring from 6 months to 2 years old. **Sequestration crisis** is a pooling of a large amount of blood, usually in the spleen and infrequently in the liver, that causes a decreased blood volume and may ultimately cause shock. **Aplastic crisis** is diminished RBC production, usually triggered by viral infection that may result in profound anemia. **Hyperhemolytic crisis** is an accelerated rate of RBC destruction characterized by anemia, jaundice, and reticulocytosis.

Another serious complication is **acute chest syndrome (ACS)**, which is clinically similar to pneumonia. It is the presence of a new

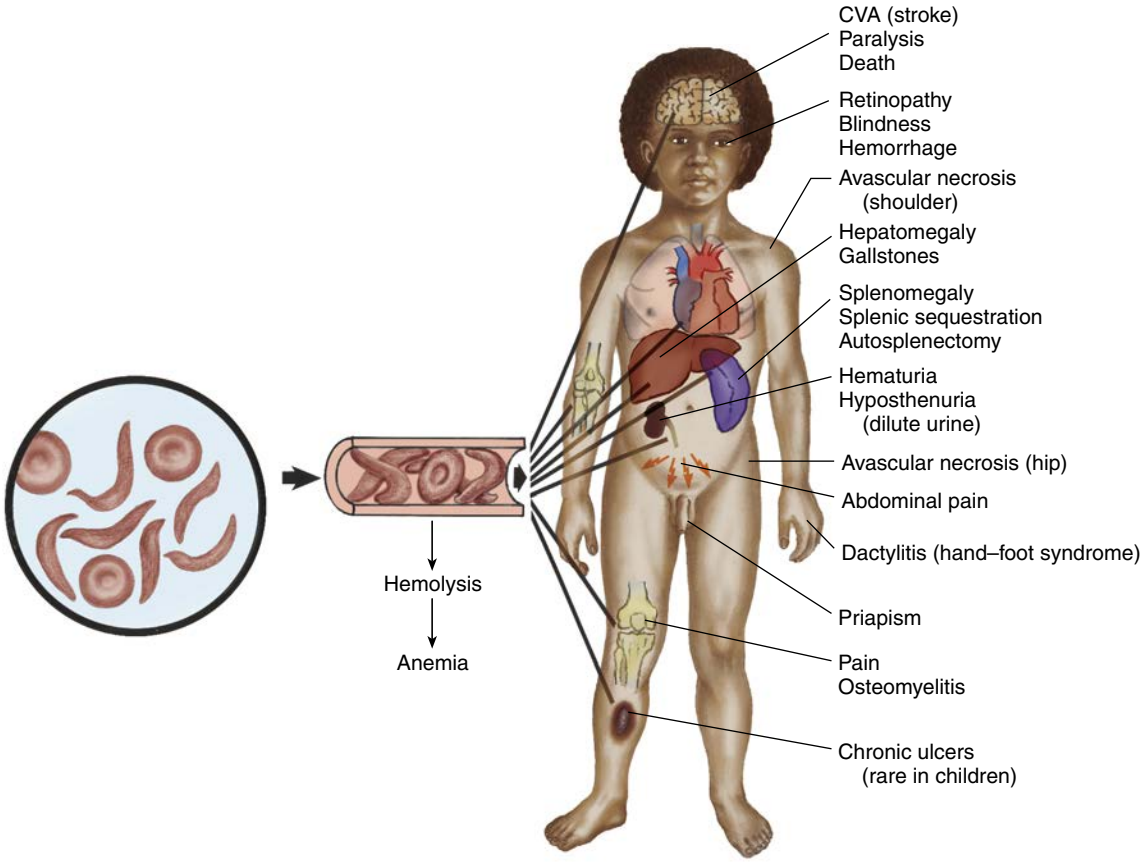

Fig. 24.2 Clinical features of sickle cell anemia (SCA) from red blood cell (RBC) obstruction and destruction. *CVA,* Cerebrovascular accident.

pulmonary infiltrate and may be associated with chest pain, fever, cough, tachypnea, wheezing, and hypoxia.

A **cerebrovascular accident (CVA, stroke)** is a major complication, often primarily vascular as sickled cells block the blood vessels in the brain, resulting in cerebral infarction, which causes variable degrees of neurologic impairment. Before the development of transcranial Doppler ultrasonography (TCD; described later in the chapter) to screen for stroke risk among children with sickle cell anemia, approximately 11% experienced an overt stroke and 20% a silent stroke before age 18 years (Estcourt, Fortin, Hopewell, et al., 2017; Smith-Whitley & Kwiatkowski, 2020). A functional definition of overt stroke is the presence of a focal neurologic deficit lasting for more than 24 hours and/or abnormal neuroimaging of the brain indicating a cerebral infarct on magnetic resonance imaging (MRI) corresponding to the focal neurologic deficit, whereas a silent cerebral infarct lacks focal neurologic findings lasting more than 24 hours and is diagnosed as an abnormality on MRI (Smith-Whitley & Kwiatkowski, 2020). Any number of neurologic symptoms, such as headache, aphasia, weakness, convulsions, visual disturbances, or unilateral hemiplegia, can indicate a minor cerebral insult. Cognitive impairment (e.g., developmental delays, poor or declining school performance) from SCA without any other overt signs tends to be associated with silent cerebral infarct (Choudhury, DeBaun, Rodeghier, et al., 2018; DeBaun, Armstrong, McKinstry, et al., 2012; Kawadler, Clayden, Clark, et al., 2016; Yawn, Buchanan, Afenyi-Annan, et al., 2014).

Diagnostic Evaluation

Universal screening of newborns for SCD has become standard in all US states and territories (McGann, Nero, & Ware, 2013; Meier & Miller, 2012). The global newborn screening program varies by country and is not a common practice in most countries where SCD is a public health concern, but such programs are being developed in India and some African countries (Huttle, Maestre, Lantigua, et al., 2015; Piel et al., 2017). The screening provides early identification of these children before complications develop. At birth, infants have up to 80% of HbF, which does not carry the defect. Because levels of HbS are low at birth, Hgb electrophoresis or other tests that measure Hgb concentrations are indicated.

Although SCD is usually reported during the prenatal or neonatal periods, it may not be recognized until the toddler and preschool periods during a crisis precipitated by an acute respiratory tract or GI infection. Early diagnosis (before the age of 2 months) facilitates parental education on the importance of maintaining hydration, current immunizations, administering prophylaxtic antibiotics, detecting splenomegaly, recognizing early signs of infection and other SCD complications, and seeking prompt medical attention as indicated.

Several specific tests detect abnormal Hgb in the homozygous or heterozygous form of SCD. For screening purposes, the sickle-turbidity test (Sickledex) is used because it can be performed on blood from a finger or heel stick and yields accurate results in 3 minutes, yet it is not able to distinguish between the sickle cell trait and SCD. If the test result is positive, Hgb electrophoresis is necessary to distinguish between children with the trait and those with the disease. **Hemoglobin electrophoresis,** referred to as "fingerprinting" of the protein, is a specially prepared blood test that separates various hemoglobins by high voltage. The blood test is accurate, rapid, and specific for detecting the homozygous and heterozygous forms of the disease, as well as the percentages of the various types of Hgb. The hemoglobin electrophoresis increasingly is used as the initial screening test in centers within the United States.

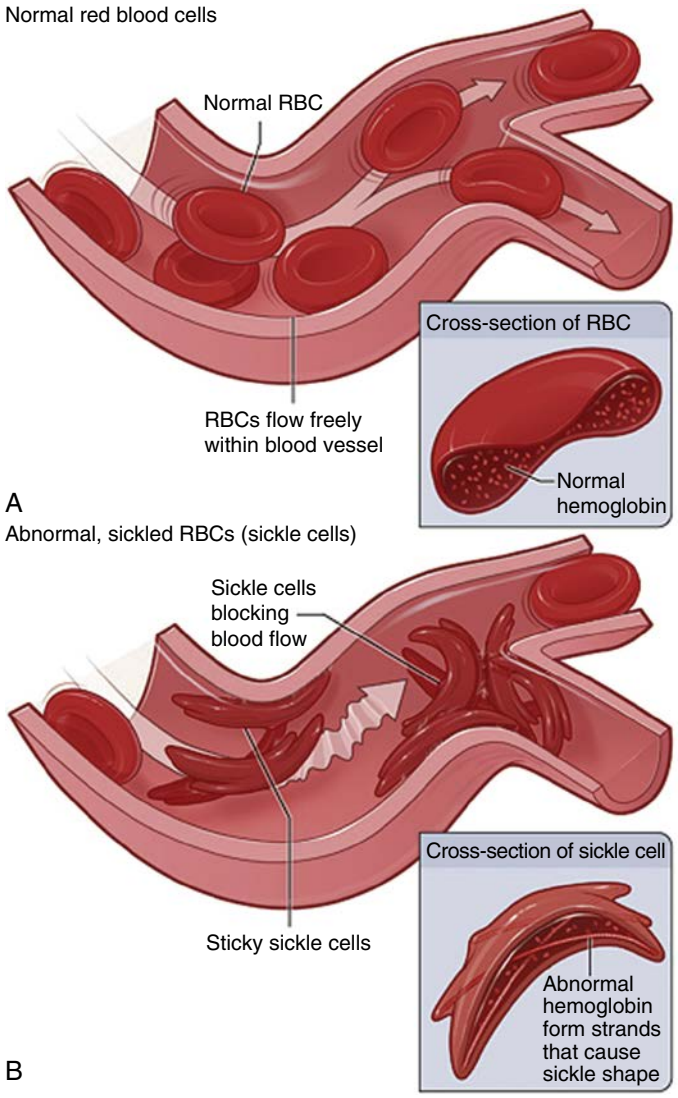

Fig. 24.3 A, Normal red blood cells *(RBCs)* flowing freely in a blood vessel. The *inset* shows a cross-section of a normal RBC with normal hemoglobin. B, Abnormal, sickled RBCs clumping and blocking blood flow in a blood vessel. (Other cells also may play a role in this clumping process.) The *inset* shows a cross-section of a sickle cell with abnormal hemoglobin. (From National Heart, Lung, and Blood Institute. [2016]. *What is sickle cell anemia?* Bethesda, MD: National Institutes of Health.)

BOX 24.2 Clinical Manifestations of Sickle Cell Anemia

General
Possible growth retardation
Chronic anemia (hemoglobin level of 6 to 9 g/dl)
Possible delayed sexual maturation
Marked susceptibility to sepsis

Vasoocclusive Crisis
Pain in area(s) of involvement
Manifestations related to ischemia of involved areas
- **Extremities:** Painful swelling of hands and feet (sickle cell dactylitis, or hand-foot syndrome), painful joints
- **Abdomen:** Severe pain resembling acute surgical condition
- **Cerebrum:** Stroke, visual disturbances
- **Chest:** Symptoms resembling pneumonia, protracted episodes of pulmonary disease
- **Liver:** Obstructive jaundice, hepatic coma
- **Kidney:** Hematuria
- **Genitalia:** Priapism (persistent painful penile erection)

Sequestration Crisis
Pooling of large amounts of blood
- Hepatomegaly
- Splenomegaly
- Circulatory collapse

Effects of Chronic Vasoocclusive Phenomena
Heart: Cardiomegaly, systolic murmurs
Lungs: Altered pulmonary function, susceptibility to infections, pulmonary insufficiency
Kidneys: Inability to concentrate urine, enuresis, progressive renal failure
Liver: Hepatomegaly, cirrhosis, intrahepatic cholestasis
Spleen: Splenomegaly, susceptibility to infection, functional reduction in splenic activity progressing to autosplenectomy
Eyes: Intraocular abnormalities with visual disturbances; sometimes progressive retinal detachment and blindness
Extremities: Avascular necrosis of hip or shoulder; skeletal deformities, especially lordosis and kyphosis; chronic leg ulcers; susceptibility to osteomyelitis
Central nervous system (CNS): Hemiparesis, seizures

Therapeutic Management

The aims of therapy are to prevent the sickling phenomena, which are responsible for the pathologic sequelae, and treat the medical emergencies of sickle cell crisis. The successful achievement of these aims depends on prompt nursing interventions, medical therapies, patient and family preventive measures, and use of innovative treatments.

Medical management of a crisis is usually directed toward supportive, symptomatic, and specific treatments. The main objectives are to provide (1) rest to minimize energy expenditure and to improve oxygen use; (2) hydration through oral and IV therapy; (3) electrolyte replacement because hypoxia results in metabolic acidosis, which also promotes sickling; (4) analgesia for the severe pain from vasoocclusion; (5) blood replacement to treat progressing severe anemia; and (6) antibiotic therapy to treat any existing infection.

Administration of pneumococcal, *Haemophilus influenzae,* and meningococcal vaccines is recommended for these children because of their susceptibility to infection as a result of functional asplenia. In addition to routine immunizations, children with SCD should receive a yearly influenza vaccination (see Chapter 6, Immunizations). Oral penicillin prophylaxis is recommended by 2 months old to reduce the chance of pneumococcal sepsis (see Translating Evidence Into Practice box).

Oxygen therapy is of little therapeutic value unless the patient has hypoxia (Heeney & Ware, 2015). Severe hypoxia must be prevented because it causes massive systemic sickling that can be fatal. Oxygen administration is usually not effective in reversing sickling or reducing pain because the oxygen is unable to reach the enmeshed sickled erythrocytes through the clogged vessels. In addition, prolonged administration of oxygen can depress bone marrow, further aggravating the anemia.

Another important component of care is the use of blood transfusions. Exchange RBC transfusion (erythrocytapheresis) is the replacement of sickle cells with normal RBCs. Exchange transfusion is a successful, rapid method of reducing the number of circulating sickle cells and therefore slowing down the vicious cycle of hypoxia,

Critically Analyze the Evidence

- Rankine-Mullings and Owusu-Ofori (2017) conducted an update of a Cochrane review first published in 2002 and previously updated in 2014. Five randomized or quasi-randomized control trials were identified by the searches, of which three trials (880 children randomized) met the inclusion criteria. All of the included trials showed a reduced incidence of infection in children with SCD (HgbSS or HgbSβ0Thal) receiving prophylactic penicillin. The evidence examined suggests that prophylactic penicillin significantly reduces risk of pneumococcal infection in children with HgbSS and is associated with minimal adverse reactions.
- Hirst and Owusu-Ofori (2014) conducted an updated systematic Cochrane review of three trials that showed a reduced rate of infection in children with homozygous sickle cell disease (HgbSS or HgbSβ0Thal) receiving prophylactic penicillin. Two trials looked at whether treatment was effective. The third trial followed from one of the early trials and looked at when it was safe to stop treatment. Adverse drug effects were rare and minor. Penicillin given prophylactically significantly reduces the risk of pneumococcal infection in children with SCD younger than 5 years old and is associated with minimal adverse reactions. Support for the same conclusion that there is strong evidence that daily oral penicillin prophylaxis greatly reduces the risk of pneumococcal infection in children with SCA younger than 3 years old was reported in a systematic review (Gwaram & Gwaram, 2014).
- Researchers combined the clinical experiences of three sickle cell programs in the eastern United States in an attempt to determine the age and disease-specific risk of *Streptococcus pneumoniae* bacteremia and meningitis in children with SCD at a time when penicillin prophylaxis was routine. Forty-seven pneumococcal infections (44 bacteremia, 3 meningitis) among 40 patients with SCD were observed. Most children in whom infections developed were taking prophylactic penicillin and received Pneumovax at 24 months old. The observed severe pneumococcal infection rate in children with HgbSS younger than 5 years old was less than that reported before penicillin prophylaxis in this specific population (Hord, Byrd, Stowe, et al., 2002).
- Administration of oral prophylactic penicillin was compared with the 14-valent pneumococcal vaccine in preventing pneumococcal infection in 242 children with HgbSS between the ages of 6 months and 3 years. In the first 5 years of the trial, there were 11 pneumococcal infections in the pneumococcal vaccine group and higher infection rates in those given the vaccine before 1 year of age. No pneumococcal isolates were found in the group receiving penicillin, although four pneumococcal isolates were found in this group within 1 year of stopping the penicillin prophylaxis at 3 years old. This study supported the use of penicillin prophylaxis to prevent pneumococcal infection in children younger than 3 years old (John, Ramlal, Jackson, et al., 1984).
- In a multicenter, randomized, double-blind, placebo-controlled clinical trial, 105 children received penicillin twice daily; a control group of 110 children received a placebo twice daily. The trial was terminated 8 months early when an 84% reduction in the incidence of pneumococcal infections was observed in the group treated with penicillin compared with the placebo group. There were no deaths in the penicillin group, but three deaths from infection occurred in the placebo group. Researchers stressed the importance of screening children during the neonatal period and prescribing prophylactic penicillin to decrease the morbidity and mortality associated with pneumococcal infection (Gaston, Verter, Woods, et al., 1986).
- Zarkowsky and colleagues (1986) conducted a retrospective analysis of 178 episodes of bacteremia in children with sickle hemoglobinopathies that occurred during 13,771 patient-years of follow-up ($n = 3451$). The predominant pathogen in patients younger than 6 years old was *S. pneumoniae* (66%), and gram-negative organisms were responsible for 50% of the bacteremias in patients 6 years of age and older. The incidence of pneumococcal bacteremia in children with SCA younger than 3 years old was 6.1 events per 100 patient-years. The results of this study supported prophylactic administration of penicillin for prevention of pneumococcal bacteremia in children younger than 3 years old.
- A cohort study of 315 patients with HgbSS who lived in Jamaica was conducted between June 1973 and December 1981. The patients were divided into three groups to determine whether interventions such as penicillin prophylaxis, parental education on early diagnosis of acute splenic sequestration, and close monitoring in a sickle cell clinic improved survival. A significant decline in deaths from acute splenic sequestration and pneumococcal septicemia and meningitis was found. The research indicated that early detection of SCD and prophylactic measures could significantly reduce deaths associated with HgbSS (Lee, Thomas, Cupidore, et al., 1995).
- Riddington and Owusu-Ofori (2002) conducted a systematic review of randomized controlled trials evaluating the effectiveness of prophylactic antibiotic administration in preventing pneumococcal infection in children with SCD. The review of published research found that penicillin prophylaxis significantly reduced the risk of pneumococcal infection in children with HgbSS with minimal adverse reactions.
- McCavit, Gilbert, and Buchanan (2013) conducted a cross-sectional electronic survey of 106 pediatric hematologists with expertise in SCD regarding their practices related to penicillin prophylaxis in children with SCD older than 5 years of age. Eighty-four percent of pediatric hematologists from 76 centers completed the survey, and 76% routinely recommended cessation of penicillin prophylaxis after 5 years of age.

Apply the Evidence: Nursing Implications

There is **good evidence** with a **strong recommendation** (Guyatt, Oxman, Vist, et al., 2008) that penicillin prophylaxis significantly reduces the risk of pneumococcal infection in children with SCA. The epidemiologic studies strongly suggest that all children with SCA should be started on prophylactic penicillin at 2 months old. Parents and children with SCA should be instructed on the importance of taking the prophylactic penicillin twice daily and seeking medical attention immediately for acute illness, especially if the temperature exceeds 38.3°C (101°F), regardless of the use of prophylaxis. Most pediatric hematologists with SCD expertise recommend cessation of prophylactic penicillin after 5 years of age.

Quality and Safety Competencies: Evidence-Based Practice[a]

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Summarize the epidemiologic studies that strongly suggest that children with SCA should be started on prophylactic penicillin. A survey of pediatric experts recommends stopping prophylactic penicillin after 5 years of age.

Continued

TRANSLATING EVIDENCE INTO PRACTICE—cont'd

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by making sure infants with SCD are started on penicillin at 2 months old. Most pediatric SCD experts recommend stopping prophylactic penicillin in children with SCD after 5 years of age.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate the strength and weakness of evidence for preventing pneumococcal infection in children with SCD.

HgbSβ0Thal, Sickle Beta 0 Thalassemia; *HgbSS,* homozygous sickle cell disease; *SCD,* sickle cell disease.

thrombosis, tissue ischemia, and injury. Therapy including simple and exchange transfusions is used in life-threatening ACS and also after acute overt stroke to prevent reoccurrence and further tissue damage (Azar & Wong, 2017; Fortin, Hopewell, & Estcourt, 2018; Hirtz & Kirkham, 2019; Rees, Robinson, & Howard, 2018; Wang & Dwan, 2013).

Children with HgbSS disease and sickle beta thalassemia have the highest risk of stroke and should be monitored with annual TCD (Heeney & Ware, 2015). TCD is a cost-effective, noninvasive ultrasound technique that screens for stroke risk in children who have SCD. TCD is performed on children with SCD from 2 to 16 years of age and measures the average velocity of intracranial vascular flow within the large cerebral arteries (Smith-Whitley & Kwiatkowski, 2020; Yawn et al., 2014; Yawn & John-Sowah, 2015). The recommended treatment for children with confirmed abnormal TCD is chronic transfusion therapy (Armstrong-Wells, Grimes, Sidney, et al., 2009; Fortin et al., 2018; Hirtz & Kirkham, 2019; Kwiatkowski, Yim, Miller, et al., 2011; Smith-Whitley & Kwiatkowski, 2020; Wang & Dwan, 2013). The duration of transfusion is indefinite, although studies are addressing whether patients may be transitioned safely from red cell transfusions and chelation to hydroxyurea and phlebotomy to prevent stroke and decrease iron concentration (Estcourt et al., 2017). Hydroxyurea and phlebotomy were found to be an acceptable alternative to standard treatment (transfusion/chelation therapy) for primary stroke prevention in children with abnormal TCD velocities without evidence of severe vasculopathy on brain MRI or magnetic resonance angiography (MRA) (Helton, Adams, Kesler, et al., 2014).

After a CVA, blood transfusions are usually given every 3 to 4 weeks to help prevent a repeat stroke. Multiple transfusions carry the risk of transmission of viral infection, hyperviscosity, transfusion reactions, alloimmunization, hemosiderosis, and transfusion-related acute lung injury (Heeney & Ware, 2015; Pahuja, Puri, Mahajan, et al., 2017; Rees et al., 2018; Secher, Stensballe, & Afshari, 2013; Yawn et al., 2014). To reduce iron overload from chronic transfusion therapy, chelation therapy may be started (see later in the chapter).

In children with recurrent life-threatening splenic sequestration, splenectomy may be a life-saving measure. However, the spleen usually atrophies on its own through progressive fibrotic changes (**functional asplenia**) by 6 years of age in children with SCA. Prophylactic penicillin and pneumococcal vaccines have decreased the incidence of pneumococcal sepsis in children with SCD. Packed RBC transfusions are recommended for treatment of not only splenic sequestration but also stroke and are used preoperatively accompanied by maintenance IV hydration for major surgical procedures in children with SCD.

Painful VOC, the most common acute SCD complication, is considered the clinical hallmark of SCD that is usually accompanied by increasing health care cost because of prolonged hospitalization (Bou-Maroun, Meta, Hanba, et al., 2018; Meier & Rampersad, 2017; Raphael, Mei, Mueller, et al., 2012; Yawn et al., 2014). The chronic nature of this pain can greatly affect the child's development. A multidisciplinary team (e.g., physician, psychologist, child life specialist, family, nurse, social worker) approach is best for vasoocclusive pain management that includes pharmacologic treatments, hydration, physical therapy, and nonpharmacologic and complementary treatment (e.g., prayer, spiritual healing, massage, heating pads, herbs, relaxation, breathing exercises, distraction, music, guided imagery, exercise, self-motivation, acupuncture, biofeedback) (Brown, Weisberg, Balf-Soran, et al., 2015; Campelo, Oliveira, Magalhaes, et al., 2018; Meier & Rampersad, 2017; Williams & Tanabe, 2016). When mild to moderate VOC is reported, nonsteroidal antiinflammatory medication (e.g., ibuprofen, ketorolac) or nonopioids (e.g., acetaminophen) are used initially. If these drugs are not effective alone, an opioid may be added. The dosages of both drugs are titrated (adjusted) to a therapeutic level. Opioids such as immediate- and sustained-release morphine, oxycodone, hydrocodone, hydromorphone (Dilaudid), and methadone are administered intravenously or orally for severe pain and are given around the clock. In conjunction with the opioid, IV ketorolac for a maximum 5-day course is commonly used to enhance the pain management effect. Patient-controlled analgesia (PCA) has been used successfully for sickle cell–related pain. PCA reinforces the patient's role and responsibility in managing the pain and provides flexibility in dealing with pain, which may vary in severity over time (see Chapter 5, Pain Management).

DRUG ALERT

Meperidine (Demerol) is not recommended. Normeperidine, a metabolite of meperidine, is a central nervous system (CNS) stimulant that produces anxiety, tremors, myoclonus, and generalized seizures when it accumulates with repetitive dosing. Patients with sickle cell disease (SCD) are particularly at risk for normeperidine-induced seizures (National Institutes of Health, National Heart, Lung, and Blood Institute, Division of Blood Disease and Resources, 2014).

Prognosis

The prognosis varies, but most patients live into the fifth decade. The greatest risk is usually in children younger than 5 years old, and most deaths in these children are caused by overwhelming infection. Consequently, SCA is a chronic illness with a potentially terminal outcome. Physical and sexual maturation are delayed in adolescents with SCA. Although adults achieve normal height, typically below normal weight, and normal sexual function, the delay may present problems to the adolescent (Heeney & Ware, 2015). A recent retrospective study of children with SCA reported the effect of disease-modifying therapies (hydroxyurea, transfusion) on growth and puberty patterns compared to no therapy, with transfusion therapy demonstrating an earlier height velocity as compared to either hydroxyurea or no therapy (Nagalapuram, Kulkami, Leach, et al., 2019).

Individuals with SCD who have higher levels of HbF tend to have a milder disease with fewer complications than those with lower levels of HbF (Meier & Miller, 2012; Meier & Rampersad, 2017). Hydroxyurea is a US Food and Drug Administration–approved medication that increases the production of HbF, reduces endothelial adhesion of sickle cells, improves the sickle cell hydration and cell size, increases nitric oxide production (a vasodilator), and lowers leukocyte and reticulocyte counts (National Institutes of Health, National Heart, Lung, and Blood Institute, Division of Blood Disease and Resources, 2014; Nevitt, Jones, & Howard, 2017; Yawn et al., 2014). Long-term follow-up of patients taking hydroxyurea alone revealed at least a 40% reduction in mortality and decreased frequency of VOC, ACS, hospital admissions, and need for transfusions, thus making SCD crises milder (DeBaun & Kirkham, 2016; Ghafuri, Chaturvedi, Rodeghier, et al., 2016; Nevitt et al., 2017; Quarmyne, Dong, Theodore, et al., 2017; Smith-Whitley & Kwiatkowski, 2020; Thomas, Dulman, Lewis, et al., 2019). Pediatric studies have shown that hydroxyurea can be safely used in children (Estepp, Smeltzer, Kang, et al., 2017; Rodriguez, Duez, Dedeken, et al., 2018; Thomas et al., 2019; Wang, Ware, Miller, et al., 2011). The 2014 National Heart, Lung, and Blood Institute evidence-based management guidelines for sickle cell disease recommends that all infants 9 months of age and older with SCA be offered hydroxyurea as treatment, regardless of the frequency or severity of disease complications (National Institutes of Health, National Heart, Lung, and Blood Institute, Division of Blood Disease and Resources, 2014; Yawn et al., 2014).

Despite the positive effects of hydroxyurea, new therapeutic agents are being investigated that focus on preventing sickle red cell dehydration, reducing endothelial adhesion, and using antioxidant treatments (Matte, Zorzi, Mazzi, et al., 2019). Since there has not been any long-term use of these agents, further clinical studies are required.

Hematopoietic stem cell transplantation (HSCT) from a human leukocyte antigen (HLA)–matched sibling or unrelated donor is the only potential cure for SCD, with a high risk of neurologic complications (Azar & Wong, 2017; Heeney & Ware, 2015; Locatelli & Pagliara, 2012). Allogeneic HSCT offers a curative treatment for children with SCD, with overall survival of 92% to 95% and event-free survival of 82% to 86% (Hsieh, Fitzhugh, Weitzel, et al., 2014; Krishnamurti, Neuberg, Sullivan, et al., 2019; Locatelli & Pagliara, 2012). Children and adolescents younger than 16 years of age who have severe complications (e.g., stroke, recurrent ACS, refractory pain, abnormal TCD) and have an HLA-matched donor available may be offered HSCT as a treatment modality (Haining, Duncan, El-haddad, et al., 2015; Lucarelli, Isgro, Sodani, et al., 2012; Smith-Whitley & Kwiatkowski, 2020). Substantial risks such as graft rejection, infections, prolonged immunosuppression, graft-versus-host disease, and disease relapse are associated with HSCT and limit its broad acceptance in SCD patients (Khemani, Katoch, & Krishnamurti, 2019; National Institutes of Health, National Heart, Lung, and Blood Institute, Division of Blood Disease and Resources, 2014). Eventually, improved survival with other HSCT modalities, such as umbilical cord blood transplantation, haploidentical transplants, and nonmyeloablative conditioning regimens, may augment sibling donor protocols and widen the availability of HSCT as a potential cure to SCD patients (Khemani et al., 2019; Lucarelli et al., 2012).

Since SCD is an autosomal recessive disorder, investigative strategies for correction, replacement, addition, or modulation of the globin gene continue to evolve in the basic and clinical research settings (Bourzac, 2017; Matte et al., 2019; Negre, Eggimann, Beuzard, et al., 2016; Sii-Felice, Giorgi, Leboulch, et al., 2018). With fewer than 20% of people with SCD having a matched sibling donor for HSCT, gene therapy may be an attractive curative option (Matte et al., 2019; Meier & Rampersad, 2017; Rubin, 2019).

QUALITY PATIENT OUTCOMES: Sickle Cell Disease

- Early recognition of signs and symptoms of sickle cell anemia (SCA)
- Tissue deoxygenation minimized
- Sickle cell crisis prevented or quickly managed
- Pain appropriately managed
- Stroke prevented
- Prophylactic penicillin regimen followed
- Hypoxia prevented when surgery is necessary
- Pneumococcal, *Haemophilus influenzae* type b, and meningococcal vaccines administered

Nursing Care Management

Educate the Family and Child

Family education begins with an explanation of the disease and its consequences (see Nursing Care Plan and Case Study box). After this explanation, the most important issues to teach the family are to (1) seek early intervention for problems, such as fever of 38.5°C (101.3°F) or greater; (2) give penicillin as ordered; (3) recognize signs and symptoms of stroke, splenic sequestration, as well as respiratory problems that can lead to hypoxia; and (4) treat the child normally.

The nurse emphasizes the importance of adequate hydration to prevent sickling and delay the vasoocclusion and hypoxia-ischemia cycle. It is not sufficient to advise parents to "force fluids" or "encourage drinking." They need specific instructions on how many daily glasses or bottles of fluid are required. Many foods are also a source of fluid, particularly soups, flavored ice pops, ice cream, sherbet, gelatin, and puddings.

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

The Child With Sickle Cell Anemia

Day 1, 9:00 am

1. A 12-year-old male with sickle cell anemia (homozygous sickle cell disease [HgbSS]) is being seen in the emergency department (ED) for increasing pain over the past 2 days. The mother is giving him the pain medications as prescribed by the hematology team, but she feels that his pain is getting worse. Which assessment findings require follow-up by the nurse? **Select all that apply.**
   - A. Pulse oximetry 96%
   - B. Hematocrit = 34%
   - C. Pulse = 112 beats/min
   - D. Hemoglobin = 10.6 g/dL
   - E. Respiration = 24 breaths/min
   - F. Abdomen tender to palpation
   - G. 8/10 on the number pain scale
   - H. Blood pressure = 102/50 mm Hg
   - I. Total serum bilirubin = 0.3 mg/dL
   - J. Oral temperature = 100.4° F (38° C) K. Weight = 40 kg
2. **Review the case study above. Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.** As a result of this child's diagnosis of sickle cell disease, the nurse is aware, based on the assessment findings, that the child may be experiencing_____1_____. This is caused by_____2_____

Options for 1	Options for 2
Aplastic crisis	High blood pressure
Sequestration crisis	Ischemia
Acute chest syndrome	Bleeding
Vasoocclusive crisis	Infection
Hyper hemolytic crisis	Diminished red blood cell production
Cerebral vascular accident	Decreased serum sodium

Day 1, 9:30 am

3. The hematologist arrives to examine the child. At this time the child has findings that are consistent with a vasoocclusive crisis (VOC). When planning care for this child, which **priority** interventions would the nurse consider at this time? **Select all that apply.**
   - A. Hydration
   - B. Antibiotics
   - C. Strict bedrest
   - D. Pain medication
   - E. Pain assessment
   - F. Blood transfusion
   - G. Oxygen therapy

Day 1, 10:00 am

4. In the last hour an IV dose of morphine (0.1 mg/kg) was given every 10 minutes for three doses. The numeric pain score of 7/10 is assessed after these initial doses. A decision is made to start both morphine and ketorolac since the pain was not relieved after three doses of IV morphine. The morphine is changed to patient-controlled analgesia (PCA). Ketorolac 1 mg/kg for the first dose, then 0.5 mg/kg/dose (maximum of 30 mg/dose) IV every 6 hours also is started. IV fluids at 1½ maintenance rate are administered. What are the **most appropriate** nursing interventions for this child with SCD experiencing pain who is now receiving morphine by PCA and IV Ketorolac? **Indicate which nursing action listed in the far-left column is appropriate for each potential complication listed in the middle column. Indicate the nursing action number in the far-right column. Note that ONLY one nursing action can be used for each potential complication and that NOT all nursing actions will be used.**

Nursing Action	Potential Complication	Nursing Action for Complication
1. Discuss schedule of medication around the clock with parents.	Uncontrolled pain	
2. Encourage high level of fluid intake.	Breakthrough pain	
3. Recognize that various analgesics, including opioids and medication schedules, may need to be tried.	To avoid needless suffering because of unfounded fears	
4. Reassure child and family that analgesics, including opioids, are medically indicated; that high doses may be needed; and that children rarely become addicted.	To prevent vasoconstriction that may enhance sickling with cold applications	
5. Apply heat application or massage to affected area. Avoid applying cold compresses.	Dehydration	
6. Provide protein shake with each meal.		
7. Weigh the child each morning with the same scale.		

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—cont'd

Day 1, 2:00 pm

5. The patient is now resting comfortably having been admitted to the pediatric unit. His mother is at the bedside and the last numeric pain assessment reveals his level of pain a 3/10. These are the PCA doses used: Loading dose of 0.1 mg/kg (maximum 8 mg); basal rate of 0.01 mg/kg and intermittent dose 0.035 mg/kg (maximum 8 mg) with the interval lockout at approximately 10 minutes. A 4-hour limit of 0.5 mg/kg is set. His weight is 40 kg. **Based on these PCA loading doses above, choose the most likely options for the information missing from the table by selecting from the list of options provided.**

Loading Dose	Basal Rate	Intermittent Dose	Interval Lockout
1	2	3	4

Options for 1	Options for 2	Options for 3	Options for 4
6	0.4	2.2	5 min
4	0.2	1.8	6 min
8	0.8	1.4	8 min
2	0.9	1.2	10 min

Day 1, 7:00 pm

6. A 12-year-old male with sickle cell anemia (homozygous sickle cell disease [HgbSS]) was seen this morning in the emergency department (ED) for increasing pain over the past 2 days. He is admitted for pain management and is on IV Morphine and Ketorolac. His pain assessment is 2/10 on the numeric scale. Assessment findings at the nurse's change of shift at 7pm reveal:
   - Oral temperature = 99.0° F (37.2° C)
   - Pulse = 60 beats/min
   - Respiration = 16 breaths/min
   - Blood pressure = 100/48 mm Hg
   - Weight = 89 lbs (40kg)
   - Abdomen slightly tender to palpation
   - 2/10 on the number pain scale
   - Pulse oximetry 98%

The patient is resting comfortably and the nurse at the end of her shift is assessing important nursing actions for the care of this child.**For each nursing action, use an X to indicate whether it was Effective (helped to meet expected quality patient outcomes), Ineffective (did not help to meet expected quality patient outcomes), or Unrelated (not related to the quality patient outcomes).**

Nursing Action	Effective	Ineffective	Unrelated
Administer morphine and ketorolac safely.			
Monitor for side effects of morphine; assess respiratory status closely and prevent constipation.			
Monitor for side effects of ketorolac; assess for bleeding (gastrointestinal [GI] or renal) closely.			
Educate parents on the safety and effectiveness of IV morphine and ketorolac when using them at home.			
Reassess the child's pain level once a shift after administering morphine and ketorolac.			
Read a children's book to the child while he is asleep.			
Recognize that various analgesics and doses may need to be tried.			

NURSING TIP: One simple yet graphic way to demonstrate the effect of sickling is to roll rounded objects, such as marbles or beads, through a tube to simulate normal circulation and then roll pointed objects, such as screws or jacks, through the tube. The effect of sickling and clumping of the pointed objects is especially noticeable at a bend or slight narrowing of the tube.

Increased fluids combined with impaired kidney function result in the problem of **enuresis**. Parents who are unaware of this fact frequently use the usual measures to discourage bedwetting, such as limiting fluids at night, and may resort to punishment and shame to force bladder control. The nurse should discuss this problem with the parents, stressing that the child's ability to concentrate urine is impaired. Reminding the child to urinate frequently during the day and prior to bedtime may be helpful, as may be waking the child during the night if the child's sleep pattern is not disturbed. Enuresis is treated as a complication of the disease, such as joint pain or some other symptom, to alleviate parental pressure on the child.

Promote Supportive Therapies During Crises

The success of many of the medical therapies relies heavily on nursing implementation. Management of pain is an especially difficult problem and often involves experimenting with various analgesics, including opioids, and schedules before relief is achieved. Unfortunately, these children tend to be undermedicated, which results in "clock watching" and demands for additional doses sooner than might be expected. Often this incorrectly raises suspicions of drug addiction, when in fact the problem is one of improper dosage (see Family-Centered Care box). In choosing and scheduling analgesics, the goal should be *prevention* of pain.

FAMILY-CENTERED CARE

Fear of Addiction

Although the pain during a sickle cell crisis is usually severe and opioids are needed, many families fear that their child will become addicted to the narcotic. Unfortunately, misinformed health professionals may foster this unfounded fear, which results in needless suffering. Extremely few children who receive opioids for severe pain become behaviorally addicted to the drug (American Pain Society, 2015). Opioid dependency in children with sickle cell disease is rare and should never be used as a reason to withhold pain medication (Smith-Whitley & Kwaitkowski, 2020). Families and older children, especially adolescents, need to be reassured that opioids are medically indicated, high doses may be needed, and children rarely become addicted.

NURSING TIP: Advise parents to be particularly alert to situations in which dehydration may be a possibility (e.g., hot weather, playing sports) and to recognize early signs of reduced fluid intake, such as decreased urinary output (e.g., fewer wet diapers) and increased thirst.

Any pain program should be combined with psychologic support to help the child deal with the depression, anxiety, and fear that may accompany the disease. This includes regular visits with the child to discuss any concerns during the hospitalization and positive reinforcement of coping skills, such as successful methods of dealing with the pain and compliance with treatment prescriptions. To reduce the negative connotation associated with the term *crisis*, it is best to say *pain episode*.

If blood transfusions or exchange transfusions are given, the nurse has the responsibility of observing for signs of transfusion reaction (see Table 24.3 later in the chapter). Because hypervolemia from too-rapid transfusion can increase the workload of the heart, the nurse also must be alert to signs of cardiac failure.

In splenic sequestration, gently measure the size of the spleen, because increasing splenomegaly is an ominous sign (see Chapter 4, Abdomen). A decrease in spleen size denotes response to therapy. The nurse also closely monitors vital signs and blood pressure to detect impending shock. Anemia is typically not a presenting complication in VOC but is a critical problem in other types of crises. The nurse monitors for evidence of increasing anemia and institutes appropriate nursing interventions (see earlier in the chapter). Oxygen therapy does not reverse sickled RBCs, and if used in a nonhypoxic patient, it will decrease erythropoiesis (Vichinsky & Styles, 1996). Because prolonged use of oxygen can aggravate the anemia, report any signs of lack of therapeutic benefit, such as restlessness, increased pallor, and continued pain.

Record intake, especially of IV fluids, and output. The child's weight should be taken on admission, because it serves as a baseline for evaluating hydration. Because diuresis can result in electrolyte loss, the nurse observes for signs of hypokalemia and should be familiar with normal serum electrolyte values to report changes.

Recognize Other Complications

Nurses also need to be aware of the signs of ACS and CVA, which are both potentially fatal complications.

NURSING ALERT

Report signs of the following immediately:

Acute chest syndrome (ACS):

- Severe chest, back, or abdominal pain
- Fever of 38.5°C (101.3°F) or higher
- Cough
- Dyspnea, tachypnea
- Retractions
- Declining oxygen saturation (oximetry)

Cerebrovascular accident (CVA):

- Severe, unrelieved headaches
- Severe vomiting
- Jerking or twitching of the face, legs, or arms
- Seizures
- Strange, abnormal behavior
- Inability to move an arm or leg
- Stagger or an unsteady walk
- Stutter or slurred speech
- Weakness in extremities
- Changes in vision

Support the Family

Families need the opportunity to discuss their feelings regarding transmitting a potentially fatal, chronic illness to their child. Because of the widely publicized prognosis for children with SCA, many parents express their fear of the child's death. The prognosis varies; with early diagnosis and treatment, these children are living longer. Previously identified predictors of a severe course of SCA included low hemoglobin level (approximately 7 g/dl), dactylitis or painful episode, and elevated WBC count exhibited before the age of 24 months (Miller, Sleeper, Pegelow, et al., 2000). However, a systematic review identified that the only predictive tests consistently associated with severe SCA outcome are elevated TCD velocities and increased reticulocyte count (Meier, Fasano, & Levett, 2017). All other prognostic predictors had mixed results that were attributed to improved supportive care with

reduction in infectious deaths and stroke rate (Meier et al., 2017). The nurse should care for the family as for any family with a child who has a chronic and life-threatening illness and consider the siblings' reactions, the stress on the marital relationship, and the childrearing attitudes displayed toward the child (see Chapter 17). Several resources are available to families with a sickling disorder.[a]

The nurse advises parents to inform all treating personnel of the child's condition. The use of medical identification, such as a bracelet, is another way to ensure awareness of the disease.

If family members have the SCD trait or SCA, genetic counseling is necessary. A primary consideration in genetic counseling is informing parents of the 25% chance with each pregnancy of having a child with the disease when both parents carry the trait.

BETA THALASSEMIA (COOLEY ANEMIA)

Thalassemia is a common genetic disorder, affecting millions globally, that occurs in approximately 4.4 of every 10,000 live births throughout the world (Smith, 2018; Yaish, 2015). In the United States, an estimated 2000 persons have beta thalassemia major (Centers for Disease Control and Prevention, 2019a; Smith-Whitley & Kwiatkowski, 2020). The term **thalassemia**, which is derived from the Greek word *thalassa,* meaning "sea," is applied to various inherited blood disorders characterized by deficiencies in the rate of production of specific globin chains in Hgb. The name appropriately refers to people living near the Mediterranean Sea, namely Italians, Greeks, Syrians, Asians, Africans, and their descendants. Evidence suggests that the high incidence of the disorders among these groups is a result of the selective advantage the trait has in protecting against malaria, as is postulated in SCD. The disorder has a wide geographic distribution, probably as a result of genetic migration through intermarriage or possibly as a result of spontaneous mutation. However, in the past few decades there has been an influx of migrants from these high-prevalence countries, mainly into North America and Central and North Europe, with rapid increase in the thalassemia population.

Beta thalassemia is the most common of the thalassemias and classified in the following forms:

- Two heterozygous forms, **thalassemia minor**, an asymptomatic silent carrier, and **thalassemia trait**, which produces a mild microcytic anemia
- **Thalassemia intermedia**, which may involve either homozygous or heterozygous abnormalities and is manifested as splenomegaly and moderate to severe anemia
- A homozygous form, **thalassemia major** (also known as **Cooley anemia**), which results in a severe anemia that that is not compatible with life without transfusion support

Mode of Transmission

Thalassemia is an autosomal recessive disorder. Both parents must be carriers of the thalassemia trait to produce a child with beta thalassemia major. The typical mode of transmission is between parents who both carry the trait and therefore have a 25% chance with each pregnancy that their child will be born with thalassemia.

BOX 24.3 Clinical Manifestations of Beta Thalassemia

Anemia (Before Diagnosis)
Pallor
Unexplained fever
Poor feeding
Enlarged spleen or liver

Progressive Anemia
Signs of chronic hypoxia
- Headache
- Precordial and bone pain
- Decreased exercise tolerance
- Listlessness
- Anorexia

Other Features
Small stature
Delayed sexual maturation
Bronzed, freckled complexion (if not receiving chelation therapy)

Bone Changes (Older Children If Untreated)
Enlarged head
Prominent frontal and parietal bossing
Prominent malar eminences
Flat or depressed bridge of the nose
Enlarged maxilla
Protrusion of the lip and upper central incisors and eventual malocclusion
Generalized osteoporosis

Pathophysiology

Normal postnatal HbA is composed of two α- and two β-polypeptide chains. In beta thalassemia, there is a partial or complete deficiency in the synthesis of the β-chains of the Hgb molecule. Consequently, there is a compensatory increase in the synthesis of the α-chains, and γ-chain production remains activated, resulting in defective Hgb formation. This unbalanced polypeptide unit is very unstable; when it disintegrates, it damages RBCs, causing severe anemia.

To compensate for the hemolytic process, an overabundance of erythrocytes is formed unless the bone marrow is suppressed by transfusion therapy. Excess iron from packed RBC transfusions and from the rapid destruction of defective cells is stored in various organs (**hemosiderosis**).

Diagnostic Evaluation

The onset of clinical manifestations in thalassemia major may be insidious and not recognized until late infancy or early toddlerhood. The clinical effects of thalassemia major are primarily attributable to defective synthesis of HbA, structurally impaired RBCs, and shortened life span of erythrocytes (Box 24.3).

Hematologic studies reveal the characteristic changes in RBCs (e.g., microcytosis, hypochromia, anisocytosis, poikilocytosis, target cells, basophilic stippling of various stages). Low Hgb and Hct levels are seen in severe anemia, although they are typically lower than the reduction in RBC count because of the proliferation of immature erythrocytes. Hgb electrophoresis confirms the diagnosis and is helpful in distinguishing the type of thalassemia because it analyzes the quantity and kind of Hgb variants found in the blood.

Baltimore St., Suite 800, Baltimore, MD 21202; 410-528-1555, 800-421-8453; fax: 410-528-1495; email: scdaa@sicklecelldisease.org; http://www.sicklecelldisease.org; http://www.facebook.com/sicklecellcampaign; Sickle Cell Information Center, PO Box 109, Grady Memorial Hospital, 80 Jesse Hill Jr Drive SE, Atlanta, GA 30303; 404-616-3572; fax: 404-616-5998; email: aplatt@emory.edu; http://scinfo.org; National Heart, Lung, and Blood Institute Health Information Center, PO Box 30105, Bethesda, MD 20824-0105; 301-592-8573; fax: 301-592-8563; http://www.nhlbi.nih.gov; http://www.ahcpr.gov.

Therapeutic Management

The objectives of supportive therapy are to maintain sufficient Hgb levels to prevent bone marrow expansion and bony deformities and to provide sufficient RBCs to support normal growth and normal physical activity. Transfusions are the foundation of medical management, with the goal of maintaining the Hgb level at approximately 9.5 g/dl, an aim that may require transfusions as often as every 2 to 5 weeks. The advantages of this therapy include (1) improved physical and psychologic well-being because of the ability to participate in normal activities, (2) decreased cardiomegaly and hepatosplenomegaly, (3) fewer bone changes, (4) normal or near-normal growth and development until puberty, and (5) fewer infections.

One of the potential complications of frequent blood transfusions is iron overload (hemosiderosis). Because the body has no effective means of eliminating the excess iron, the mineral is deposited in body tissues. To minimize the development of hemosiderosis and hemochromatosis in patients with thalassemia major, there are three approved iron-chelating agents: deferoxamine, deferasirox, and deferiprone (Khandros & Kwaitkowski, 2019; Origa, 2017; Smith-Whitley & Kwiatkowski, 2020).

In some children with severe splenomegaly who require repeated transfusions, a splenectomy may be necessary to decrease the disabling effects of abdominal pressure and to increase the life span of supplemental RBCs. Over time, the spleen may accelerate the rate of RBC destruction and thus increase transfusion requirements. After a splenectomy, children generally require fewer transfusions, although the basic defect in Hgb synthesis remains unaffected. A major postsplenectomy complication is severe and overwhelming infection. Therefore these children are often on prophylactic antibiotics with close medical supervision for many years and should receive the pneumococcal and meningococcal vaccines in addition to the regularly scheduled immunizations (see Chapter 6, Immunizations).

NURSING TIP: Ensure that the family and patient understand the need to notify the health professional of all fevers of 38.5°C (101.3°F) or greater because of the risk of sepsis in a child with asplenia.

Prognosis

Most children treated with blood transfusions and early chelation therapy have a remarkably improved survival and quality of life as they survive well into adulthood (Cappellini, Porter, Viprakasit, et al., 2018; Sankaran, Nathan, & Orkin, 2015). The most common causes of death are heart disease, liver damage with cirrhosis, postsplenectomy sepsis, and multiorgan failure secondary to hemochromatosis (Choudhry, 2017; Sankaran et al., 2015; Yaish, 2015). The three adverse prognostic factors for event-free survival are presence of hepatomegaly, iron overload, and portal fibrosis (Choudhry, 2017). Children without these adverse prognostic factors have greater than 97% event-free survival (Choudhry, 2017). A curative treatment for some children is HSCT. Children younger than 14 years of age without excessive iron stores and hepatomegaly who undergo allogeneic HSCT have a high rate of complication-free survival; approximately 80% to 97% of these children are cured (Issaragrisil & Kunacheewa, 2016; Origa, 2017; Smith-Whitley & Kwiatkowski, 2020). Also, related cord-blood transplantation has a disease-free survival of about 90% (Higgs, Engel, & Stamatoyannopoulos, 2012; Issaragrisil & Kunacheewa, 2016). Children without a matched donor may benefit from haploidentical family member transplant, which has shown encouraging results (Locatelli, Merli, & Strocchio, 2016; Lucarelli et al., 2012). New approaches for correction of thalassemia through the introduction of gene therapy strategies, including the use of lentiviral vectors, generation of pluripotent stem cells, gene targeting, and gene editing, are ongoing but continue to have concerns (Arlet, Dussiot, Moura, et al., 2016; El-Beshlawy & El-Ghamrawy, 2019; Makis, Hatzimichael, Papassotiriou, et al., 2016; Sankaran et al., 2015; Xu, Luk, Yao, et al., 2019).

Nursing Care Management

The objectives of nursing care are to (1) promote compliance with transfusion and chelation therapy, (2) assist the child in coping with the anxiety-provoking treatments and the effects of the illness, (3) foster the child's and family's adjustment to a chronic illness, and (4) observe for complications of multiple blood transfusions. Basic to each of these goals is explaining to parents and older children the defect responsible for the disorder, its effect on RBCs, and the potential effects of untreated iron overload (e.g., delayed growth and maturation, heart disease). Because this condition is prevalent among families of Mediterranean descent, the nurse also inquiries about the family's previous knowledge about thalassemia. All families with a child with thalassemia should be tested for the trait and referred for genetic counseling.

As with any chronic illness, the family's needs must be met for optimal adjustment to the stresses imposed by the disorder (see Chapter 17). Sources of information for the family include the Cooley's Anemia Foundation[b] and the Northern California Comprehensive Thalassemia Center. Genetic counseling for the parents and fertile offspring is mandatory, and both prenatal diagnosis using amniocentesis or fetal blood sampling and screening for thalassemia trait are available.

APLASTIC ANEMIA

Aplastic anemia (AA) is a rare and life-threatening disorder that affects approximately 2 to 6 in 1 million children and adults each year (Fargo & Hord, 2020; Korthof, Bekassy, & Hussein, 2013). AA refers to a bone marrow failure condition in which the formed elements of the blood are simultaneously depressed. The peripheral blood smear demonstrates cytopenia with at least two of the following present: profound anemia, leukopenia, and thrombocytopenia. In contrast, **hypoplastic anemia** is characterized by a profound depression of RBCs but normal or slightly decreased WBCs and platelets.

Etiology

AA can be primary (**congenital**, or present at birth) or secondary (**acquired**). The best-known congenital disorder of which AA is an outstanding feature is **Fanconi syndrome**, a rare hereditary disorder characterized by pancytopenia, hypoplasia of the bone marrow, and patchy brown discoloration of the skin resulting from the deposit of melanin. It is associated with multiple congenital anomalies of the musculoskeletal and genitourinary systems. The syndrome appears to be inherited as an autosomal recessive trait with varying penetrance; therefore affected siblings may demonstrate several different combinations of defects.

Several etiologic factors contribute to the development of acquired AA; however, most cases are considered idiopathic (Box 24.4). The following discussion focuses on severe acquired AA, which carries a poorer prognosis and follows a more rapidly fatal course than the primary types.

Diagnostic Evaluation

The onset of clinical manifestations, which include anemia, leukopenia, and decreased platelet count, is usually insidious. Definitive diagnosis is

[b]330 Seventh Ave., No. 200, New York, NY 10001; 800-522-7222; fax: 212-279-5999; email: info@cooleysanemia.org; http://www.thalassemia.org; www.facebook.com/pages/Thalassemia-org/162500870481012.

BOX 24.4 Common Causes of Acquired Aplastic Anemia

- Human parvovirus infection, hepatitis, or overwhelming infection
- Irradiation
- Immune disorders, such as eosinophilic fasciitis and hypoimmunoglobulinemia
- Drugs, such as certain chemotherapeutic agents, anticonvulsants, and antibiotics
- Industrial and household chemicals, including benzene and its derivatives, which are found in petroleum products, dyes, paint remover, shellac, and lacquers
- Infiltration and replacement of myeloid elements, such as in leukemia or the lymphomas
- Idiopathic (In most cases, no identifiable precipitating cause can be found.)

determined from bone marrow examination, which demonstrates the conversion of red bone marrow to yellow, fatty bone marrow. Severe AA is based on Camitta criteria, which include less than 25% bone marrow cellularity with at least two of the following findings: absolute granulocyte count less than 500/mm^3, platelet count less than 20,000/mm^3, and absolute reticulocyte count less than 40,000/mm^3 (Miano & Dufour, 2015; Passweg & Marsh, 2010). Moderate AA is defined as less than 50% bone marrow cellularity with presence of mild to moderate cytopenia (Shimamura & Williams, 2015).

Therapeutic Management

The objectives of treatment are based on the recognition that the underlying disease process is failure of the bone marrow to carry out its hematopoietic functions. Therefore therapy is directed at restoring function to the marrow and involves two main approaches: (1) immunosuppressive therapy (IST) to remove the presumed immunologic functions that prolong aplasia or (2) replacement of the bone marrow through transplantation. Bone marrow transplantation is the treatment of choice for severe AA when a suitable donor exists (see later in the chapter).

Antilymphocyte globulin (ALG) or **antithymocyte globulin (ATG)** is the principal drug treatment used for AA. The rationale for using ATG is based on the theory that AA may be a result of autoimmunity. IST is a combination of ATG and cyclosporine that suppress T cell–dependent autoimmune responses by recognizing human lymphocyte cell surface antigen and decreasing the lymphocytes without causing bone marrow suppression (Peinemann & Labeit, 2014; Young, 2018). ATG usually is administrated intravenously over 12 to 16 hours for 4 days after a test dose to check for hypersensitivity. Cyclosporine is administered orally for several months to a year after ATG therapy until achievement of stable maximally improved blood counts, then is slowly tapered over the course of approximately a year (Fargo & Hord, 2020; Peslak, Olson, & Babushok, 2017). Response to IST is typically delayed, and responses generally do not start before 3 to 4 months with a median time of 6 months (Fargo & Hord, 2020; Samarasinghe & Webb, 2012; Shimamura & Williams, 2015). An IST course may be repeated, depending on the reduction in circulating lymphocytes and the patient's response. Because of the hypersensitivity response associated with ATG (i.e., fever, chills, myalgias), methylprednisolone is given intravenously to prevent these side effects. Granulocyte colony-stimulating factor (G-CSF) is usually ineffective, with no clear evidence of improving the overall survival when added to IST, therefore routine G-CSF used outside febrile neutropenic episodes is controversial (Fargo & Hord, 2020; Tichelli, Schrezenmeier, Socie, et al., 2011; Young, 2018). However, studies reported the use of another growth factor with encouraging preliminary results when eltrombopag (thrombopoietic growth factor) was added to IST in treatment of refractory severe AA (Desmond, Townsley, Dumitriu, et al., 2014; Townsley, Scheinberg, Winkler, et al., 2017). Androgens may be used with ATG to stimulate erythropoiesis if the AA is unresponsive to initial therapies.

HSCT should be considered early in the course of the disease if a compatible donor can be found. Transplantation is more successful when performed before multiple transfusions have sensitized the child to leukocyte and **human leukocyte antigens (HLAs)**. HSCT is associated with an approximately 90% survival rate in patients who receive a bone marrow transplant from an HLA-identical sibling, but the risk of graft failure, graft-versus-host disease, and infectious complications should also be taken into account (Fargo & Hord, 2020; Halkes, de Wreede, Knol-Bout, et al., 2019; Scheinberg, 2012). Recently, survival outcomes from unrelated HLA-matched bone marrow transplantation have been approaching the success seen with HLA-identical sibling bone marrow transplant (Georges & Storb, 2016).

Nursing Care Management

The care of the child with AA is similar to that of the child with leukemia (see Chapter 25) and includes preparing the child and family for the diagnostic and therapeutic procedures, preventing complications from the severe pancytopenia, and emotionally supporting them in the face of a potentially fatal outcome. Information and support are available from the Aplastic Anemia and MDS International Foundation.[c]

The drug ATG is usually administered by way of a central vein. If not, vigilant care must be directed to the IV infusion to prevent extravasation. Meticulous care of the venous access is essential because of the child's susceptibility to infection. Chemotherapeutic agents have been used in the treatment of relapsed patients with AA after unresponsive IST. Many of the side effects associated with chemotherapy, such as nausea and vomiting, alopecia, and mucositis, are experienced by children receiving treatment for AA. Specialized care is required for children with AA who have HSCT (discussed in Chapter 25).

DEFECTS IN HEMOSTASIS

Hemostasis is the process that stops bleeding when a blood vessel is injured. Vascular and plasma clotting factors, as well as platelets, are required. A complex system of clotting, anticlotting, and clot breakdown (**fibrinolysis**) mechanisms exists in equilibrium to ensure clot formation only in the presence of blood vessel injury and to limit the clotting process to the site of vessel wall injury. Dysfunction in these systems leads to bleeding or abnormal clotting. Although the coagulation process is complex, clotting depends on three factors: (1) vascular influence, (2) platelet role, and (3) clotting factors.

HEMOPHILIA

The term **hemophilia** refers to a group of bleeding disorders resulting from congenital deficiency or dysfunction, or absence of specific coagulation proteins or factors (Di Paola, Montgomery, Gill, et al., 2015; Sharathkumar & Pipe, 2008). Although the symptomatology is similar regardless of which clotting factor is deficient, the identification of specific factor deficiencies allows definitive treatment with replacement agents.

In about 80% of all cases of hemophilia, the inheritance pattern is demonstrated as X-linked recessive. The two most common forms of the disorder are **factor VIII deficiency** (hemophilia A, or classic hemophilia) and **factor IX deficiency** (hemophilia B, or Christmas disease) with prevalence of approximately 1 in 5000 and 1 in 20,000 to 30,000 live births, respectively (Centers for Disease Control and Prevention,

[c]100 Park Avenue, Suite 108, Rockville, MD 20850; 800-747-2820, 301-279-7202; fax: 301-279-7205; email: help@aamds.org; http://www.aamds.org; http://www.facebook.com/aamds.

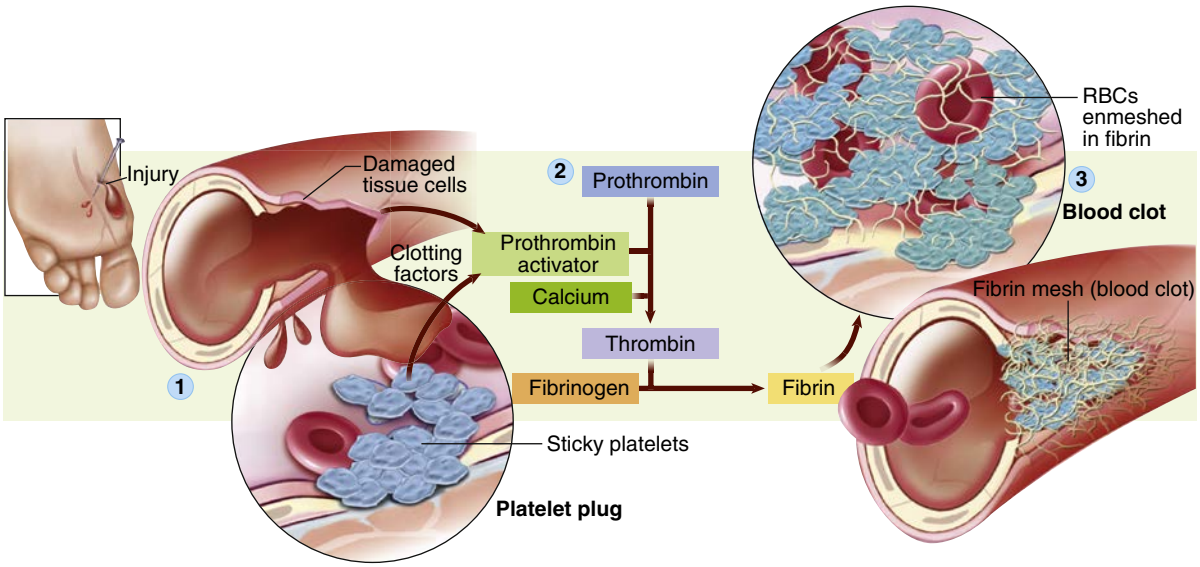

Fig. 24.4 Blood clotting. The extremely complex clotting mechanism can be distilled into three basic steps: (1) release of clotting factors from both injured tissue cells and sticky platelets at the injury site (which form a temporary platelet plug); (2) a series of chemical reactions that eventually result in the formation of thrombin; and (3) formation of fibrin and trapping of red blood cells *(RBCs)* to form a clot. (From Thibodeau, G. A. [2010]. *The human body in health and disease* [5th ed.]. St Louis, MO: Mosby.)

2018b; Scott & Flood, 2020a; Sharathkumar & Carcao, 2011). There are about 20,000 people of all races and ethnic groups affected with hemophilia in the United States (National Hemophilia Foundation, 2019). **Von Willebrand disease (vWD)** is another hereditary bleeding disorder characterized by a deficiency, abnormality, or absence of the protein called *von Willebrand factor (vWF)*. The following discussion is primarily concerned with factor VIII deficiency, which accounts for 80% to 85% of all hemophilia cases.

Pathophysiology

The basic defect of hemophilia A is a deficiency of **factor VIII (antihemophilic factor [AHF])**. Factor VIII is produced by the liver and is necessary for the formation of thromboplastin in phase I of blood coagulation (Fig. 24.4). The less factor VIII that is found in the blood, the more severe the disease. Individuals with hemophilia have two of the three factors required for coagulation: vascular influence and platelets. Therefore they may bleed for longer periods but not at a faster rate.

A major feature of hemophilia is that its expression varies markedly regarding the degree of bleeding severity. Hemophilia is generally classified into three groups (severe, moderate, mild) according to the severity of the factor deficiency; 60% to 70% of children with hemophilia demonstrate the severe form of the disorder. With severe factor deficiencies, hemorrhage can occur spontaneously or as a result of minor trauma, such as after circumcision. In children with less severe deficiencies (moderate, mild), however, the bleeding tendency may not be noted until the onset of walking.

Subcutaneous and IM hemorrhages are common. Hemarthrosis, which refers to bleeding into joint cavities, especially the knees, elbows, and ankles, is the most frequent form of internal bleeding. Bony changes and crippling deformities occur after repeated bleeding episodes over several years. Early signs of hemarthrosis are a feeling of stiffness, tingling, or achiness in the affected joint, followed by decrease in joint movement. Obvious affected joint signs and symptoms are increased warmth, redness, and swelling and severe pain with loss of movement. Bleeding in the neck, mouth, or thorax is serious because the airway can become obstructed. Intracranial hemorrhage can have fatal consequences and is one of the major causes of death. Hemorrhage anywhere along the GI tract can lead to anemia, and bleeding into the retroperitoneal cavity is especially hazardous because of the large space for blood to accumulate. Hematomas in the spinal cord can cause paralysis.

Diagnostic Evaluation

The diagnosis is usually made from a history of bleeding episodes, evidence of X-linked inheritance (only one-third of the cases are new mutations), and laboratory findings. To understand the significance of various tests of hemostasis, it is helpful to recall the usual mechanism to control bleeding (e.g., the function of platelets and clotting factors). The test specific for hemophilia plasma includes factor VIII and factor IX assay, procedures normally performed in specialized laboratories. Other tests are those that depend on specific factors for a reaction to occur, especially the partial thromboplastin time (PTT). Carrier detection is possible in classic hemophilia using deoxyribonucleic acid (DNA) testing and is an important consideration in families in which female offspring may have inherited the trait.

Therapeutic Management

The primary therapy for hemophilia is replacement of the missing clotting factor. The products available are **factor VIII concentrates**, either produced through genetic engineering (recombinant form) or derived from pooled plasma, which are reconstituted with sterile water immediately before use. A synthetic form of vasopressin, **1-deamino-8-d-arginine vasopressin (DDAVP)**, increases plasma factor VIII activity and is the treatment of choice in mild hemophilia and vWD types I and IIA only if the child shows an appropriate response. After DDAVP administration, a threefold to fourfold rise in factor VIII level activity should occur. It is not effective in the treatment of severe hemophilia A, severe vWD, or any form of hemophilia B. Aggressive factor concentrate replacement therapy is initiated to prevent chronic crippling effects from joint bleeding.

Other drugs may be included in the therapy plan, depending on the source of the hemorrhage. Corticosteroids are given for hematuria,

acute hemarthrosis, and chronic synovitis. It is recommended that patients with hemophilia avoid aspirin and traditional nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen because they inhibit platelet function associated with GI bleeding (Scott & Flood, 2020a; World Federation of Hemophilia, 2012). However, cyclooxygenase-2 (COX-2) inhibitors, selective NSAIDs that have comparable analgesic effect to traditional NSAIDs with less chance of GI bleeding, have been recommended as a suitable option for hemophilic arthropathy (Arachchillage & Markis, 2016; World Federation of Hemophilia, 2012). Oral administration of ε-aminocaproic acid (Amicar) prevents clot destruction. Its use is limited to mouth trauma or surgery, with a dose of factor concentrate given first.

A regular program of exercise and physical therapy is an important aspect of management. Physical activity within reasonable limits strengthens muscles around joints and may decrease the number of spontaneous bleeding episodes.

Treatment without delay results in more rapid recovery and a decreased likelihood of complications; therefore most children are treated at home. The family is taught the technique of venipuncture and to administer the AHF to children older than 2 to 3 years old. The child learns the procedure for self-administration at 8 to 12 years old. Home treatment is highly successful, and the rewards, in addition to the immediacy, are less disruption of family life, fewer school or work days missed, and enhancement of the child's self-esteem and independence.

Prophylactic therapy is periodic factor replacement for children with severe hemophilia to prevent bleeding complications, including arthropathy and spontaneous life-threatening bleeding events (Di Paola et al., 2015; Scott & Flood 2020a; von der Lippe, Frich, Harris, et al., 2017). Primary prophylaxis involves the infusion of factor VIII concentrate on a regular basis before the onset of joint damage. Secondary prophylaxis involves the infusion of factor VIII concentrate on a regular basis after the child experiences his or her first joint bleed. The administration of infusions differs among treatment centers and may range from every other day to three times a week for several weeks to promote healing. On-demand factor replacement may be a cost-effective alternative to primary prophylaxis, but prophylaxis decreases the development of joint disease and preserves joint function compared with on-demand factor replacement treatment (Chozie, Primacakti, Gatot, et al., 2019; Iorio, Marchesini, Marcucci, et al., 2011; Nugent, O'Mahony, Dolan, et al., 2018). Prompt appropriate treatment of hemorrhage and prophylactic therapy are key to excellent care and prevention of long-term morbidity in patients with hemophilia (Di Paola et al., 2015; Hanley, McKernan, Creagh, et al., 2017; Lillicrap, 2013; Nugent et al., 2018).

Prognosis

Although there is no cure for hemophilia, its symptoms can be controlled and its potentially crippling deformities greatly reduced or even avoided. Today, many children with hemophilia function with minimal or no joint damage. They have an average life expectancy and are normal in every respect but one—they have a tendency to bleed, which is a significant inconvenience but not necessarily a life-threatening event.

Unfortunately, those individuals with hemophilia who were treated before the development of current purification techniques for factor VIII concentrate (between 1979 and 1985) may have been exposed to human immunodeficiency virus (HIV). It is estimated that 90% of severe hemophiliacs seroconverted to HIV-positive status (National Hemophilia Foundation, 2019). Individuals with hemophilia diagnosed since the 1990s and treated with recombinant factor products are at virtually no risk for developing HIV infection from treatment. Recombinant factor VIII and factor IX products that are devoid of human protein materials have become the treatment of choice for children and previously untreated hemophilia patients (Di Paola et al., 2015).

Gene therapy may prove to be a treatment option in the future. Techniques are under development to introduce factor VIII and factor IX genes into hepatocytes, fibroblast, and endothelial cells using adeno-associated viral vectors and other novel ideas for genetic correction (Branchford, Monahan, & Di Paola, 2013; Nienhuis, Nathwani, & Davidoff, 2017; Walsh & Batt, 2013). Efforts are underway to improve viral vector strategies, including selection of both appropriate vectors and the appropriate cell in which to express the gene, and to obtain a better understanding of the immune consequences of gene transfer (Di Paola et al., 2015; Doshi & Arruda, 2018; Lytle, Brown, Paik, et al., 2016; Nienhuis et al., 2017).

QUALITY PATIENT OUTCOMES: Hemophilia

- Early recognition of signs and symptoms of hemophilia
- Bleeding episodes prevented
- Bleeding episodes treated early with factor replacement
- Adherence to prophylactic factor replacement program when indicated
- Hemarthrosis prevented when possible with limited joint damage
- Exercise program and physical therapy ongoing

Nursing Care Management

The earlier a bleeding episode is recognized, the more effectively it can be treated. Signs that indicate internal bleeding are especially important to recognize. Children are aware of internal bleeding and are reliable in telling the examiner the location of an internal bleed. In addition to the manifestations described (Box 24.5), the nurse maintains a high level of suspicion when a child with hemophilia shows signs such as headache; slurred speech; loss of consciousness (from cerebral bleeding); and black, tarry stools (from GI bleeding).

Prevent Bleeding

The goal of prevention of bleeding episodes is directed toward decreasing the risk of injury. Prevention of bleeding episodes is geared mostly toward appropriate exercises to strengthen muscles and joints and to allow age-appropriate activity. During infancy and toddlerhood, the normal acquisition of motor skills creates innumerable opportunities for falls, bruises, and minor wounds. Restraining the child from mastering motor development can bring more serious long-term problems than allowing the behavior. However, the environment should be made as safe as possible, with close supervision during playtime to minimize incidental injuries.

For older children, the family usually needs assistance in preparing for school. A nurse who knows the family can be instrumental in discussing the situation with the school nurse and in jointly planning an appropriate activity schedule. Because almost all individuals with hemophilia are boys, the physical limitations regarding active sports may be a difficult adjustment, and activity restrictions must be

BOX 24.5 Clinical Manifestations of Hemophilia

- Prolonged bleeding anywhere from or in the body
- Hemorrhage from any trauma: Loss of deciduous teeth, circumcision, cuts, epistaxis, injections
- Excessive bruising, even from a slight injury, such as a fall
- Subcutaneous and intramuscular (IM) hemorrhages
- Hemarthrosis (bleeding into the joint cavities), especially the knees, ankles, and elbows
- Hematomas: Pain, swelling, and limited motion
- Spontaneous hematuria

tempered with sensitivity to the child's emotional and physical needs. Use of protective equipment, such as helmets, face masks, shin/wrist/forearm guards, kneepads, and other equipment appropriate for the type of athletic activity, is encouraged to prevent injury. Children and adolescents with severe hemophilia may participate in noncontact sports with a low injury risk, such as aerobic exercise, stretching exercises, swimming, yoga, archery, walking, jogging, tennis, golf, fishing, and bowling (Anderson & Forsyth, 2017; World Federation of Hemophilia, 2012). Athletic participation is recommended after careful consideration of different activities with proper prophylaxis, precautions, and surveillance by caregivers and physicians (Howell, Scott, & Patel, 2017; National Hemophilia Foundation, 2019)

To prevent oral bleeding, some readjustment in terms of dental hygiene may be needed to minimize trauma to the gums, such as use of a water irrigating device, softening the toothbrush in warm water before brushing, or using a sponge-tipped disposable toothbrush. A regular toothbrush should be soft bristled and small. Adolescents also need to be advised of the dangers of using safety razors with blades and should use an electric shaver.

Because any trauma can lead to a bleeding episode, all persons caring for these children must be aware of their disorder. These children should wear medical identification, and older children should be encouraged to recognize situations in which disclosing their condition is important, such as during dental extraction or injections. Health personnel need to take special precautions to prevent the use of procedures that may cause bleeding, such as IM injections. The subcutaneous route is substituted for IM injections whenever possible. Venipunctures for blood samples are usually preferred for these children. There is usually less bleeding after the venipuncture than after finger or heel punctures. Neither aspirin nor any aspirin-containing compound should be used. Acetaminophen is a suitable aspirin substitute, especially for controlling pain at home.

Recognize and Control Bleeding

As noted, the earlier a bleeding episode is recognized, the more effectively it can be treated. Factor replacement therapy should be instituted according to established medical protocol, and supportive measures may be implemented, such as **RICE**, which stands for *r*est, *i*ce, *c*ompression, and *e*levation. When parents and older children are taught such measures beforehand, they can be prepared to initiate immediate treatment. Plastic bags of ice or cold packs should be kept in the freezer for such emergencies. However, such measures do not take the place of factor replacement.

Prevent Crippling Effects of Bleeding

As a result of repeated episodes of hemarthrosis, incompletely absorbed blood in the joints, and limitation of motion, bone and muscle changes occur that result in flexion contractures and joint fixation. During bleeding episodes, the joint is elevated and immobilized. Active range-of-motion exercises are usually instituted after the acute phase. This allows the child to control the degree of exercise according to the level of discomfort. If an exercise program is instituted in the home, a physical therapist or public health nurse may need to supervise compliance with the regimen. Rarely, orthopedic intervention (such as casting, application of traction, or aspiration of blood) may be necessary to preserve joint function. Diet is also an important consideration because excessive body weight can increase the strain on affected joints, especially the knees, and predispose the child to hemarthrosis. Consequently, calories need to be supplied in accordance with energy requirements.

Support the Family and Prepare for Home Care

Genetic counseling is essential as soon as possible after diagnosis. Unlike many other disorders in which both parents carry the trait, the feeling of responsibility for this condition usually rests with the mother. Unless she has an opportunity to discuss her feelings, the couple's relationship can suffer. Technology is available to identify classic hemophilia carriers using DNA testing and may reduce the anxiety regarding childbearing in women who may be at risk of carrying the defective gene. Factor concentrates have greatly changed the outlook for these children by minimizing bleeding and allowing the child to live a normal, unrestricted life. Children are taught to take responsibility for their disease at an early age. They learn their limitations, preventive measures, and self-administration of the prophylactic AHF.

The needs of families who have children with hemophilia are best met through a comprehensive team approach of physicians (pediatrician, hematologist, orthopedist), nurse practitioner, nurse, social worker, and physical and psychologic therapists. Parent-group discussions are beneficial in meeting the needs that are often best met by similarly affected families. For example, with the improved prognosis for these children, parents and adolescents with hemophilia face vocational and financial problems in addition to concern over future childbearing. This can be disastrous in terms of the cost of treatment, which can exceed $100,000 a year. Financial support is particularly important. The National Hemophilia Foundation[d] and the Canadian Hemophilia Society[e] provide numerous services and publications for both health providers and families.

Children who have become infected with HIV through transfusions and factor replacement products are faced with the consequences of this dreaded disease. Consequently, they need the support of health professionals, especially in the areas of safe sexual practices to avoid disease transmission and public education regarding acquired immune deficiency syndrome (AIDS) and ways to deal with public reactions to persons who have AIDS.

IMMUNE THROMBOCYTOPENIA (IDIOPATHIC THROMBOCYTOPENIC PURPURA)

Idiopathic thrombocytopenic purpura (ITP), the term formerly used because purpura is an infrequent sign at presentation, is now referred to as *immune thrombocytopenia* (Rodeghiero, Stasi, Gernsheimer, et al., 2009). ITP is an acquired hemorrhagic disorder characterized by (1) **thrombocytopenia**, (2) absence or minimal signs of bleeding (easy bruising, mucosal bleeding, petechiae) in most childhood cases, and (3) normal bone marrow with a normal or increased number of immature platelets (**megakaryocytes**) and **eosinophils**. Although the causes are not known, it is understood that ITP involves the evolution of antibodies against multiple platelet antigens and cytotoxic T cells that cause platelet destruction in blood and spleen and/or inhibition of platelet production in the bone marrow (Consolini, 2011; Scott & Flood, 2020b; Wilson, 2015). ITP is the most common thrombocytopenia of childhood that typically presents 1 to 4 weeks after a viral illness, and the majority of cases are in children younger than 10 years old, with the peak incidence between 1 to 6 years old (Consolini, 2011; Cooper, 2017; Scott & Flood, 2020b; Wilson, 2015).

The disease occurs in one of the following forms: (1) as newly diagnosed acute ITP that is less than 3 months from diagnosis, (2) as persistent

[e]400–1255 University St., Montreal, Quebec, Canada H3B 3B6; 800-668-2686, 514-848-0503; fax: 514-848-9661; email: chs@hemophilia.ca; http://www.hemophilia.ca; http://www.facebook.com/CanadianHemophiliaSociety.

BOX 24.6 Clinical Manifestations of Immune Thrombocytopenia (Idiopathic Thrombocytopenic Purpura)

Easy Bruising
- Petechiae
- Ecchymoses
- Most often over bony prominences

Bleeding From Mucous Membranes
- Epistaxis
- Bleeding gums
- Internal hemorrhage evidenced by the following:
  - Hematuria
  - Hematemesis
  - Melena
  - Hemarthrosis
  - Menorrhagia
  - Hematomas over lower extremities

ITP that occurs from 3 months to 1 year, or (3) as a chronic condition lasting more than 12 months' duration (Cooper, 2017; Onisai, Vladareanu, Spinu, et al., 2019). The acute form occurs most commonly after upper respiratory tract infections; after the childhood diseases measles, rubella, mumps, and chickenpox; or after infection with human parvovirus.

Diagnostic Evaluation

The diagnosis is suspected based on clinical manifestations (Box 24.6). In ITP, the platelet count is reduced to less than 20,000/mm^3; therefore tests that depend on platelet function, such as the tourniquet test, bleeding time, and clot retraction, are abnormal. There is no definitive test that establishes a diagnosis of ITP; several tests are usually performed to rule out other disorders in which thrombocytopenia is a manifestation, such as systemic lupus erythematosus, lymphoma, or leukemia.

Therapeutic Management

Management of ITP is primarily supportive because the disease is self-limiting in most cases. Activity is restricted at the onset while the platelet count is low and while active bleeding or progression of lesions is occurring. Treatment for acute presentation is symptomatic and has included prednisone, intravenous immunoglobulin (IVIG), and anti-D antibody. These are not curative therapies. Experts suggest that no therapy is necessary for asymptomatic patients because there is no difference in the recovery time of platelet counts with and without treatment (Cooper, 2017; Kuhne & Imbach, 2013; Scott & Flood, 2020b; Wilson, 2015). **Anti-D antibody** is a plasma-derived immunoglobulin that causes a transient hemolytic anemia in Rh (D)-positive patients with ITP. With the clearance of antibody-coated RBCs, there is prolonged survival of platelets resulting from the blockade of the Fc receptors of the reticuloendothelial cells. The platelet count usually increases approximately 48 hours after an infusion of anti-D antibody; therefore it is not appropriate therapy for patients who are actively bleeding. The benefits of choosing anti-D antibody IV therapy over prednisone or IVIG are that anti-D antibody can be given in one dose over 5 to 10 minutes and is significantly less expensive than IVIG. Before receiving the initial dose of anti-D antibody, patients must meet certain criteria (Box 24.7). Premedication with acetaminophen 5 to 10 minutes before the infusion is recommended. Bone marrow examination is not recommended in patients with typical ITP, particularly in patients who respond well to treatment, but bone marrow examination may be done in patients with refractory disease (Cooper, 2017; Onisai et al., 2019).

BOX 24.7 Criteria for Anti-D Antibody Therapy

- Age between 1 and 19 years; Rh (D)–positive blood type
- Normal WBC count and hemoglobin level for age; platelet count of 20,000/mm^3
- No active mucosal bleeding
- No history of reaction to plasma products
- No known immunoglobulin A deficiency
- No concurrent infection
- Absence of Evans syndrome (characterized by the combination of ITP and autoimmune hemolytic anemia)
- No suspicion of lupus erythematosus or other collagen vascular disorder
- No splenectomy

ITP, Idiopathic thrombocytopenic purpura; *WBC,* white blood cell.

NURSING TIP: After administration of anti-D antibody, observe the child for a minimum of 1 hour and maintain a patent intravenous (IV) line. Obtain baseline vital sign measurements before the infusion and again 5, 20, and 60 minutes after beginning the infusion. If fever, chills, and headache occur during or shortly after the infusion, the nurse should administer acetaminophen, diphenhydramine (Benadryl), and/or hydrocortisone (Solu-Cortef) as ordered and observe the patient for an additional hour after the reaction.

Splenectomy is for patients who have chronic ITP that is not responsive to pharmacologic management and have increased risk of severe hemorrhage. It is an option associated with long-term remission for these children and reduces the risk of hemorrhage but increases the risk of lifelong postsplenectomy infection (Onisai et al., 2019; Scott & Flood, 2020b; Wilson, 2015). Before splenectomy is considered, it is recommended to wait until the child is older than 5 years of age because of the increased risk of bacterial infection. Administration of pneumococcal, meningococcal, and *H. influenzae* vaccines is recommended before splenectomy (see Chapter 6, Immunizations). The child also receives penicillin prophylaxis after splenectomy. The length of prophylactic therapy is controversial, but in general a minimum of 3 years of therapy is recommended.

Prognosis

Most children have a self-limited course without major complications. Some children may develop chronic ITP and require ongoing therapies such as rituximab, azathioprine, or agents (romiplostim, eltrombopag) that stimulate thrombopoiesis (Cooper, 2017; Scott & Flood, 2020b). A splenectomy may modify the disease process, and the child may be asymptomatic.

QUALITY PATIENT OUTCOMES: Idiopathic Thrombocytopenic Purpura
- Serious bleeding episode prevented
- Activities that increase risk for serious bleeding avoided
- Treatment administered without serious side effects

Nursing Care Management

Nursing care is largely supportive and should include teaching on the possible side effects of therapy and restriction of contact sports while the child's platelet count is less than 50,000/mm^3 (Consolini, 2011; Kumar, Lambert, Breakey, et al., 2015). Restricted physical activities or contact sports should include football, rugby, bike

riding, skateboarding, in-line skating, gymnastics, climbing, and running. Parents may engage their children in physical activities such as swimming (no diving), golf, walking, fishing, and aim to prevent any injuries, especially to the child's head. Instruct the parents to obtain prompt medical evaluation if the child sustains head or abdominal trauma. As in any condition with an uncertain outcome, the family needs emotional support.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC), also known as **consumption coagulopathy**, is characterized by diffuse fibrin deposition in the microvasculature, consumption of coagulation factors, and endogenous generation of thrombin and plasmin. DIC is a secondary disorder of coagulation that occurs as a complication of a number of pathologic processes, such as hypoxia, acidosis, shock, endothelial damage (e.g., burns), and many severe systemic diseases (e.g., congenital heart disease, necrotizing enterocolitis, gram-negative bacterial sepsis, rickettsial infections, some severe viral infections). The hallmarks of this disorder are bleeding and clotting that occurs simultaneously.

Pathophysiology

DIC occurs when the first stage of the coagulation process is abnormally stimulated. Although no well-defined sequence of events occurs, two distinct phases can be identified. First, when the clotting mechanism is triggered in the circulation, thrombin is generated in greater amounts than can be neutralized by the body. Consequently, there is rapid conversion of fibrinogen to fibrin, with aggregation and destruction of platelets. Local and widespread fibrin deposition occurs in blood vessels, which causes obstruction of blood flow with eventual necrosis of tissues. Concurrently, the fibrinolytic mechanism is activated, which causes extensive destruction of clotting factors. With a deficiency of clotting factors, the child is vulnerable to uncontrollable hemorrhage into vital organs. An additional complication is damage and hemolysis of RBCs.

Diagnostic Evaluation

DIC is suspected when the patient has an increased tendency to bleed (Box 24.8). Hematologic findings include prolonged prothrombin time, PTT, thrombin time, and increased D-dimer antigen (byproduct of fibrinolytic process). There is a profoundly depressed platelet count, fragmented RBCs, and depleted fibrinogen.

Therapeutic Management

Treatment of DIC is directed toward control of the underlying or initiating cause, which in most instances stops the coagulation problem spontaneously. Platelets and fresh-frozen plasma may be needed to replace lost plasma components, especially in children whose underlying disease remains uncontrolled. Extremely ill newborn infants may require exchange transfusion with fresh blood. The administration of IV heparin to inhibit thrombin formation is most often restricted to patients who have no response to treatment of the underlying disease or replacement of coagulation factors and platelets.

Nursing Care Management

The goals of nursing care are to be aware of the possibility of DIC in severely ill children and to recognize signs that might indicate its presence. The skills needed to monitor IV infusion and blood transfusions and to administer heparin are the same as for any child receiving these therapies. (See Chapter 17 for care of children with life-threatening illnesses.)

BOX 24.8 Clinical Manifestations of Disseminated Intravascular Coagulation

Petechiae
Purpura
Bleeding from openings in the skin
- Venipuncture site
- Surgical incision

Bleeding from umbilicus, trachea (newborn)
Evidence of gastrointestinal (GI) bleeding
Hypotension
Organ dysfunction from infarction and ischemia

EPISTAXIS (NOSEBLEEDING)

Isolated and transient episodes of epistaxis, or nosebleeding, are common in childhood. The nose, especially the septum, is a highly vascular structure, and bleeding usually results from direct trauma, including blows to the nose, foreign bodies, and nose picking, or from mucosal inflammation associated with allergic rhinitis and upper respiratory tract infections. The bleeding usually stops with minimal pressure and requires no medical evaluation or therapy.

Recurrent epistaxis and severe bleeding may indicate an underlying disease, particularly vascular abnormalities, leukemia, thrombocytopenia, and clotting factor deficiency diseases (e.g., hemophilia, vWD). Nosebleeds are sometimes associated with administration of aspirin, even in normal amounts. Persistent episodes of epistaxis require medical evaluation.

Nursing Care Management

In the event of a nosebleed, an essential intervention is to remain calm. Otherwise, the child will become more agitated, the blood pressure will increase, and the child may not cooperate. Although in most instances a nosebleed is not serious, it can be upsetting to family members as well. They need reassurance that the loss of blood is not serious and that the bleeding usually stops in less than 10 minutes with nasal pressure.

To control the bleeding, the child is instructed to sit up and lean forward (not to lie down or hold the head backwards) to avoid aspiration of blood. Most of the nosebleeding originates in the anterior part of the nasal septum and can be controlled by applying pressure to the soft lower portion of the nose with the thumb and forefinger (see Emergency Treatment box). During this time, the child breathes through the mouth.

If hemorrhage continues, the child should be evaluated by a practitioner, who may pack the nose with epinephrine-soaked gauze. After a nosebleed, a water-soluble jelly can be inserted into each nostril

EMERGENCY TREATMENT

Epistaxis

- Have child sit up and lean forward (not lie down or tilt head backwards).
- Apply continuous pressure to tip of nose with thumb and forefinger for at least 10 minutes.
- Do not insert cotton or wadded tissue into each nostril, as it may reopen wound when removed.
- Discourage nose blowing or picking or rubbing nose, as this may dislodge the clot.
- Apply ice pack or cold cloth to bridge of nose if bleeding persists.
- Keep child calm and quiet.

to prevent crusting of old blood and to lessen the likelihood of the child's picking at the nose and restarting the hemorrhage. If a child has numerous nosebleeds, factors believed to increase the likelihood of bleeds are eliminated, such as discouraging nose picking or altering the household humidity by placing a cool-mist humidifier in the child's room. Repeated bleeding episodes lasting longer than 30 minutes may be an indication to refer the child for evaluation for the possibility of a bleeding disorder.

IMMUNOLOGIC DEFICIENCY DISORDERS

A number of disorders can cause profound, often life-threatening alterations within the body's immune system. The most serious are those conditions that completely depress immunity, such as severe combined immunodeficiency disease (SCID). However, the one disorder that generates the most anxiety in both the family and the community is HIV infection and the subsequent development of AIDS.

Several classifications of immune dysfunction exist. AIDS, SCID, and **Wiskott-Aldrich syndrome (WAS)** are disorders wherein the body is unable to mount an immune response. The immune response can also be misdirected. In **autoimmune disorders**, antibodies, macrophages, and lymphocytes attack healthy cells.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNE DEFICIENCY SYNDROME

HIV infection and AIDS is a persistent global problem that has generated intense medical investigation and constitutes one of world's most serious medical, public health, and social challenges of our time (Centers for Disease Control and Prevention, 2019b; Grace, 2015; United Nations AIDS, 2016). Research has led to early diagnosis and improved medical treatments for HIV infection, changing this disease from a rapidly fatal one to a chronic disease.

Epidemiology

The first AIDS cases in the pediatric population in the United States were identified in children born to HIV-infected mothers and in children who received blood products. More than 90% of these children acquired the disease perinatally from their mothers. Smaller numbers of children were infected through the transfusion of contaminated blood or blood products before blood products were routinely screened for HIV. Currently, the principal modes of HIV transmission to the pediatric population are mother-to-child transmission and adolescent and young adult (13 to 24 years of age) risky behaviors, such as unprotected sexual activity and IV drug use (Centers for Disease Control and Prevention, 2019b; Hayes, 2020; Siberry, 2014; UN Joint Programme on HIV/AIDS [UNAIDS], 2019).

New cases of perinatally acquired HIV have declined approximately 70% with the use of preventive measures such as HIV counseling; voluntary testing practices; antiretroviral therapy (ART) during pregnancy, intrapartum, and neonatal periods; elective cesarean delivery; avoidance of breastfeeding; and avoidance of premastication of food by a caregiver with HIV (Centers for Disease Control and Prevention, 2017a; Hayes, 2020; Nesheim, Fitzharris, Gray, et al., 2019). ART is typically a combination of three or more antiretroviral drugs, with each drug inhibiting a specific stage of the HIV cycle. Two nucleoside analog reverse transcriptase inhibitors in combination with either a nonnucleoside reverse transcriptase inhibitor protease inhibitor or an integrase inhibitor is the current standard in the United States for the treatment of HIV-infected pregnant women and has significantly reduced the transmission of HIV to babies more than 90% of the time (Centers for Disease Control and Prevention, 2019b; Givens, Dotters-Katz, Stringer, et al., 2018; Siberry, 2014). Routine HIV counseling and voluntary testing using the opt-in (must agree) or opt-out (right of refusal) approach is the recommended standard of care for pregnant women in the United States (American Academy of Pediatrics Committee on Pediatric AIDS, 2008; Centers for Disease Control and Prevention, 2017a, 2019b; Siberry, 2014).

BOX 24.9 Common Clinical Manifestations of Human Immunodeficiency Virus Infection in Children

- Lymphadenopathy
- Hepatosplenomegaly
- Oral candidiasis
- Chronic or recurrent diarrhea
- Failure to thrive
- Developmental delay
- Parotitis

Etiology

HIV is a retrovirus that is the primary cause of AIDS. It is found in the blood, semen, vaginal secretions, rectal fluids, and breast milk. It has an incubation or latency period of months to years (Hayes, 2020). There are different strains of HIV. Whereas HIV-2 is prevalent in Africa, HIV-1 is the dominant strain in the United States and elsewhere. **Horizontal transmission** of HIV occurs through intimate sexual contact or parenteral exposure to blood or body fluids containing visible blood. **Perinatal (vertical) transmission** occurs when an HIV-infected pregnant woman passes the infection to her infant. There is no evidence that *casual* contact between infected and uninfected individuals can spread the virus.

Pathophysiology

The HIV virus primarily infects a specific subset of T lymphocytes, the $CD4^+$ T cells, but it can also invade cells of the monocyte-macrophage lineage. The virus takes over the machinery of the $CD4^+$ lymphocyte, using it to replicate itself, rendering the $CD4^+$ cell dysfunctional. The $CD4^+$ lymphocyte count gradually decreases over time; at some point, physical symptoms appear. The count eventually reaches a critical level at which there is substantial risk of opportunistic illnesses, followed by risk of death.

Clinical Manifestations

Common clinical manifestations of HIV infection in children vary (Box 24.9). The diagnosis of AIDS is associated with certain illnesses or conditions. The most common AIDS-defining conditions observed among American children are listed in Box 24.10. Other problems in these children may include short stature, malnutrition, and cardiomyopathy. CNS abnormalities resulting from HIV infection may include neuropsychologic deficits; developmental disabilities; and deficits in motor skills, communication, and behavioral functioning.

Diagnostic Evaluation

For children 18 months of age and older, the HIV enzyme-linked immunosorbent assay (ELISA) and Western blot immunoassay are performed to determine HIV infection. In infants born to HIV-infected mothers, results of these assays are positive because of the presence of maternal antibodies derived transplacentally. Since maternal antibodies may persist in the infant up to 18 to 24 months of age, other diagnostic tests are used—most commonly the HIV polymerase

chain reaction (PCR) for detection of proviral DNA (US Department of Health and Human Services, 2018a).

Currently, several rapid HIV inexpensive tests are available with sensitivity and specificity better than those of the standard enzyme immunoassay, with only a single step that allows test results to be reported within 30 minutes (Hayes, 2020). A positive rapid test is either confirmed by Western blot testing or two different positive rapid tests (testing different HIV-associated antibodies). Viral diagnostic assays, such as HIV DNA or ribonucleic acid (RNA) PCR or HIV culture, are considerably more useful in young infants, allowing a definitive diagnosis in most infected infants by 1 to 4 months of age (Hayes, 2020; US Department of Health and Human Services, 2018b). In the United States, HIV testing approved by the Food and Drug Administration includes (1) combination tests that detect both HIV antigen and antibody and (2) tests that accurately differentiate HIV-1 from HIV-2 antibodies (Centers for Disease Control and Prevention, 2019b; US Department of Health and Human Services, 2018b). With the identification of HIV antigen, individuals may be diagnosed with HIV infection prior to development of symptoms.

The Centers for Disease Control and Prevention (1994, 2006, 2008, 2014) has developed a revised classification system to describe the spectrum of HIV disease in children (Selik, Mokotoff, Branson, et al., 2014) (Table 24.2). The system indicates the degree of immunosuppression and the severity of clinical signs and symptoms. The immune categories are based on $CD4^+$ lymphocyte counts and percentages that are divided into the following categories: 0 = previous negative or indeterminate test (not included on table), 1 = no evidence of immune suppression, 2 = moderate suppression, and 3 = severe suppression (Selik et al., 2014; Weinberg, 2018) (see Table 24.2). Age adjustment of the category numbers is necessary because normal counts, which are relatively high in infants, decline steadily until 6 years of age, when they reach adult norms.

The clinical categories are defined by the presence or absence of certain opportunistic infections or cancers (e.g., non-Hodgkin lymphoma, leiomyosarcoma, Kaposi sarcoma) (Weinberg, 2018). The nonsymptomatic category includes either no signs and symptoms or one of the conditions listed in the mildly symptomatic category. The mildly symptomatic category includes signs and symptoms such as lymphadenopathy, parotitis, hepatosplenomegaly, dermatitis, and recurrent or persistent sinusitis or otitis media. The moderately symptomatic category includes signs and symptoms such as lymphoid interstitial pneumonitis (LIP) and a variety of organ-specific dysfunctions or infections. The severely symptomatic category includes signs and symptoms such as AIDS-defining illnesses, with the exception of LIP. Children with LIP have a better prognosis than those with other AIDS-defining illnesses.

The immunologic and clinical categories are becoming less relevant in the era of combination ART. When ART is taken as prescribed, it almost invariably increases $CD4^+$ T-cell counts and decreases the symptoms. Therefore the categories are useful for clinical research and for describing the severity of illness at time of diagnosis in children younger than 13 years old (Selik et al., 2014; Weinberg, 2018) (see Table 24.2). For adolescents older than 13 years of age and adults, classification systems use $CD4^+$ T-cell count as the major staging unless AID-defining conditions (opportunistic infections) are present (Selik et al., 2014; Weinberg, 2018) (see Table 24.2).

BOX 24.10 Common Defining Conditions for Acquired Immune Deficiency Syndrome in Children

- *Pneumocystis carinii* pneumonia (PCP)
- Lymphoid interstitial pneumonitis (LIP)
- Recurrent bacterial infections
- Wasting syndrome
- Candidal esophagitis
- Human immunodeficiency virus (HIV) encephalopathy
- Cytomegalovirus disease
- *Mycobacterium avium-intracellulare* complex infection
- Pulmonary candidiasis
- Herpes simplex disease
- Cryptosporidiosis

Therapeutic Management

The goals of therapy for HIV infection include slowing the growth of the virus, preventing and treating opportunistic infections, and providing nutritional support and symptomatic treatment. **Antiretroviral drugs** work at various stages of the HIV life cycle to prevent reproduction of functional new virus particles. Although antiretroviral drugs are not a cure, they can delay progression of the disease (Centers for Disease Control and Prevention, 2016; Hayes, 2020). Classes of antiretroviral agents include nucleoside reverse transcriptase inhibitors (e.g., zidovudine, didanosine, stavudine, lamivudine, abacavir), nonnucleoside reverse transcriptase inhibitors (e.g., nevirapine, delavirdine, efavirenz), nucleotide reverse transcriptase inhibitors (e.g., adefovir), protease inhibitors (e.g., indinavir, saquinavir, ritonavir, nelfinavir,

TABLE 24.2 Human Immunodeficiency Virus Infection Stage[a] Based on Age-Specific $CD4^+$ T-Lymphocte or $CD4^+$ T-Lymphocyte Percentage of Total Lymphocytes

	AGE ON DATE OF $CD4^+$ T LYMPHOCYTE TEST		
Stage	**<1 Year (cells/μL, %)**	**1-6 Years (cells/μL, %)**	**>6 Years (cells/μL, %)**
1	>1500, >34	>1000, >30	>500, >26
2	750-1499, 26-33	500-999, 22-29	200-499, <14-25
3	<750	<500, <22	<200, <14

[a]The stage is based primarily on the $CD4^+$ T-lymphocyte count; the $CD4^+$ T-lymphocyte count takes precedence over the CD4 T-lymphocyte percentage, and the percentage is considered only if the count is missing. There are three situations in which the stage is not based on this table: (1) if the criteria for stage 0 are met, the stage is 0 regardless of criteria for other stages (CD4 T-lymphocyte test results and opportunistic illness diagnoses); (2) if the criteria for stage 0 are not met and a stage 3–defining opportunistic illness has been diagnosed, the stage is 3 regardless of CD4 T-lymphocyte test results; and (3) if the criteria for stage 0 are not met and information on the above criteria for other stages is missing, the stage is classified as unknown.

Modified from Centers for Disease Control and Prevention. (1994). 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. *MMWR Recommendations and Reports, 43*(RR-12), 1–10; and Selik, R. M., Mokotoff, E. D., Branson, B., et al. (2014). Revised surveillance case definition for HIV infection—United States. *Morbidity and Mortality Weekly Report, 63*(RR-3), 1–10.

amprenavir), and fusion inhibitors (e.g., enfuvirtide) (Givens et al., 2018). Combinations of antiretroviral drugs are used to stall the emergence of drug resistance, including the addition of other drug classes approved by the US Food and Drug Administration (e.g., entry inhibitors, integrase inhibitors, pharmacokinetic enhancers) (Huang, Chen, Dolan, et al., 2017; US Department of Health and Human Services, 2019). Antiretroviral therapy regimens and guidelines are continually evolving. Therapy is lifelong, making adherence difficult. Laboratory markers ($CD4^+$ lymphocyte count, viral load) assist in monitoring both disease progression and response to therapy. If people with HIV take ART as prescribed, their viral load can become undetectable (Centers for Disease Control and Prevention, 2019b).

Pneumocystis carinii pneumonia (PCP) is the most common opportunistic infection of children infected with HIV. It occurs most frequently between 3 and 6 months old. All infants born to HIV-infected women should receive prophylaxis until HIV infection is reasonably excluded (Hayes, 2020; Siberry, 2014; Simpkins, Siberry, & Hutton, 2009). Trimethoprim/sulfamethoxazole (TMP-SMZ) is the agent of choice. If adverse effects are experienced with TMP-SMZ, dapsone, atovaquone, or pentamidine can be used.

Prophylaxis is often given for other opportunistic infections, such as disseminated *Mycobacterium avium-intracellulare* complex, candidiasis, or herpes simplex. Intravenous gamma globulin (IVGG) has been helpful in preventing recurrent or serious bacterial infections in some HIV-infected children.

Immunization against common childhood illnesses, including the pneumococcal and influenza vaccines, is recommended for all children exposed to and infected with HIV (Bamford, Manno, Mellado, et al., 2016; Leggat, Iyer, Ohtola, et al., 2015; Simpkins et al., 2009). Varicella (chickenpox) vaccine and measles, mumps, and rubella (MMR) vaccine can be administered if there is no evidence of severe immunocompromise (Hayes, 2020; Weinberg, 2018). Because antibody production to vaccines may be poor or decrease over time, immediate prophylaxis after exposure to several vaccine-preventable diseases (e.g., measles, varicella) is warranted. It should be recognized that children receiving IVGG prophylaxis may not respond to the MMR vaccine if it is given in close proximity to the IVGG dose (McLean, Fiebelkorn, Temte, et al., 2013).

HIV infection often leads to marked failure to thrive and multiple nutritional deficiencies. Nutritional management may be difficult because of recurrent illness, diarrhea, and other physical problems. The nurse should implement intensive nutritional interventions if the child's growth begins to slow or weight begins to decrease.

Prognosis

Early recognition and improved medical care have changed HIV disease from a rapidly fatal illness to a chronic disease. After the introduction of combination ART, the numbers of new AIDS cases and deaths declined substantially. In the United States, from 2009 to 2013, the annual estimated number and rate of deaths of HIV-infected children younger than 13 years old has remained stable (Centers for Disease Control and Prevention, 2015; Simpkins et al., 2009). In contrast, adolescents and young adults (13 to 24 years old) with AIDS represent a minority of cases in the United States yet constitute one of the fastest-growing groups of newly infected persons in the country, most likely because they are unaware of the infection (Centers for Disease Control and Prevention, 2019b; Hayes, 2020; Simpkins et al., 2009). During the 20th International AIDS Conference in Melbourne, Australia, in 2014, the 90–90–90 targets were launched as a global quest with a December 2020 deadline (UN Joint Programme on HIV/AIDS [UNAIDS], 2017). Targets were aimed at maximizing viral suppression among people living with HIV, with a focus on 90% of people living with HIV knowing their status, 90% of those who know their status being on treatment, and 90% of those on treatment being virally suppressed (UN Joint Programme on HIV/AIDS [UNAIDS], 2017).

QUALITY PATIENT OUTCOMES: Human Immunodeficiency Virus

- Early recognition of human immunodeficiency virus (HIV) infection
- HIV infection slowed or maintained
- Growth and development promoted
- No infectious complications or cancer development
- Adherence to antiretroviral therapy
- Prolonged survival
- Quality of life supported

Nursing Care Management

Education on transmission and control of infectious diseases, including HIV infection, is essential for children with HIV infection and anyone involved in their care. The basic tenets of Standard Precautions should be presented in an age-appropriate manner, with careful consideration of the educational levels of the individuals (see Chapter 20, Infection Control). Safety issues, including appropriate storage of special medications and equipment (e.g., needles, syringes), are emphasized.

Unfortunately, relatives, friends, and others in the general public may be fearful of contracting HIV infection, and criticism and ostracism of the child and family may occur. In an effort to protect the child and deal with fears of the community, the family may limit the child's activities outside the home. Although certain precautions are justified in limiting exposure to sources of infections, they must be tempered with concern for the child's normal developmental needs. Both the family and the community need ongoing education about HIV to dispel many of the myths that have been perpetuated by uninformed persons.[f]

Prevention is a key component of HIV education. Educating adolescents about HIV is essential in preventing HIV infection in this age-group. Education should include the routes of transmission, the hazards of IV and other recreational drug use, and the value of sexual abstinence and safe sex practices (Hayes, 2020; United Nations AIDS, 2016). Such education should be a part of anticipatory guidance provided to all adolescent patients. Nurses should also encourage adolescents at risk to undergo HIV counseling and testing. In addition to identifying infected teenagers and getting them into care, such counseling affords adolescents an opportunity to learn about, and possibly change, their risky behaviors.

Because approximately 1 in 7 individuals living with HIV infection are unaware of their positive status, the Centers for Disease Control and Prevention recommends that clinicians screen for HIV infection in all persons 13 to 64 years old at least once during routine health care and in all those individuals who are at increased risk regardless of age (Centers for Disease Control and Prevention, 2019b; Moyer and US Preventive Services Task Force, 2013). Early detection of HIV-infected individuals and linking them to medical care and counseling through screening programs in the health care setting provides effective treatment and decreases the transmission of HIV (Suthar, Ford, Bachanas, et al., 2013; Weinberg, 2018).

[f]Additional information is available from the National HIV/AIDS Hotline: 800-342-AIDS (2437) or 800-HIV-0440 (448-0440); TTY/TDD: 800-243-7889 or 888-480-3739; outside of the United States: 301-315-2816; contactus@aidsinfo.nih.gov; http://aidsinfo.nih.gov.

The multiple complications associated with HIV disease are potentially painful. Aggressive pain management is essential for these children to have an acceptable quality of life. Their pain may be caused by infections (e.g., otitis media, dental abscess), encephalopathy (e.g., spasticity), adverse effects of medications (e.g., peripheral neuropathy), or an unknown source (e.g., deep musculoskeletal pain). Common psychosocial concerns include disclosing the diagnosis to the child, making custody plans when the parent is infected, and anticipating the loss of a family member. Other stressors may include financial difficulties, HIV-associated stigma, attempts to keep the diagnosis secret, infection of other family members, and any losses associated with HIV. Most mothers of these children are single mothers who are also HIV infected. As primary caretakers, they often attend to the needs of their child first, neglecting their own health in the process. The nurse should encourage the mother to receive regular health care. As an integral part of the multidisciplinary team, the nurse is necessary for the successful management of the complex medical and social problems of these families.

Children with HIV infection attend daycare centers and schools. It is well established that the risk of HIV transmission in these settings is minimal. These institutions are required to follow Centers for Disease Control and Prevention and Occupational Safety and Health Administration guidelines for infection control measures. Standard Precautions describing proper management of blood and body fluids should also be followed. It is recommended that school personnel receive current HIV information and include it in the health education curriculum for kindergarten through twelfth grade (Nacken, Rehfuess, Paul, et al., 2018; Naidoo & Rule, 2016; National Association of School Psychologists, 2012). School nurses play a vital role in educating the school staff, students, and parents. They are also invaluable in monitoring the needs of known affected children.

Confidentiality is another major issue in daycare or school attendance. Parents and legal guardians have the right to decide whether they inform the daycare or school of their child's HIV diagnosis. Unfortunately, myths about HIV infection continue to exist, and the family often wishes to avoid any potential criticism or ostracism of the child.

SEVERE COMBINED IMMUNODEFICIENCY DISEASE

SCID is a defect characterized by absence of both humoral and cell-mediated immunity. The terms **Swiss-type lymphopenic agammaglobulinemia,** which refers to the autosomal recessive form of the disease, and **X-linked lymphopenic agammaglobulinemia** have been used to describe this disorder, which, as the names imply, can follow either mode of inheritance.

The most common manifestation is susceptibility to infection early in life, most often in the first month. The disorder in children is characterized by chronic infections, failure to recover completely from infections, frequent reinfection, and infection with unusual agents. Failure to thrive is a consequence of the persistent illnesses.

Diagnosis is usually based on a history of recurrent, severe infections from early infancy; a familial history of the disorder; and specific laboratory findings, which include lymphopenia, lack of lymphocyte response to antigens, and absence of plasma cells in the bone marrow. Documentation of immunoglobulin deficiency is difficult during infancy because of the normally delayed response of infants in producing their own immunoglobulins and material transfer of immunoglobulin G (IgG). Currently, newborn screening for SCID can be performed by quantifying levels of T-cell receptor (TCR) excision circles (TRECs) in dried blood spots collected at birth (Centers for Disease Control and Prevention, 2017b; Cross, 2013; Dorsey, Dvorak, Cowan, et al., 2017; King & Hammarstrom, 2018). TRECs are a byproduct of rearrangement of TCR genes during intrathymic T-cell development, and the TREC levels are extremely low or absent in patients with SCID. Since newborn screening for SCID, most states as well as the District of Columbia and Puerto Rico have identified several cases of SCID at birth in otherwise healthy-looking newborns (Centers for Disease Control and Prevention, 2019c; Dorsey et al., 2017; King & Hammarstrom, 2018). Quantification of TRECs represents an important yet nonspecific indicator of a possible severe T-cell immunodeficiency, the diagnosis of which must be confirmed by appropriate immunophenotypic, functional, and molecular tests (Bonilla & Notarangelo, 2015). Advances in SCID newborn screening have profoundly improved outcomes of children born in the United States, with identification of an increased number of expected cases from approximately 40 to 69 annually, equating to an additional 29 cases each year managed with potentially curative treatment (Dorsey & Puck, 2017; King & Hammarstrom, 2018).

Therapeutic Management

The definitive treatment for SCID is HSCT. If the condition is diagnosed at birth or within the first 3 months of life, more than 95% of cases can be treated successfully with HLA-identical or T-cell depleted haploidentical donor (usually a parent) or a matched unrelated donor bone marrow stem cells transplant or umbilical cord donor (Bonilla & Notarangelo, 2015; Sullivan & Buckley, 2020). Before newborn screening for SCID became a reality, most patients were infected when initially diagnosed and required immediate aggressive interventions (Bonilla & Notarangelo, 2015). Approaches to manage SCID patients include providing passive immunity with IVIG and maintaining the child in a sterile environment. The latter is effective only if the measure is instituted before any infectious process takes hold in the infant, and it represents an extreme effort to prevent life-threatening infections. Investigators using research protocols reported tremendous advances with gene therapy, offering hope that gene therapy may eventually be the treatment of choice for cases of SCID (Bonilla & Notarangelo, 2015; Booth, Romano, Roncarolo, et al., 2019; Dorsey & Puck, 2017; Sullivan & Buckley, 2020).

Nursing Care Management

Nursing care focuses on preventing infection and supporting the child and family. The care is consistent with that needed for HSCT for any condition (see earlier in the chapter). Because the prognosis for SCID is very poor if a compatible bone marrow donor is not available, nursing care is directed at supporting the family in caring for a child with a life-threatening illness (see Chapter 17). Genetic counseling is essential because of the modes of transmission in either form of the disorder.

WISKOTT-ALDRICH SYNDROME

WAS is a congenital X-linked recessive disorder characterized by a triad of abnormalities: thrombocytopenia, eczema, and immunodeficiency of selective functions of B and T lymphocytes. An abnormal gene has been identified on the proximal arm of the X chromosome and designated the WAS protein (Bonilla & Notarangelo, 2015). Today, it is well recognized that the syndrome has a wide clinical spectrum ranging from mild, isolated thrombocytopenia to the severe classic presentation that can be complicated by life-threatening hemorrhages, immunodeficiency, atopy, autoimmunity, and cancer (Candotti, 2018). However, it is important to keep in mind that patients with initial mild form can transition to severe condition with the development of chronic or life-threatening clinical problems (Candotti, 2018). At birth, the presenting feature may be prolonged bleeding at the circumcision site or

bloody diarrhea as a result of thrombocytopenia. As the child grows older, recurrent infection and eczema become more severe, and the bleeding becomes less frequent.

Eczema is typical of the allergic type and readily becomes superinfected. Chronic infection with herpes simplex is a frequent problem and may lead to chronic keratitis of the eye with loss of vision. Chronic pulmonary disease, sinusitis, and otitis media result from repeated infections. In children who survive the bleeding episodes and overwhelming infections, malignancy presents an additional risk to survival.

Since medical and supportive care is tailored toward the degree of severity and specific clinical manifestations, it primarily involves counteracting the bleeding tendencies with platelet transfusions, promoting appropriate nutrition, giving IVIG to provide passive immunity, using G-CSF to correct neutropenia and prevent infections, administering prophylactic antibiotics to prevent and control infection, and providing aggressive local therapy for the eczema (Bonilla & Notarangelo, 2015; Candotti, 2018; Dale, 2017; Sullivan & Buckley, 2020). Splenectomy may improve the platelet count, although the risk of asplenic sepsis in these infants is extremely high. These children require the same prophylactic antibiotics and appropriate immunizations as any child with asplenia. Despite their immunodeficiency, they can mount an adequate immunologic response to the inactivated vaccines. When an HLA-matched donor exists, WAS is usually cured with HSCT, which should be performed as early as possible (Albert, Notarangelo, & Ochs, 2011; Mahlaoui, Pellier, Mignot, et al., 2013; Sullivan & Buckley, 2020). However, further research is needed to determine optimal conditioning for WAS to minimize the HSCT-related complications (Iguchi, Cho, Hiromasa, et al., 2019).

More recently, transplantation of autologous gene-corrected hematopoietic stem or progenitor cells (gene therapy) has become an alternative, albeit still investigational, option (Booth et al., 2019; Candotti, 2018). Therefore gene therapy provides a valuable treatment for patients with severe WAS, particularly those who do not have a suitable HSCT donor. The efficiency, efficacy, and long-term safety are yet largely untested in humans, but there is likely to be rapid evolution of the technology with autologous somatic gene modification that may become a standard of care within 5 to 10 years (Booth et al., 2019; Ferrua, Cicalese, Galimberti, et al., 2019).

Nursing Care Management

Because of the poor prognosis for children with WAS, the main nursing consideration is supporting the family in the care of a fatally ill child (see Chapter 17). Physical care should be directed at controlling the problems imposed by the disorder. The measures used to control bleeding are similar to those for hemophilia and vWD (see discussions earlier in the chapter). Another major goal is prevention or control of infection. Because eczema is a troublesome problem, nursing measures specific to this condition are especially important. The genetic implications of this X-linked recessive disorder differ little from those of any other X-linked disease. Since the multiplicity of defects tends to affect emotional adjustment and physical care, the nurse must be especially supportive by providing short-term goals during periods of hospitalization and by focusing on long-range needs through coordinated efforts with a public health nurse.

TECHNOLOGIC MANAGEMENT OF HEMATOLOGIC AND IMMUNOLOGIC DISORDERS

BLOOD TRANSFUSION THERAPY

Technologic advances in blood banking and transfusion medicine enable the administration of only the blood component needed by the child, such as packed RBCs in anemia or platelets for bleeding disorders. Regardless of the blood component administered, the nurse must be aware of the possible transfusion reactions. Table 24.3 summarizes the major complications of transfusions, the signs and symptoms typically associated with each, and nursing responsibilities. General guidelines that apply to all transfusions include:

TABLE 24.3 Nursing Care of the Child Receiving Blood Transfusions

Complication	Signs and Symptoms	Precautions and Nursing Responsibilities
Immediate Reactions		
Hemolytic reactions Most severe type but rare Incompatible blood Incompatibility in multiple transfusions	Sudden, severe headache Chills Shaking Fever Pain at needle site and along venous tract Nausea and vomiting Sensation of tightness in chest Red or black urine Flank pain Progressive signs of shock or renal failure	Identify donor and recipient blood types and groups before transfusion is begun; verify with another nurse or practitioner. Transfuse blood slowly for the first 15-20 min or initial 20% of blood volume; remain with patient. Stop transfusion immediately in the event signs or symptoms occur, maintain patent IV line, and notify practitioner. Save donor blood to recrossmatch with patient's blood. Monitor for evidence of shock. Insert urinary catheter and monitor hourly outputs. Send samples of patient's blood and urine to laboratory for presence of hemoglobin (indicates intravascular hemolysis). Observe for signs of hemorrhage resulting from DIC. Support medical therapies to reverse shock.
Febrile reactions Leukocyte or platelet antibodies Plasma protein antibodies	Fever Chills	May give acetaminophen for prophylaxis. Leukocyte-poor RBCs are less likely to cause reaction. Stop transfusion immediately; report to practitioner for evaluation.

Continued

TABLE 24.3 Nursing Care of the Child Receiving Blood Transfusions—cont'd

Complication	Signs and Symptoms	Precautions and Nursing Responsibilities
Allergic reactions Recipient reaction to allergens in donor's blood	Urticaria Pruritus Flushing Asthmatic wheezing Laryngeal edema	Give antihistamines for prophylaxis to children with tendency to allergic reactions. Stop transfusion immediately. Administer epinephrine for wheezing or anaphylactic reaction.
Circulatory overload Too rapid transfusion (even a small quantity) Transfusion of excessive quantity of blood (even slowly)	Precordial pain Dyspnea Rales Cyanosis Dry cough Distended neck veins Hypertension	Transfuse blood slowly. Prevent overload by using packed RBCs or administering divided amounts of blood. Use infusion pump to regulate and maintain flow rate. Stop transfusion immediately if there are signs of overload. Place child upright with feet in dependent position to increase venous resistance.
Air emboli May occur when blood is transfused under pressure	Sudden difficulty in breathing Sharp pain in chest Apprehension	Normalize pressure before container is empty when infusing blood under pressure. Clear tubing of air by aspirating air with syringe at nearest Y connector if air is observed in tubing; disconnect tubing and allow blood to flow until air has escaped only if a Y connector is not available.
Hypothermia	Chills Low temperature Irregular heart rate Possible cardiac arrest	Allow blood to warm at room temperature (<1 h). Use approved mechanical blood warmer or electric warming coil to warm blood rapidly; never use microwave oven. Take temperature if patient complains of chills; if subnormal, stop transfusion.
Electrolyte disturbances Hyperkalemia (in massive transfusions or in patients with renal problems)	Nausea, diarrhea Muscular weakness Flaccid paralysis Paresthesia of extremities Bradycardia Apprehension Cardiac arrest	Use washed RBCs or fresh blood if patient is at risk.
Delayed Reactions		
Transmission of infection Hepatitis HIV infection Malaria Syphilis Other bacterial or viral infection	Signs of infection (e.g., jaundice) Toxic reaction: High fever, severe headache or substernal pain, hypotension, intense flushing, vomiting, or diarrhea	Blood is tested for antibodies to HIV, hepatitis C virus, and hepatitis B core antigen; in addition, blood is tested for hepatitis B surface antigen and alanine aminotransferase, and a serologic test is performed for syphilis. Units that test positive are destroyed. Individuals at risk for carrying certain viruses are deterred from donation. Report any sign of infection, and if it occurs during transfusion, stop transfusion immediately, send sample for culture and sensitivity testing, and notify practitioner.
Alloimmunization Antibody formation Occurs in patients receiving multiple transfusions	Increased risk of hemolytic, febrile, and allergic reactions	Use limited number of donors. Observe carefully for signs of reactions.
Delayed hemolytic reaction	Destruction of RBCs and fever 5-10 days after transfusion	Observe for posttransfusion anemia and decreasing benefit from successive transfusion.

DIC, Disseminated intravascular coagulation; *HIV,* human immunodeficiency virus; *IV,* intravenous; *RBC,* red blood cell.

- Take vital signs, including blood pressure, *before* administering blood to establish baseline data for pretransfusion and posttransfusion comparison; 15 minutes after initiation; hourly while blood is infusing; and on completion of transfusion.
- Check the identification of the recipient and the blood type and group of the recipient against the donor's, regardless of the blood product being used.
- Administer the first 50 ml of blood or initial 20% of the volume (whichever is smaller) *slowly* and stay with the child.

- Administer with normal saline on a piggyback setup or have normal saline available.
- Administer blood through an appropriate filter to eliminate particles in the blood and prevent the precipitation of formed elements; gently shake the container frequently.
- Use blood within 30 minutes of its arrival from the blood bank; if it is not used, return it to the blood bank—do not store it in the regular unit refrigerator.
- Infuse a unit of blood (or the specified amount) within 4 hours. If the infusion will exceed this time, the blood should be divided into appropriate-size quantities by the blood bank and the unused portion refrigerated under controlled conditions.
- If a reaction of any type is suspected, stop the transfusion, take vital signs, maintain a patent IV line with normal saline and new tubing, notify the practitioner, and do not restart the transfusion until the child's condition has been medically evaluated.

Although hemolytic reactions are rare, ABO incompatibility remains the most common cause of death from blood transfusion, and human error is usually responsible (e.g., administration of the wrong type to the patient or mislabeling of the blood product) (Josephson & Strauss, 2020; Pahuja et al., 2017). Hemolysis can also cause the release of large quantities of phospholipids, which are capable of stimulating DIC. Acute kidney shutdown and eventual renal failure are a result of renal vasoconstriction from antigen–antibody complexes derived from the RBC surface.

Blood is usually administered to children by infusion pump; therefore the usual precautions and management related to pumps apply. When the blood infusion begins with a standard transfusion set, the filter chamber is filled to allow the total filter to be used. The drip chamber is partially filled with blood to permit counting of the drops. In adjusting the flow rate, it is important to remember that blood administration sets do not use microdrops (60 drops/ml) but regular drops (usually 10 to 15 drops/ml). The nurse must consider this when calculating the flow rate.

APHERESIS

Apheresis is the removal of blood from an individual, separation of the blood into its components, retention of one or more of these components, and reinfusion of the remainder of the blood into the individual. These transfusion components have greatly prolonged the survival of patients with hematologic and oncologic diseases.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A 10-month-old boy is scheduled for a follow-up clinic visit. His mother reports that her son is anemic and needs further evaluation. What assessment findings below would the nurse expect to find to confirm iron deficiency anemia? **Select all that apply.**
   - **A.** MCV = 67 fl
   - **B.** Hematocrit = 30%
   - **C.** Poor intake of solid food
   - **D.** Pulse oximetry 98%
   - **E.** Hemoglobin = 10.2 g/dL
   - **F.** Respirations- 14 breaths/min
   - **G.** Blood pressure = 102/50 mm Hg
   - **H.** Serum iron concentration- 12 mcg/dL
   - **I.** Total iron-binding capacity = 450 mcl/dL
   - **J.** History of 28-32 oz/day of cow's milk intake

2. The nurse is working with a 4-year-old girl who is newly diagnosed with beta thalassemia. Hemoglobin electrophoresis confirms the diagnosis of β-thalassemia. In preparing for discharge teaching with the parents and patient, which statements below would be discussed? **Use an X for the health teaching statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
"We need to check your iron level to make sure you are not anemic."			
"I believe your disease is most common in those of Hispanic descent, although you are Mediterranean."			
"I would like to talk to you about the diagnosis and provide you with some information about β-thalassemia."			
"You look much younger than I would expect. I guess you are a late bloomer."			
"I think a transfusion will be ordered because your hemoglobin level is 9.5."			

3. A 9-year-old girl has been diagnosed with severe aplastic anemia. She presented with a two-week history of nosebleeds and developed a fever to 102 F the past few days. She complains of fatigue and notices bruising of her arms and legs. Her peripheral blood counts show marked reduction in the red blood cells, white blood cells and platelets. A bone marrow aspiration and biopsy were performed and demonstrated conversion of the red bone marrow to yellow, fatty bone marrow with a bone marrow cellularity of 20%. Based on her diagnosis, what are the **most appropriate** nursing actions at this time? **Select all the apply.**
   - **A.** Advise the family what to do if fever develops.
   - **B.** Recommend eating fruits and vegetables each day.
   - **C.** Review the importance of the spleen and how it works.
   - **D.** Discuss the diagnosis with the child in an age appropriate manner.
   - **E.** Review how to use an epinephrine pen at home if anaphylaxis should occur.
   - **F.** Provide opportunities for the child and family to ask questions and express feelings.
   - **G.** Discuss how blood cells work and what side-effects to look for due to low blood cell counts.

4. The nurse is discharging a 5-year-old patient newly diagnosed with hemophilia. He was hospitalized because of a severe joint bleed following a fall. Which of the following responses are appropriate for the nurse to discuss with the parents? **Use an X for the health teaching statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Health Teaching	Indicated	Contraindicated	Non-Essential
"Your child should remain active to decrease joint problems, and most children with hemophilia can participate in the same activities as their peers."			
"Care should be taken to avoid bleeding of gums; soften the toothbrush in warm water before brushing or using a sponge-tipped disposable toothbrush may be helpful."			
"Signs of internal bleeding should be recognized, such as headache, slurred speech, loss of consciousness (from cerebral bleeding), and black, tarry stools (from gastrointestinal bleeding)."			
"If there is bleeding in a joint, elevation, ice, and rest should prevent the need for factor VIII replacement."			
"All of your son's teachers need to be aware of what to do if he gets a bloody nose."			
"Your child should drink a lot of fluids to decrease the possibility of dehydration."

CANCER IN CHILDREN

Few situations in nursing exceed the challenges of caring for a child with cancer. Despite dramatic improvements in prognosis, cancer remains a life-threatening, life-altering illness that has a major impact on family life and places significant demands on family strengths in coping with informational and support needs. Nurses should base support of patients and their families on the premise that with clear communication and compassionate care, fear diminishes, hope emerges, and the cancer journey feels less overwhelming. Effective communication, including nurse listening behaviors, also promotes understanding that aids treatment adherence.

This chapter summarizes clinical overviews and nursing care issues for the most common types of pediatric cancer. Chapter 17 discusses situations when the disease is imminently life threatening, as well as the general psychologic needs of these children and their families in terms of chronic illness.

EPIDEMIOLOGY: INCIDENCE RATES

Childhood cancer is rare; approximately 16,400 cases are diagnosed in children younger than 20 years of age in the United States each year (Scheurer, Lupo, & Bondy, 2016). Approximately 1700 children die of the disease in the United States annually, making cancer the leading cause of death from disease after infancy in this age-group (Scheurer et al., 2016). Worldwide, it is estimated that 300,000 new cases are diagnosed annually and that there are an estimated 80,000 deaths per year; in addition, survival rates in low-income countries are lower than in high-income countries (American Childhood Cancer Organization, 2016).

The incidence of specific types of childhood cancer varies according to demographic risk factors such as age, sex, and race or ethnicity. Cancer incidence is higher in children from infancy to 4 years of age and in adolescents ages 15 to 19 years; however, the types of cancers occurring among these two groups are distinct, with neuroblastoma and retinoblastoma more common in young children and lymphoma and sarcoma more common in adolescents (Scheurer et al., 2016). Males have a higher overall incidence of cancer compared to females, with a ratio of 1.1:1 (Scheurer et al., 2016). This difference reflects the higher incidence of acute lymphoblastic leukemia (ALL), non-Hodgkin lymphoma (NHL), and central nervous system (CNS) tumors—the most common types of childhood cancer—in young boys. White children have an overall higher incidence of cancer compared with African American children. This is accounted for by the higher incidence of ALL, Ewing sarcoma, and melanoma in white children.

Childhood cancer survival has dramatically increased over the past 5 decades with improved treatment and supportive care. In the 1960s, the overall (all cancer types combined) survival rate for childhood cancer was 28% compared with 3-year survival rates that now exceed 80% (Scheurer et al., 2016). Improvement in survival among adolescents has lagged behind younger age-groups, although that is changing. Survival rates remain low for some types of cancer, such as a brain tumor called diffuse intrinsic pontine glioma (DIPG), and for some age-groups, such as older children with a kidney tumor called Wilms tumor. ALL and NHL have demonstrated the greatest improvement in survival rates. Recent estimates indicate that there are now more than 400,000 survivors of childhood and adolescent cancer in the United States. A general definition of "cure" includes completion of all therapy, no clinical and radiologic evidence of disease, and a period of 5 years since diagnosis.

ETIOLOGY

Often the first questions asked by parents of children newly diagnosed with cancer are "How did my child get this, and could it have been prevented?" Lifestyle-related behaviors are the main factors that increase the risk of cancer in adults, but as far as is now known, they have little to no effect on cancer incidence in children. Apart from exposure to high-dose radiation and prior chemotherapy, there is relatively little evidence to support a major external or environmental role in the development of childhood cancer (Spector, Pankratz, & Marcote, 2015). Thus, given current understanding, it is unlikely that parents could have done anything to prevent their child's cancer.

On the other hand, characteristics such as birth weight, advanced parental age, and congenital anomalies have been found to be risk factors for childhood cancer (Spector et al., 2015). In addition, a small percentage of cancer occurs in children with cancer predisposition syndromes. The intrinsic risk factors, the association of germline

TABLE 25.1 Risk Factors Associated With Childhood Cancers

Cancer Type	Risk Factors	Selected Examples of Genomic Lesions
Acute lymphoblastic leukemia	• Ionizing radiation (primarily of historical importance) • Race (i.e., White) • Genetic conditions (i.e., Down syndrome, Bloom syndrome, and others) • Birth weight more than 400 g	• *ABL* family genes activated by translocation in a subset of cases
Acute myeloid leukemia (NIH, 2019d)	• Chemotherapeutic agents (i.e., alkylating agents and epipodophyllotoxins) • Genetic conditions (i.e., Down syndrome and neurofibromatosis 1)	
Brain tumors	• Therapeutic radiation to the head • Genetic conditions (i.e., neurofibromatosis 1, tuberous sclerosis, and others)	• BRAF and other kinase genomic mutations associated with subsets of pediatric glioma cases • Hedgehog pathway mutations associated with a subset of medulloblastoma cases
Hodgkin disease	• Family history (i.e., monozygotic twins) • Infections (i.e., Epstein-Barr virus)	
Non-Hodgkin lymphoma	• Immunodeficiency (i.e., acquired and congenital immunodeficiency, immunosuppressive therapy) • Infections (i.e., Epstein-Barr virus associated with Burkitt lymphoma in African countries)	
Osteosarcoma	• Ionizing radiation (i.e., cancer radiation therapy and high radium exposure) • Chemotherapy (i.e., alkylating agents) • Genetic conditions (i.e., Li-Fraumeni syndrome, hereditary retinoblastoma)	
Ewing sarcoma	• Race (White)	
Neuroblastoma	• None known	• *ALK* point mutations in a subset of neuroblastoma cases
Retinoblastoma	• No known nonhereditary risk factors	
Wilms tumor	• Congenital anomalies (i.e., aniridia, Beckwith-Wiedemann syndrome, other congenital and genetic conditions) • Race (White and Black)	
Rhabdomyosarcoma	• Congenital anomalies and genetic conditions (i.e., Li-Fraumeni syndrome and neurofibromatosis 1)	
Hepatoblastoma	• Genetic conditions (i.e., Beckwith-Wiedemann syndrome, hemihypertrophy, Gardner syndrome, family history of adenomatous polyposis)	
Malignant germ cell tumors	• Cryptorchidism associated with testicular germ cell tumors	

From Scheurer, M. E., Lupo, P. J., & Bondy, M. L. (2016). Epidemiology of childhood cancer. In P. A. Pizzo & D. G. Poplack (Eds.), *Principles and practice of pediatric oncology* (7th ed.). Philadelphia, PA: Lippincott. Also from https://www.cancer.gov/types/childhood-cancers/pediatric-genomics-hp-pdq

mutations (passed from parents to children) with certain malignancies such as retinoblastoma, and the existence of familial cancer predisposition syndromes point to the importance of genetic mechanisms in childhood cancer etiology.

Genomic technology, including the ability to analyze vast amounts of data and data sharing across institutions and organizations, is rapidly advancing understanding of the biology of childhood cancer. A working definition of genomics is the study of a person's complete set of genes, their functions, and their interrelationships (World Health Organization, 2019). Genome-wide association studies (GWASs) compare the genomes of people who have a disease such as cancer with people who do not have it. Scientists look for genetic variations and/or mutations that may be involved in the development of the disease. These changes could be small, such as substitution, deletion, or addition of a single base pair, or large, such as deletion of thousands of bases. The value of this research is the ability to identify subsets of patients whose prognosis is associated with a particular genetic change; these subsets could be studied separately in the future to find the most effective and least toxic treatment specifically for them. Genomic research also offers the opportunity for developing new treatment approaches that are precisely tailored to the particular cancer's molecular abnormality. This is the promise of precision medicine. Risk factors associated with childhood cancer, including genetic mutations, are summarized in Table 25.1.

Prevention

Knowledge of the risk factors that increase the likelihood of cancer holds the promise of prevention. However, there are no generally recognized preventive measures for childhood cancer.

Nevertheless, pediatric health professionals have another role in cancer prevention, namely educating parents and children about the hazards of known carcinogens associated with adult-type cancers. This is particularly true for the effects of cigarette smoking (and exposure to secondhand smoke) and excessive exposure to ultraviolet radiation (e.g., exposure to sunlight and tanning) because lung cancer is the leading cause of death from cancer in adults, and malignant melanoma is the leading cause of death from diseases of the skin. Children at higher risk for skin cancer are those with sun or tanning bed exposure; light-colored eyes, complexion, and hair; a history of sunburn; skin that burns, freckles, and reddens easily; and certain types of moles (Centers for Disease Control and Prevention, 2019). Not only these children but all children should be protected from overexposure to the sun and to tanning beds.

To provide early detection of other types of cancer, clinicians have historically recommended that males learn testicular self-examination and that females learn breast self-examination. However, teaching breast self-examination and testicular self-examination is no longer supported by the US Preventive Services Task Force (2016, 2018). Some clinicians endorse being breast "self-aware," meaning that females should know what is normal for their own breasts. All children and teens should have periodic health examinations by a health care professional, including a Papanicolaou smear for females and testicular examination for males when developmentally appropriate. In addition, to prevent human papillomavirus (HPV)–associated malignancies, HPV vaccine is recommended for routine vaccination at age 11 or 12 years (Centers for Disease Control and Prevention, 2018).

DIAGNOSTIC EVALUATION

The evaluation of a child suspected of having cancer may take several days to complete. The essential components of a comprehensive evaluation include complete history and review of symptoms, physical examination, laboratory tests, diagnostic imaging, diagnostic procedures (e.g., lumbar puncture [LP], bone marrow aspirate, biopsy), and surgical pathology depending on whether biopsy or surgical resection is performed.

Laboratory Tests

Several laboratory tests must be performed to accurately diagnose and treat children with cancer. Most patients have a complete blood count (CBC), serum chemistries, liver function tests, coagulation studies, and urinalysis done on initial presentation. For example, the CBC for patients with leukemia often reveals low hemoglobin; low platelet count; and low, normal, or high white blood cell (WBC) counts. In addition, these patients may have elevated lactate dehydrogenase, creatinine, and uric acid, which require close monitoring when therapy is initiated. Frequent CBCs are necessary to monitor effects of therapy and, in some hematologic malignancies, response to therapy.

Blood chemistry yields important information with regard to kidney, liver, and bone function and electrolyte balance. These tests are important to help detect the extent of disease and also to monitor for side effects during therapy. For example, a patient with bone metastasis may have elevated alkaline phosphatase. Elevations in blood urea nitrogen and creatinine may reflect kidney damage from chemotherapy agents. Consequently, regular blood chemistries and urinalysis are standard procedures throughout the course of the disease and its treatment.

Diagnostic Procedures

An LP is a routine test used in leukemia, brain tumors, and other cancers that may metastasize to the CNS. An LP also is used to administer intrathecal drugs in patients with various malignancies, such as leukemia.

A bone marrow test is performed by aspirating marrow with a large- or fine-bore needle. A bone marrow biopsy is performed by obtaining a piece of bone through a special type of needle. These tests are performed to determine the presence or absence of cancer cells or response to therapy in the bone marrow. For example, the type of leukemia can be identified by examination of the patient's bone marrow and core biopsy. Also, patients with other solid tumors, such as neuroblastoma, may have spread of disease to the bone marrow, which can be determined by these procedures.

Diagnostic Imaging

Modern diagnostic imaging has greatly improved the ability to accurately diagnose childhood cancers. The most commonly used modes of imaging include x-rays, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET); in addition, metaiodobenzylguanidine (MIBG) scan is used in certain pediatric malignancies such as neuroblastoma and soft tissue tumors. Interventional radiology uses imaging to guide diagnostic and treatment procedures in the diagnosis and management of pediatric malignancies. The nurse should be aware of the Image Gently campaign to improve safe and effective imaging care of children. Parents who have heard of this effort may have questions about radiation exposure in the imaging of their children (Image Gently, 2014).

Pathologic and Molecular Evaluation

For most solid tumors, a biopsy is necessary to establish the diagnosis. Besides determining what type of cancer the patient has, this tissue sample can also be sent for various biologic or molecular studies that help define the patient's risk of relapse or recurrence and allow the health care team to plan risk-adapted therapy. For example, a bone marrow biopsy determines whether the patient has acute lymphoblastic leukemia or acute myeloid leukemia and indicates the specific leukemia subtype that is the basis for how aggressively it should be treated (NIH, 2019d). Similarly, patients with neuroblastoma undergo a biopsy of the tumor to establish the diagnosis and to evaluate the tumor for amplification of an oncogene, *MYCN,* which is a prognostic factor considered in treatment planning. Increasingly, the diagnostic evaluation includes molecular genetic testing (e.g., deoxyribonucleic acid [DNA] sequencing, reverse transcription polymerase chain reaction [RT-PCR], fluorescence in situ hybridization [FISH]) to find biologic abnormalities of the cancer cells. As more is learned about these cell changes in cancer, it is becoming possible to design therapies that target these abnormalities or block their effects; this is called **targeted therapy**, which is the basis of precision medicine.

TREATMENT MODALITIES

Survival of children with cancer has greatly improved through the use of (1) multimodal therapy consisting of surgery, chemotherapy or biotherapy, blood or marrow transplant (now referred to as hematopoietic stem cell transplant [HSCT]), and radiation therapy; (2) enrollment of large numbers of children in cooperative group clinical trials or protocols; and (3) improvements in supportive care. Current efforts are aimed at increasing the survival of patients with high-risk malignancies, decreasing the acute and long-term side effects of treatment, and studying the biology and genomics of the diseases to better identify

TABLE 25.2 Early Side Effects of Radiation Therapy

Site	Effects	Nursing Interventions
Gastrointestinal tract	Nausea and vomiting	Give antiemetic on schedule around the clock. Measure amount of emesis to assess for dehydration.
	Anorexia	Encourage fluids and foods best tolerated, usually light, soft, small, and frequent meals. Monitor weight.
	Mucosal ulceration	Use frequent mouth rinses and oral hygiene to prevent mucositis.
	Diarrhea	Control with antispasmodics and kaolin pectin preparations. Observe for signs of dehydration.
Skin	Alopecia (occurs within 2 weeks; hair may regrow by 3-6 months)	Introduce idea of wig. Stress necessity of scalp hygiene and need for head covering in sun and cold weather.
	Dry or moist desquamation	Do not refer to skin change as a "burn" (implies use of too much radiation). Avoid lotions and other creams to skin. Wash daily, using mild soap (e.g., Dove) sparingly. Do not remove skin marking for radiation fields. Avoid exposure to sun. For desquamation, consult radiation therapy practitioner for skin hygiene and care.
Head	Nausea and vomiting (from stimulation of vomiting center in brain)	Same as for gastrointestinal tract.
	Alopecia	Same as for skin.
	Mucositis	Encourage regular dental care, fluoride treatments.
	Potential effects: • Parotitis • Sore throat • Loss of taste • Xerostomia (dry mouth)	Provide analgesics as needed to relieve discomfort Combat severe dryness of mouth with oral hygiene and liquid diet.
Urinary bladder	Radiation cystitis (rarely)	Encourage liberal fluid intake and frequent voiding. Monitor for hematuria.
Bone marrow	Myelosuppression	Observe for fever (temperature >101°F [38.3°C]). Initiate workup for sepsis as ordered. Administer antibiotics as prescribed. Avoid use of suppositories, rectal temperatures. Institute bleeding precautions. Observe for signs of anemia.

patients who are at different risk levels for disease recurrence and can therefore benefit from risk-adapted and targeted therapies.

Surgery

The main goal of surgery, besides obtaining biopsies, is to remove the tumor and restore normal body functioning to the greatest extent possible. Surgery is most successful when the tumor is encapsulated and localized (confined to the site of origin). Surgery may be used for palliation when the cancer is regional (metastasized to an area adjacent to the original site) or advanced (widespread throughout the body). Generally, the best prognosis is directly related to early detection of the tumor because that facilitates surgical removal.

Because the majority of pediatric cancers respond well to chemotherapy, more conservative surgical excision is increasingly used in a variety of tumors in an attempt to preserve function and cosmesis. For example, in some types of bone cancer, such as osteosarcoma, patients are successfully treated with resection of the diseased portion of the bone rather than amputation.

Radiation Therapy

Radiation therapy is frequently used in the treatment of childhood cancer, usually in conjunction with chemotherapy or surgery. It can be used for curative purposes and for palliation to relieve symptoms by shrinking the size of the tumor. Recent advances in radiation therapy that allow the beam to be aimed precisely have optimized its beneficial effects and minimized many of the undesirable side effects by sparing normal tissue.

Ionizing radiation is cytotoxic in at least three different ways: (1) damaging the pyrimidine bases cytosine, thymine, and uracil needed for the synthesis of nucleic acids; (2) causing single-strand breaks in the DNA or ribonucleic acid (RNA) molecule; or (3) causing double helical-strand breaks in these molecules. Disturbing cellular metabolic and reproductive functions causes lethal or sublethal damage. *Lethal damage* refers to the death of the cell. *Sublethal damage* refers to injured cells that may subsequently be repaired. Many acute side effects are the result of lethal damage to radiosensitive tissue, particularly proliferating cells such as those of the bone marrow, gastrointestinal tract, and hair follicles. Late effects (late-occurring or long-term effects) are usually the result of cell death.

The acute untoward reactions from radiation therapy depend on the area being irradiated. Total body irradiation is associated with the most severe reactions and is used to prepare the immune system for HSCT. Table 25.2 summarizes the acute effects of radiation therapy and nursing interventions that may be helpful in mitigating or preventing them.

In some areas of the United States, proton beam radiation is available. Protons are positively charged subatomic particles. Protons deposit energy differently than x-ray beams. There is no "exit dose" beyond the tumor involved in proton radiation therapy; therefore local control of the tumor is a major benefit with no long-term effects to organs surrounding the target area (Hill-Kayser, Tochner, Both, et al., 2013). For example, some brain tumor patients receive radiation to the spine. With traditional forms of radiation therapy, lasting damage to nearby vital organs such as the heart and lungs is possible; however, with proton therapy the heart and lungs would not be affected, avoiding long-term cardiac and pulmonary damage.

Chemotherapy

Chemotherapy may be the primary form of treatment, or it may be an adjunct to surgery, radiation therapy, or HSCT. The majority of traditional chemotherapy agents work by interfering with the function or production of nucleic acids, DNA, or RNA. Although several drugs have been effective in treating different forms of cancer as single agents, the remarkable increase in survival rates has been the result of improved combination drug regimens. Combining drugs allows for optimum cell cycle destruction with minimum toxic effects and decreased resistance by the cancer cells to the agent. For example, a treatment regimen called VAC (vincristine [Oncovin], doxorubicin [Adriamycin], and cyclophosphamide [Cytoxan]) combines complementary cytotoxic effects with distinct side effects. Doxorubicin and cyclophosphamide are myelosuppressive, whereas vincristine is neurotoxic.

In addition to more effective combinations of drugs, several advances in the administration of chemotherapy have permitted continuous or intermittent intravenous (IV) administration without multiple venipunctures. The use of venous access devices (e.g., catheters, implantable infusion ports) has greatly facilitated safe and effective drug administration with minimum discomfort for the child (see Chapter 20). Continuous infusions over an extended period using syringe pumps have made possible the administration of certain drugs, such as cytosine arabinoside, in higher doses with less toxicity than when the drug is administered intermittently.

An understanding of the actions and side effects of these drugs is essential to nursing care of children with cancer. Unfortunately, almost all standard chemotherapy drugs are not selectively cytotoxic for malignant cells, and other cells with a high rate of proliferation, such as the bone marrow elements, hair, skin, and epithelial cells of the gastrointestinal tract, are also affected. Frequently the problems related to the destruction of these normal cells require more nursing care than those related to the disease itself.

Precautions in Administering and Handling Chemotherapeutic Agents

Many chemotherapeutic agents are **vesicants** (sclerosing agents) that can cause severe cellular damage if even minute amounts of the drug infiltrate surrounding tissue. Only nurses experienced with chemotherapeutic agents should administer vesicants (Fig. 25.1). Standards are available[a] and must be followed meticulously to prevent tissue damage to patients. Interventions for extravasation vary, but each nurse should be aware of the institution's policies before giving any vesicant and implement them at once if indicated.

Fig. 25.1 Nurses caring for children with cancer require expertise in the safe administration of chemotherapy.

! NURSING ALERT

Chemotherapeutic drugs must be given through a free-flowing intravenous (IV) line. The infusion is stopped immediately if any sign of infiltration (e.g., pain, stinging, swelling, redness at needle site) occurs.

! NURSING ALERT

When chemotherapy or immunotherapy agents with known anaphylactic potential are given, it is standard practice to observe the child for 1 hour after the infusion for signs of anaphylaxis (e.g., rash, urticaria, hypotension, wheezing, nausea, vomiting). Emergency equipment (especially blood pressure monitor, bag valve mask, and suction) and emergency drugs (especially oxygen, epinephrine, antihistamine, aminophylline, corticosteroids, and vasopressors) must be readily available.

In addition to the many patient-focused responsibilities during chemotherapy administration, nurses must also use safeguards to protect themselves. Handling chemotherapeutic agents may present risks to handlers and to their offspring, although the exact degree of risk is not known. The Oncology Nursing Society has published comprehensive guidelines for safe practice issues related to administration of chemotherapy.[b] The Oncology Nursing Society also has established safe management procedures for chemotherapy administered in the home.[b] Basic nursing guidelines are in the Nursing Care Guidelines box.

[b] *Chemotherapy and Biotherapy Guidelines and Recommendations for Practice* (4th edition) can be obtained from the Oncology Nursing Society, 125 Enterprise Drive, Pittsburgh, PA 15275; 866-257-4667, 412-859-6100; http://www.ons.org.

NURSING CARE GUIDELINES

Handling Chemotherapeutic Agents

- Use great care and strict aseptic technique in handling chemotherapeutic agents to prevent any physical contact with the substance.
- Drugs are prepared in a properly ventilated room (which incorporates a protective front panel and vertical laminar airflow to reduce potential for inhalation during preparation).
- Wear disposable gloves and protective clothing and discard in a special container after each use.
- Wear face and eye protection when splashing is possible and wear a respirator when the risk of inhalation is possible.
- Use a sterile gauze pad when priming intravenous (IV) tubing, connecting and disconnecting tubing, inserting syringes into vials, breaking glass ampules, or performing any other procedure in which antineoplastic drugs may be inadvertently discharged.
- Dispose of all contaminated needles, syringes, IV tubing, and other contaminated equipment in a leakproof and puncture-resistant container; do not recap or break needles.

Biologic Therapy

Biologic therapy, also called biotherapy, uses substances made from living organisms, derived from living organisms, or laboratory-produced versions of these substances to treat cancer (Ceppi, Beck-Popovic, Bourquin, et al., 2017). Biotherapies can be grouped into three main types: (1) those that do not target cancer cells directly but stimulate the body's immune system to act against cancer cells and that are collectively referred to as immunotherapy or biologic response modifier therapy; (2) those that use antibodies or segments of genetic material to target cancer cells directly; and (3) therapies that interfere with specific molecules involved in tumor growth and progression and that are referred to as targeted therapies (Ceppi et al., 2017).

Immunotherapy works by stimulating the activity of the immune system against cancer cells or by counteracting signals produced by cancer cells that suppress immune responses (US Food and Drug Administration, 2016). Immunotherapy includes the use of monoclonal antibodies that attach to proteins on cancer cells so that the immune system can find and destroy the cells. Other antibodies block pathways that allow cancer cells to escape the immune system; these are called checkpoint inhibitors. Nonspecific immunotherapies include two types of cytokines: interferons and interleukins. Other immunotherapies include oncolytic virus therapy and chimeric antigen receptor (CAR) T-cell therapy. CAR T-cell therapy is being studied in childhood acute leukemia that does not respond to traditional chemotherapy. Surveillance for and management of side effects of immunotherapy are critical nursing responsibilities. Side effects may range from mild to severe. For example, with CAR T-cell therapy, adverse events may include cytokine release syndrome, neurologic symptoms, tumor lysis syndrome, and graft-versus-host disease (Becze, 2017).

Targeted therapies are substances that interfere with specific molecules involved in cancer. They are different from standard chemotherapy in two ways (National Institutes of Health, 2019a): (1) they act on molecular targets rather than affecting all rapidly dividing normal and malignant cells; and (2) they are selected or designed to affect their target, compared with chemotherapy drugs that were identified because they kill cells. Previously, targeted therapies have had limited use in pediatric patients, but they are now being evaluated in clinical trials. Careful monitoring of side effects is essential because the profile of adverse events may be different than that seen in adults and because these agents may affect the process of growth and development in pediatric patients in unexpected ways (Gore, DeGregori, & Porter, 2013).

Hematopoietic Stem Cell Transplant

Another approach to the treatment of childhood cancer is transplantation of hematopoietic (blood-forming) stem cells. HSCT restores stem cells in children who have diseases that require high doses of chemotherapy or radiation therapy and/or replacement of dysfunctional bone marrow. Blood-forming stem cells from bone marrow, peripheral blood, or cord blood can be sources for HSCT. The main types of HSCT are **allogeneic**, where cells are obtained from a family member or volunteer donor, and **autologous**, where cells previously stored from the patient are given back to the patient by IV infusion. In either type of HSCT, if it is successful, the newly transfused cells begin to produce functioning nonmalignant blood cells. In essence, the recipient accepts a new blood-forming organ.

Children receiving an allogeneic HSCT undergo a pretransplant conditioning regimen consisting of radiation therapy and/or high-dose chemotherapy to rid the body of malignant cells and suppress the immune system to prevent rejection of the transplanted marrow (see Family-Centered Care box).

FAMILY-CENTERED CARE

Decision for Transplant

A family's decision for a child to undergo a hematopoietic stem cell transplant (HSCT) is fraught with uncertainties. Often the child faces certain death from the malignancy without the HSCT. The preparation of the child for the transplant also places the patient at great medical risk.

Once the preparatory regimen begins and the child's immune system is destroyed, there is no turning back. Unlike kidney transplantation, HSCT does not have a "rescue" procedure, such as dialysis, for supportive therapy. If the donor is a sibling, the expectation that his or her marrow will "save" the brother or sister can be a concern, especially if the transplant is not successful. Parents often must leave home to stay at the transplant center and encounter additional stressors such as arranging child care, taking leave from work, and managing finances. If old enough to understand the risks, the patient faces the greatest stress, such as fear of HSCT failure or life-threatening complications.

The selection process for a suitable donor and the potential complications in allogeneic transplantation are related to the human leukocyte antigen (HLA) system complex. Some of the major HLA antigens are A, B, C, D, DR, and DQ. There is wide diversity for each of these HLA loci. For example, more than 20 different HLA-A antigens and more than 40 different HLA-B antigens can be inherited. The genes are inherited as a single unit, or haplotype. A child inherits one unit from each parent; thus a child and each parent have one identical and one nonidentical haplotype. Because the possible haplotype combinations among siblings follow the laws of Mendelian genetics, there is a 1 in 4 chance that two siblings have identical haplotypes and are perfectly matched at the HLA loci.

The importance of HLA matching is to prevent the serious complication of graft-versus-host disease (GVHD) after allogeneic transplant. Because the child's immune system is essentially rendered nonfunctional, the recipient is unlikely to reject the bone marrow. However, the donor's marrow may contain antigens not matched to the recipient's antigens, which begin attacking body cells. The more closely the HLA systems match, the less likely GVHD is to develop. However, GVHD can occur even with a perfect HLA match because of unidentified and

thus unmatched histocompatibility antigens (Gottschalk, Naik, Hegde, et al., 2016).

Umbilical cord blood or haploidentical family donors (i.e., parents) are additional sources of hematopoietic stem cells for use in children with cancer (Gottschalk, Naik, Hegde, et al., 2016). The benefit of using umbilical cord blood is the blood's relative immunodeficiency at birth, allowing for partially matched, unrelated cord blood transplants to be successful, with a lower risk of GVHD-related problems (Sarvaria, Jawdat, Madrigal, et al., 2017). A benefit of using a haploidentical family member is the likely immediate availability of the donor, which is especially important when children urgently need HSCT.

Autologous Transplantation

Autologous transplants use the patient's own marrow that was collected from disease-free tissue, frozen, and may have been treated to remove malignant cells. Peripheral blood stem cell transplant (PBSCT) is also used in children with cancer. This type of transplant differs in the way stem cells are collected. Most commonly, colony-stimulating factor (CSF) is first given to stimulate the production of many stem cells (Karakukcu & Unal, 2015). Once the WBC count is high enough, the stem cells are collected by an apheresis machine. This machine filters out peripheral stem cells from whole blood and returns the remainder of the blood cells and plasma to the child. Stem cells have been collected without problems in even very small children weighing 20 kg (44 pounds) or less (Gottschalk et al., 2016). The peripheral stem cells are then frozen until the patient is ready for the PBSCT. Children with solid tumors such as neuroblastoma, Hodgkin lymphoma, NHL, rhabdomyosarcoma, Ewing sarcoma, and Wilms tumor have been treated with autologous transplants.

COMPLICATIONS OF THERAPY

Although great advances have been achieved through current modes of cancer therapy, the successes are not without consequences. Numerous acute side effects are commonly expected with chemotherapy or biotherapy and radiation therapy. Several complications that are less frequent but generally more serious are described here.

Pediatric Oncologic Emergencies

Tumor Lysis Syndrome

Life-threatening conditions may develop in children with cancer as a result of the malignancy and/or aggressive treatment modalities. Acute tumor lysis syndrome has hallmark metabolic abnormalities that are the direct result of rapid release of intracellular contents during the lysis of malignant cells. This typically occurs in patients with acute lymphoblastic leukemia or Burkitt lymphoma during the initial treatment period but may occur spontaneously before onset of therapy. The metabolic abnormalities of tumor lysis syndrome include hyperuricemia, hypocalcemia, hyperphosphatemia, and hyperkalemia. The crystallization of uric acid that can occur with hyperuricemia can lead to acute renal failure (Freedman, Rheingold, & Fisher, 2016).

Risk factors for development of tumor lysis syndrome include high WBC count at diagnosis, large tumor burden, cancer cell sensitivity to chemotherapy, and high proliferative rate. In addition to the described metabolic abnormalities, children may develop a spectrum of clinical symptoms, including flank pain, lethargy, nausea and vomiting, muscle cramps, pruritus, tetany, and seizures.

Management of tumor lysis syndrome consists of early identification of patients at risk, prophylactic measures, and early interventions. Patients at risk for tumor lysis syndrome should have serum chemistries and urine pH monitored frequently, strict recording of intake and output, and aggressive administration of IV fluids. Medications, such as allopurinol, that reduce uric acid formation and promote excretion of byproducts of purine metabolism are often used. If tumor lysis syndrome occurs, IV hydration continues and the specific metabolic abnormalities are treated. Hyperuricemia is now effectively treated with recombinant urate oxidase, or rasburicase. This medication converts uric acid to allantoin, which is more soluble in urine. Exchange transfusions are sometimes necessary to reduce the metabolic consequences of massive tumor lysis, especially in children with a high tumor burden.

Hyperleukocytosis

Hyperleukocytosis, defined as a peripheral WBC count greater than 100,000/mm^3, can lead to capillary obstruction, microinfarction, and organ dysfunction. Children often experience respiratory distress and cyanosis. They also experience neurologic changes, including altered level of consciousness, visual disturbances, agitation, confusion, ataxia, and delirium. Management consists of rapid cytoreduction by chemotherapy, hydration, urinary alkalinization, and allopurinol. Leukapheresis or exchange transfusion may be necessary.

Superior Vena Cava Syndrome

Space-occupying lesions located in the chest, especially from Hodgkin disease and NHL, may cause superior vena cava syndrome (SVCS), leading to airway compromise and potentially to respiratory failure. The second leading cause of SVCS is thrombotic complications of implantable IV devices, such as central venous catheters and port catheters (Freedman et al., 2016).

Children are initially seen with cyanosis of the face, neck, and upper chest; facial and upper extremity edema; and distended neck and chest veins. They may be anxious and have dyspnea, wheezing, or a frequent cough from airway obstruction. Management consists of airway protection and alleviation of respiratory distress. Rapid treatment is initiated, and symptoms typically improve as the disease is effectively treated.

Spinal Cord Compression

Malignancies can invade or impinge on the spinal cord, causing acute symptoms of cord compression. Primary CNS tumors can originate or spread to the spinal cord. Other solid tumors, such as neuroblastoma or rhabdomyosarcoma, can metastasize to the spinal cord and cause compression. Back pain is a common initial manifestation, but other symptoms can include sensation change, extremity weakness, loss of bowel and bladder function, and respiratory insufficiency. Careful physical examination is essential in early detection of symptoms, and MRI is the gold standard for diagnosis (Freedman et al., 2016). Treatment may include high-dose steroids to reduce associated edema and alleviate symptoms and rapid initiation of treatment such as emergent radiation or laminectomy if indicated.

Disseminated Intravascular Coagulation

Overwhelming infections in the immunocompromised child constitute an emergency situation. Sepsis from bacteria or fungus can result in numerous complications, including disseminated intravascular coagulation (DIC). Children with DIC form excessive microthrombi throughout the vascular system due to hyperactivation of the clotting cascade, downregulation of anticoagulants, and impaired fibrinolysis, which leaves the child susceptible to hemorrhage. Life-threatening hemorrhage can occur from DIC with thrombocytopenia (platelet count of less than 20,000/mm^3) (Andrews, Galel, Wong, et al., 2016).

Treatment is focused on identifying and treating the underlying cause, along with infusing heparin to minimize microthrombi and cryoprecipitate to replace fibrinogen.

GENERAL NURSING CARE MANAGEMENT

This section presents an overview of general nursing concepts that apply to most childhood cancers. Specific nursing care for children with a particular type of cancer is discussed under each disease section later in the chapter. This discussion focuses on the physical aspects of care. In addition, refer to Chapter 19 for family-centered care and Chapter 17 for end-of-life care (see Quality Patient Outcomes box).

QUALITY PATIENT OUTCOMES: The Child With Cancer

- Child and family educated about disease and treatment
- Child and family safely perform self-care as appropriate
- Treatment administered on schedule with appropriate drug doses
- Side effects of treatment managed
- Treatment complications prevented
- Child and family strengths and coping skills supported
- Quality of life during treatment maintained
- Child and family adjusted to chronic illness
- Growth and development maintained during treatment

SIGNS AND SYMPTOMS OF CANCER IN CHILDREN

Early detection is critical to starting treatment with the best prospect for eventual cure. Cancers in children are often difficult to recognize. Therefore being alert to the persistence of possible signs and symptoms is essential (Box 25.1). This section discusses some of the more significant clues leading to a diagnosis of pediatric cancer.

Pain may be an early or late initial sign of cancer and requires a careful history of its onset, characteristics, location, intensity, and alleviating factors. Pain may be generalized or present at a specific location. For example, bone pain occurs in approximately 20% of children with leukemia. Pain, swelling, and tenderness at the tumor site may be initial signs in solid tumors. In addition, a mass is a typical finding in children with solid tumors. An abdominal mass in a child must be evaluated for a malignancy, such as Wilms tumor or neuroblastoma.

Fever is a frequent occurrence during childhood and is caused by numerous illnesses, including cancer. The cause of fever in cancer patients is infection or the malignant process itself. The latter is often referred to as tumor-associated fever. The exact mechanism by which the malignancy causes a fever is not completely understood. Cytokines (e.g., interleukin, tumor necrosis factor) are known to be involved and are thought to be released either directly from tumor cells or from macrophages responding to tumor (Foggo & Cavenagh, 2015).

A careful skin assessment will reveal signs of a low platelet count. Ecchymosis and petechiae are most commonly found on the child's extremities and under constricting parts of clothing like waistbands. Spontaneous gum or nose bleeding may occur when the platelet count falls below 20,000/mm^3.

The child with malignant invasion of the bone marrow often appears pale, with symptoms of lethargy, weight loss, and malaise. These symptoms may be attributed to anemia caused by the replacement of normal cells with malignant cells in the bone marrow. The nurse should assess for signs and symptoms of anemia (see Chapter 24).

Swollen lymph nodes are another common finding in children. However, enlarged, firm lymph nodes in a child with fever for more than 1 week; a recent history of weight loss; or an abnormal chest x-ray film may indicate a serious disease and should be evaluated further.

Recognizing one sign is facilitated by the widespread use of cell phone photography. Leukocoria or white eye reflex can be seen as a yellow "glow" in the pupil, as opposed to the normal red pupillary reflex, in photographs. It can be a sign of retinoblastoma that needs prompt medical attention. Squinting, strabismus, or swelling can indicate other solid tumors of the eye.

The child with a brain tumor develops signs and symptoms related to the area of the brain involved. The nurse's thorough physical assessment can indicate the likely area of tumor involvement.

BOX 25.1 Possible Signs and Symptoms of Childhood Cancer

- Unusual mass or swelling
- Unexplained paleness and loss of energy
- Easy bruising
- Persistent, localized pain or limping
- Prolonged, unexplained fever or illness
- Frequent headaches, often with vomiting
- Sudden eye or vision changes
- Unexplained, rapid weight loss

Data from American Cancer Society. (2016). Finding cancer in children. Retrieved from https://www.cancer.org/cancer/cancer-in-children/finding-childhood-cancers-early.html

MANAGING COMMON ACUTE SIDE EFFECTS OF TREATMENT

Cancer care encompasses more than treatments aimed at eliminating the malignant cells. Because of the delicate balance between killing malignant cells and preserving functional cells, supportive therapy usually is needed during those times that serious damage occurs to normal body tissues. A major concern for the child receiving treatment for cancer is the risk for the development of complications secondary to the treatment.

Infection

The nurse caring for the child with fever must be aware of the signs and symptoms of septic shock, as discussed in Chapter 23. The child with fever who has an absolute neutrophil count (ANC) lower than 500/mm^3 is at risk for the following (see Nursing Care Guidelines box):

- Overwhelming infection
- Malaise
- Dehydration
- Seizures (young infants and children)
- Invasion of organisms producing secondary infections

NURSING CARE GUIDELINES

Calculating the Absolute Neutrophil Count (ANC)

1. Determine the total percentage of neutrophils ("polys, or segs" and "bands").
2. Multiply white blood cell (WBC) count by percentage of neutrophils.

Example

WBC = 1000/mm^3, neutrophils = 7%, nonsegmented neutrophils (bands) = 7%

Step 1: 7% + 7% = 14%

Step 2: 0.14 × 1000 = 140/mm^3 ANC

The child with fever is evaluated for potential sites of infection, such as from a needle puncture, mucosal ulceration, minor abrasion, or skin tears (e.g., a hangnail). Although the body may not be able to produce an adequate inflammatory response to the infection and the usual clinical signs of infection may be partially expressed or absent, fever will occur. Therefore the child's temperature is monitored closely. To identify the source of infection, the health care team takes blood, stool, urine, and nasopharyngeal cultures and chest x-rays.

Once infection is suspected, broad-spectrum IV antibiotic therapy is begun before the organism is identified and may be continued for 7 to 10 days. If the child does not have a venous access device, a heparin lock peripheral IV should be inserted to prevent the inconvenience and discomfort of multiple venipunctures in administering antibiotic therapy.

The organisms most lethal to these children are (1) viruses, particularly varicella (chickenpox), herpes zoster, herpes simplex, respiratory syncytial virus, influenza, and cytomegalovirus; (2) protozoan, *Toxoplasma gondii;* (3) fungi, especially *Pneumocystis jirovecii* (formally known as *Pneumocystis carinii*) and *Candida albicans;* (4) gram-negative bacteria, such as *Pseudomonas aeruginosa, Escherichia coli,* and *Klebsiella* organisms; and (5) gram-positive bacteria, especially *Staphylococcus* and *Enterococcus* species (Ardura & Koh, 2016).

Prophylaxis against *Pneumocystis* pneumonia, such as trimethoprim-sulfamethoxazole, is routinely given to most children during treatment for cancer (Ardura & Koh, 2016). Colony-stimulating factors (CSFs), a family of glycoprotein hormones that regulate the reproduction, maturation, and function of blood cells, are now routinely used as supportive measures to prevent the side effects caused by low blood counts. CSFs promote stem cell proliferation and stimulate a more rapid maturation of the cells, allowing them to enter the bloodstream earlier. Granulocyte colony-stimulating factor (G-CSF; filgrastim [Neupogen], pegfilgrastim [Neulasta]) directs granulocyte development and can decrease the duration of neutropenia. This reduces the incidence and duration of infection in children receiving treatment for cancer. G-CSF is also being used to decrease the bone marrow recovery time after HSCT (Ardura & Koh, 2016). G-CSF is usually administered intravenously or subcutaneously 24 hours after chemotherapy is discontinued and is given for 10 to 14 days. G-CSF is discontinued when the ANC surpasses 10,000/mm^3. The pegylated or long-acting form of G-CSF, pegfilgrastim, is given only once after completion of therapy and typically has its peak efficacy (highest WBC count) about 8 to 10 days after administration. During G-CSF therapy, children may experience bone pain, fever, rash, malaise, and headaches.

Prevention of infection continues as a priority after discharge from the hospital. Some institutions allow the child to return to school when the ANC is above 500/mm^3. Other institutions place no restrictions on the child, regardless of the blood count. If the ANC falls below 500/mm^3, cautious isolation from crowded areas, such as shopping centers or subways, is advisable. At all times, family members should be encouraged to practice good hand washing to avoid introducing pathogens into the home, and they should know how to take a temperature and who to call in the event of fever (see the Next-Generation NCLEX® Examination-Style Unfolding Case Study).

Hemorrhage

Before the use of transfused platelets, hemorrhage was a leading cause of death in children with some types of cancer. Now most bleeding episodes can be prevented or controlled with judicious administration of platelet concentrates or platelet-rich plasma. The incidence of severe spontaneous internal hemorrhage varies but usually does not occur until the platelet count is 20,000/mm^3 or less (Hockenberry, Kline, & Rodgers, 2016).

Because infection increases the tendency toward hemorrhage and because bleeding sites become more easily infected, special care should be taken to avoid performing skin punctures whenever possible. When performing finger sticks, venipunctures, intramuscular injections, and bone marrow tests, use aseptic technique with continued observation for bleeding. Meticulous mouth care is essential because gingival bleeding with resultant mucositis is a frequent problem. Because the rectal area is prone to ulceration from various drugs, hygiene is essential. To prevent additional trauma, avoid rectal temperatures and suppositories. Frequent turning and the use of a pressure-reducing mattress under bony prominences prevent development of pressure sores and decubital ulcers.

Platelet transfusions are generally reserved for active bleeding episodes that do not respond to local treatment and that may occur during induction or relapse therapy. Epistaxis and gingival bleeding are the most common. The nurse teaches parents and children measures to control nose bleeding. Applying pressure at the site without disturbing clot formation is the general rule. Platelet concentrates normally do not have to be cross-matched for blood group or type. However, because platelets contain specific antigen components similar to blood group factors, children who receive multiple transfusions may become sensitized to a platelet group other than their own. Therefore platelets are cross-matched with the donor's blood components whenever possible.

Transfused platelets generally survive in the body for 1 to 3 days. The peak effect is reached in about 1 hour and decreased by half in 24 hours. After a transfusion, the nurse observes and records the approximate time when hemostasis of bleeding sites occurs. Delayed hemostasis is evidence of platelet destruction. For long-term patients, multiple transfusion therapy becomes progressively less effective.

During bleeding episodes the parents and child need much emotional support. The sight of oozing blood is upsetting. Often parents request a platelet transfusion, unaware of the necessity of trying local measures first. The nurse can help calm their anxiety by explaining the reason for delaying a platelet transfusion until absolutely necessary. Because compatible donors decrease the risk of antigen formation in the recipient, the nurse should encourage parents to locate suitable donors for eventual blood use.

Children at home who have low platelet counts (usually <100,000/mm^3) should avoid activities that might cause injury or bleeding, such as riding bicycles or skateboards, skating, climbing trees or playground equipment, and contact sports such as football or soccer. Once the platelet count rises, these restrictions are not necessary. In addition, aspirin and aspirin-containing products are not used; for mild pain or significantly elevated temperature, acetaminophen is substituted.

Anemia

Initially anemia may be profound if there is complete replacement of the bone marrow by cancer cells. During induction therapy, blood transfusions with packed red blood cells may be necessary to raise the hemoglobin to levels approaching 10 g/dl. The usual precautions in caring for the child are instituted (see Chapter 24).

Anemia is also a consequence of drug-induced myelosuppression. Although not as severely affected as the WBCs, erythrocyte production may be delayed. Because children have an amazing capacity to withstand low hemoglobin levels, the best approach is to allow the child to regulate activity with reasonable adult supervision. It may be necessary for the parents to alert the schoolteacher to the child's physical limitations, particularly in terms of strenuous activity.

Nausea and Vomiting

The nausea and vomiting that occur shortly after administration of several of the drugs and as a result of cranial or abdominal irradiation can be profound and debilitating. The advent of serotonin receptor blockers (5-hydroxytryptamine-3 or 5-HT3 receptor antagonists) has greatly improved management of nausea and vomiting caused by chemotherapy and radiation therapy. The advantage of these agents over conventional drugs is that they produce no extrapyramidal side effects, such as difficulty speaking or swallowing, shuffle walk, slow movements, trembling, stiffness of the arms and legs, or loss of balance. Published guidelines recommend 5-HT3 antagonists and corticosteroids for children receiving highly or moderately emetogenic chemotherapy (Patel, Robinson, Thackray, et al., 2017).

For mild to moderate vomiting, phenothiazine-type drugs remain the mainstay of therapy. Promethazine (Phenergan), prochlorperazine (Compazine), or trimethobenzamide (Tigan) may be effective agents. Metoclopramide is a more effective antiemetic for acute nausea or vomiting. Unfortunately, the drug causes a number of side effects in children, particularly extrapyramidal reactions, such as muscle tremors or twitching, agitation, grimacing, dysarthria, and oculogyric crisis (fixation of eyes in one position for minutes or hours). Prophylaxis with diphenhydramine (Benadryl) is recommended to reduce the incidence of extrapyramidal symptoms when metoclopramide is given (Krane, Casillas, & Zeltzer, 2016).

There is increasing interest in the use of cannabis and its components, cannabinoids, for symptom relief in pediatric patients, including antiemetic effects, appetite stimulation, pain relief, and improved sleep (National Institutes of Health, 2019b). Although cannabis has been approved by a number of states for medical use, some have limited approval to only one ingredient (e.g., cannabidiol, or CBD). It remains illegal by federal law in the United States (except in approved research settings), is not approved by the US Food and Drug Administration, and is not endorsed by the American Academy of Pediatrics because of concerns about brain development (National Institutes of Health, 2019b). These constraints have limited clinical trials and thus the evidence for practice. Commercially available synthetic cannabinoids (e.g., dronabinol, nabilone) are approved drugs for chemotherapy-induced nausea and vomiting (CINV) and have shown evidence of effectiveness for relief of CINV (Wong & Wilens, 2017).

The most beneficial regimen for antiemetic control has been the administration of the antiemetic before chemotherapy begins (30 minutes to 1 hour before) and regular (not as-needed) administration for at least 24 hours after chemotherapy. The goal is to prevent the child from ever experiencing nausea or vomiting in order to prevent the development of anticipatory symptoms (the conditioned response of developing nausea and vomiting before receiving the drug). Other nonpharmacologic interventions (similar to those discussed for pain management in Chapter 5) can be useful in controlling posttherapy and anticipatory nausea and vomiting. Giving the antineoplastic drug with a mild sedative at bedtime is also helpful for some children, and there is evidence that nighttime administration of drugs such as methotrexate and 6-mercaptopurine may be more effective than morning administration.

More detailed information about preventing and treating CINV is available in the Children's Oncology Group's COG Supportive Care Endorsed Guidelines (https://childrensoncologygroup.org/downloads/COG_SC_Guideline_Document.pdf). This resource lists the strength of each recommendation and the quality of the evidence wherever possible.

Altered Nutrition

Altered nutrition is a common side effect of treatment. Continued assessment of the child's nutritional status, child's intake, and energy expenditure must occur throughout treatment. The child's height, weight, and head circumference (for children younger than 3 years old) must be measured routinely during visits to the hospital or clinic. Energy reserves should be evaluated with routine skinfold measurements. Biochemical assays such as serum prealbumin, transferrin, and albumin may be helpful to evaluate nutritional status in some children, but a single assay should not be used alone for a nutritional evaluation (Lawson, Daley, Sams, et al., 2013). There are no specific criteria that mandate nutritional interventions in children undergoing cancer treatment. Instead, each child should have an individualized nutritional care plan based on routine assessments. Most pediatric cancer treatment centers have a nutritionist who can be consulted to develop the nutritional care plan and revise it as needed. Nutritional status is important to maintain because a compromised nutritional status can contribute to reduced tolerance to treatment, altered metabolism of chemotherapy drugs, prolonged episodes of neutropenia, and increased risk for infection.

! NURSING ALERT

Some children develop conditioned aversions to certain foods if they are eaten during a period of chemotherapy. It is best to refrain from offering the child's favorite foods while the child is receiving chemotherapy.

Supportive nutrition measures include oral supplements with high-protein and high-calorie foods. Ways to increase calories include using whole milk; adding tofu (high in protein) to most meals; and serving full-fat yogurt, ice cream, and milk instead of nonfat or low-fat items. Cooking with butter; putting sugar on cereal; and making high-calorie snacks such as trail mix, peanut butter, or dried fruit readily available for the child are other ways to increase calories. Enteral feeding may be necessary when children are unable to maintain the necessary calories to prevent weight loss. Parenteral hyperalimentation is used most frequently for children who have digestive problems, after surgery, or with HSCT. Chapter 22 discusses these interventions in more detail.

Despite such approaches, some children still do not eat. Theories to explain persistent anorexia include the following: (1) a nonspecific physical effect related to the cancer and/or substances it secretes or evokes from the immune system; (2) a conditioned aversion to food from nausea and vomiting during treatment; (3) a response to stress in the environment related to eating or to the child's condition; (4) a result of depression; and (5) a control mechanism when so much else has been imposed on the child. When loss of appetite and weight loss persist, the nurse should investigate the family situation to determine whether any of these variables are contributing to the problem and discuss with the treatment team.

Mucosal Ulceration

One of the most distressing side effects of several drugs is gastrointestinal mucosal cell damage, which results in ulcers anywhere along the alimentary tract. Oral ulcers (stomatitis) are red, eroded, painful areas in the mouth or pharynx (see Chapter 6, Stomatitis). Similar lesions may extend along the esophagus and occur in the rectal area. Mucositis greatly compounds anorexia because eating becomes extremely uncomfortable.

NURSING ALERT

Viscous lidocaine is not recommended for young children. If applied to the pharynx, it may depress the gag reflex, increasing the risk of aspiration. Seizures have also been associated with the use of oral viscous lidocaine, most likely as a result of the rapid absorption into the bloodstream via the oral lesions (Lutwak, Howland, Gambetta, et al., 2013).

Some helpful interventions when oral ulcers develop are feeding a bland, moist, soft diet; using a soft sponge toothbrush (Toothette) instead of a toothbrush; frequently rinsing the mouth with chlorhexidine mouthwash or sodium bicarbonate and salt mouth rinses (using a solution of 1 tsp of baking soda and ½ tsp of table salt in 1 quart of water); using sucralfate; and administering local anesthetics without alcohol, such as a solution of diphenhydramine and Maalox (aluminum and magnesium hydroxide) or UlcerEase (Chaveli-Lopez & Bagan-Sebastian, 2016). Although local anesthetics are effective in temporarily relieving the pain, many children dislike the taste and numb feeling they produce.

More detailed information about preventing and treating mucositis is available in the Children's Oncology Group's COG Supportive Care Endorsed Guidelines (https://childrensoncologygroup.org/downloads/COG_SC_Guideline_Document.pdf). This resource lists the strength of each recommendation and the quality of the evidence wherever possible.

NURSING ALERT

Avoid agents such as lemon glycerin swabs and hydrogen peroxide because of their drying effects on the mucosa. In addition, the acidity of lemon may be very irritating, especially on eroded tissue.

Administering mouth care is particularly difficult in infants and toddlers. A satisfactory method of cleaning the gums is to wrap a piece of gauze around a finger; soak it in saline or plain water; and swab the gums, palate, and inner cheek surfaces with the finger. Mouth care should be performed routinely before and after any feeding and as often as every 2 to 4 hours to rid mucosal surfaces of debris, which becomes an excellent medium for bacterial and fungal growth if left undisturbed.

Dental hygiene can become a serious problem if the child wears an orthodontic appliance. The accumulated debris on braces is difficult to remove without vigorous brushing, and the appliance itself traumatizes the gums. For this reason, sometimes braces are removed before starting chemotherapy treatment.

Difficulty eating is a major problem with stomatitis and may warrant hospitalization if the child refuses fluids. The child usually chooses the foods that are best tolerated. Surprisingly, some children prefer salty foods to bland ones. Drinking can usually be encouraged if a straw is used to bypass the ulcerated oral mucosa. The nurse should encourage parents to relax any eating pressures because the anorexia accompanying stomatitis is well justified. In addition, because it is a temporary condition, the child can resume good food habits once the ulcers heal. Ordinarily, severe mucosal ulceration indicates a need for reduced chemotherapy until complete healing takes place, usually within a week. Analgesics, including opioids, may be needed when treatment cannot be altered, such as during HSCT.

If rectal ulcers develop, meticulous toilet hygiene, warm sitz baths after each bowel movement, and an occlusive ointment applied to the ulcerated area promote healing; the use of stool softeners is necessary to prevent further discomfort. The child may avoid defecation to prevent discomfort; for this reason, parents should record bowel movements to keep track. Rectal temperatures and suppositories are always avoided because they may traumatize the area.

Neurologic Problems

Vincristine, and to a lesser extent vinblastine, can cause various neurotoxic effects. One of the more common neurotoxic effects is severe constipation caused by decreased bowel innervation. Administration of opioids can further aggravate constipation. The nurse advises parents to record bowel movements and to notify the practitioner of a change in stool habits. Physical activity and stool softeners are helpful in preventing the problem, but laxatives, such as polyethylene glycol, are often necessary to stimulate evacuation. Dietary changes such as increased fiber may not be effective because the increased bulk tends to increase fecal distention and discomfort without producing the necessary mechanical stimulation.

Footdrop and weakness and numbness of the extremities may cause difficulty in walking or fine hand movement. The nurse should observe for these problems and warn parents of these side effects, which are reversible once the drug is stopped. Wearing high-top tennis shoes or using a footboard in bed may help preserve proper alignment. If weakness occurs while the child is attending school, temporary alteration of activity may be necessary. Parents should inform the teacher of the situation to avoid unrealistic expectations of the child's abilities.

Another neurotoxic effect is severe jaw pain. Analgesics may help relieve the discomfort. Children may avoid movement by not talking or chewing, although continuous chewing, such as with gum, may actually help reduce the pain.

A neurologic syndrome, postirradiation somnolence, may develop 5 to 8 weeks after CNS irradiation and last for 4 to 15 days. It is characterized by somnolence with or without fever, anorexia, and nausea and vomiting. Parents should be warned of the possibility of such symptoms and be encouraged to seek medical evaluation because somnolence may be an early indicator of long-term neurologic sequelae after cranial irradiation.

Hemorrhagic Cystitis

Sterile hemorrhagic cystitis is a side effect of chemical irritation to the bladder from chemotherapy. It can be prevented by (1) a liberal oral or parenteral fluid intake (at least 1.5 times the recommended daily fluid requirement [2 L/m^2/day]); (2) frequent voiding immediately after feeling the urge, including immediately before bed, one nighttime void, and on arising; (3) administration of chemotherapy early in the day to allow for sufficient fluids and frequent voiding; and (4) administration of mesna, a drug that inhibits the urotoxicity of cyclophosphamide and ifosfamide (Freedman et al., 2016).

NURSING ALERT

If signs of cystitis such as burning on urination occur, prompt medical evaluation is needed. Hemorrhagic cystitis warrants a full workup and timely intervention.

In most cases IV fluids are given before, during, and after the drug to ensure adequate hydration, thereby eliminating the need for the child to drink large amounts of fluid. If oral home administration is prescribed, the family needs specific instructions on exactly how much fluid the child must have.

Alopecia

Hair loss is a side effect of several chemotherapeutic drugs and cranial irradiation. Not all children lose their hair during chemotherapy, and

some children may experience thinning of the hair rather than baldness. However, retaining hair is the exception rather than the rule. It is better to warn children and parents of this side effect to allow them some time to adapt to hair loss.

The family should know that the hair falls out in clumps, causing patchy baldness. To lessen the trauma of seeing large amounts of hair on bed linens or clothing, the child can wear a disposable surgical cap to collect the shed hair during the period of greatest hair loss, or the hair can be cut short or the head shaved. Families should also be aware that wigs are a tax deductible expense. Hair typically regrows in 3 to 6 months, and it is often a different color and texture than before cancer treatment.

NURSING TIP: Encouraging children to choose a wig similar to their own hairstyle and color before the hair falls out is helpful in fostering later adjustment to hair loss.

If the child chooses not to wear a wig, attention to some type of head covering is important, especially in cold or sunny climates. Scalp hygiene is also important. The scalp should be washed regularly as with any other body part.

Steroid Effects

Short-term steroid therapy produces physical changes and alterations in body image, which although not clinically significant, can be extremely distressing to older children. One of these is Cushingoid appearance. The child's face becomes rounded and puffy (see Fig. 28.2). Unlike hair loss, little can be done to camouflage this obvious change, although careful avoidance of salt and salt-containing foods can help reduce fluid accumulation. It is not unusual for other children to tease the child. It is helpful to reassure the child that, after the drug is stopped, the facial contours will return to normal. The use of loose-fitting clothes can help camouflage changes in weight.

The moon face, red cheeks, supraclavicular fat pads, protuberant abdomen, and fluid retention in children receiving steroid therapy indicate weight gain. However, the actual weight gain resulting from increased muscle mass and subcutaneous tissue may be small. Therefore the nurse should evaluate weight gain by observing the extremities and measuring skinfold thickness and arm circumference during steroid therapy to determine whether the weight gain is a result of increased dietary intake.

Shortly after beginning steroid therapy, children may experience mood changes, which range from feelings of well-being and euphoria to depression and irritability. If parents are unaware of these drug-induced changes, they may become unduly concerned. Therefore the nurse should warn them of the reactions and encourage them to discuss the behavioral changes with each other and the child.

NURSING CARE DURING HEMATOPOIETIC STEM CELL TRANSPLANTATION

Because of the aggressive preconditioning therapy used to remove the marrow and the potential for complications while waiting for engraftment of transplanted stem cells, children undergoing HSCT are usually hospitalized for several weeks. HSCT patients must have numerous procedures performed, such as the insertion of a venous access device, administration of intensive chemotherapy and irradiation, and strict infection precautions. During the period after transplantation and before the new marrow begins adequately replacing granulocytes, the child is extremely susceptible to infection, and any infection can be life threatening. In addition, many of the side effects previously discussed occur in the child undergoing HSCT.

The most common complication in allogeneic transplants is acute GVHD, which can affect the skin, gastrointestinal tract, and liver. The characteristics and severity of the manifestations vary according to the severity and area affected. Emphasis is now placed on the prevention of GVHD, using various agents such as a calcineurin inhibitor in conjunction with mycophenolate mofetil, methotrexate, or sirolimus (Gottschalk et al., 2016). Treatment involves the use of steroids or other immunosuppressive medications. However, this treatment further increases the risk of infection in the already susceptible patient. All blood products are irradiated to minimize the introduction of additional antigens.

Skin breakdown and delayed wound healing frequently occur in the patient undergoing HSCT. Preventive interventions to minimize pressure on dependent areas of the skin include the use of pressure-relieving or pressure-reducing beds or mattresses and frequent movement. Measures to promote healing when breakdown occurs include frequent sitz baths to the perianal area and protective skin barriers, such as hydrocolloid dressings or occlusive ointments.

Throughout this long ordeal the family is worried about successful engraftment and possible fatal complications. An unfortunate post-transplant possibility is recurrence of the disease after engraftment. Consequently, nurses need to provide sensitive care and maintain a supportive attitude during the many crises that may arise. If the procedure is not successful, the care needed by these families is consistent with that required by the family of any child with a life-threatening disorder (see Chapter 17).

PREPARATION FOR PROCEDURES

Children in particular need psychologic preparation for the various treatment interventions, which often involve surgery, IV injections, bone marrow aspirations, and LPs. The diagnostic procedures initially used to confirm the diagnosis and those that are repeated to monitor treatment can be a source of discomfort and stress to the child and family. Even noninvasive procedures such as imaging and radiologic tests are frightening to a young child and may be stressful at any age. Some of these tests require the child to lie motionless for a prolonged time in a confined space with little or no communication. Consequently, infants and young children are usually sedated, and older children need an explanation of what to expect and reminders during the test of how much longer they must remain still. The same principles for preparing children for procedures that are discussed in Chapter 20 apply here, including the option of having parents stay with the child whenever possible. Children who undergo repeated tests need additional preparation and emotional support to manage their stress.

Two procedures, bone marrow studies and LPs, are so commonly performed in many types of childhood cancer that they deserve special consideration (Fig. 25.2). Both tests can be frightening because they are done behind the child's field of vision. Professionals caring for children with cancer recommend the use of developmentally appropriate support using both pharmacologic and nonpharmacologic approaches and sedation if required (see Chapter 20).

Topical anesthetics such as eutectic mixture of local anesthetics (EMLA) and LMX4 creams are used as a local anesthetic before intrusive procedures, including venipunctures, implanted port access, LPs, and subcutaneous or intramuscular injections (Hockenberry et al., 2016). Local intradermal anesthesia with lidocaine is frequently used for LP and bone marrow examination. To reduce the stinging sensation from lidocaine, sodium bicarbonate should be added (see Chapter 5, Pain Management). Deeper infiltration of the muscle and periosteum of the bone with buffered lidocaine further reduces the

Fig. 25.2 Child with leukemia undergoing bone marrow aspiration.

pain from the large-bore aspiration or biopsy needle entering the bone.

For bone marrow studies, LPs, and other procedures, children of preschool age and older should be prepared beforehand. Physical care after the procedures is minimal. A small pressure bandage is applied to the bone marrow puncture site, and an adhesive bandage is applied to the LP site. No activity restriction is necessary after the bone marrow test, although the site is usually sore and the child may prefer to remain quiet. Recommendations after LP vary, and nurses should know their institutional practice. If medication was instilled, the child may be placed in a slight Trendelenburg position to facilitate circulation of the medicated spinal fluid.

PAIN MANAGEMENT

Nurses must be knowledgeable about the basic pathophysiology of cancer pain and treatment-related side effects. The World Health Organization's three-step analgesic pain ladder should be incorporated into the approach to pain management for every child with cancer (Ullrich, Sourkes, & Wolfe, 2016). Nurses must acquire extensive knowledge of nonopioid and opioid analgesics, as well as nonpharmacologic approaches used in pediatric pain management (see Chapter 5). Interdisciplinary pain management teams are used in many pediatric cancer centers. These teams serve as consultants and provide expertise in the assessment and management of pain. The nurse often serves as the coordinator of care, playing a key role in cancer pain management and implementing the pain team's plan of care.

Pharmacologic management of disease-related pain involves a variety of methods. It may take more than one trial of one type of medication to find the appropriate agent to manage a patient's pain. The route of administration must be considered as well. Providing "pain relief" by administering painful intramuscular injections as an alternative to the IV route is not appropriate therapy because many oral preparations are now available with comparable efficacy. Furthermore, children may refuse needed pain medication if it involves an injection. Nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen with codeine, oxycodone, and morphine are commonly used in the management of disease-related pain (Fielding, Sanford, & Davis, 2013). All are available in the oral form, and morphine and the NSAID ketorolac (Toradol) are available as IV preparations. Appropriate dosing is imperative. Doses are titrated to increase the amount of analgesia and minimize side effects. If opioids are prescribed, families will need guidance from the treatment team regarding pharmacy and regulatory practices enacted in the context of the opioid epidemic, such as barriers and restrictions to accessing adequate pain control (Page & Blanchard, 2019).

HEALTH PROMOTION

Children with cancer require the same basic health supervision as do any children. Sometimes the overwhelming needs and demands placed on the family, coupled with the singular concern focused on the cancer by both family and health care professionals, result in a lack of attention to typical health care needs. Nurses should monitor the type of primary care the child receives, using guidelines for recommended medical supervision (American Academy of Pediatrics, 2019). Areas of particular concern are (1) dental care because of potential side effects from treatment, and (2) immunizations because of concerns with live virus vaccines and immunosuppression.

Dental Care

Irradiation to the head and neck can cause a number of late complications (Landier, Armenian, Meadows, et al., 2016). Some are irreversible, such as facial asymmetry, but those affecting the teeth and gums (e.g., caries, periodontal disease) benefit from excellent oral hygiene, including regular use of systemic and topical fluoride and regular dental examinations and cleaning (see Chapter 12, Dental Health). Delayed or absent development of the permanent teeth can occur (Effinger, Migliorati, Hudson, et al., 2014). Depending on the child's age, this can be a source of acute psychologic distress, especially during early school-age years, when "losing a tooth" is a status symbol. Children need to be aware of this possibility and need help to explain the delay to peers.

Daily toothbrushing and flossing are encouraged in children with granulocyte counts in excess of 500/mm^3 and platelet counts above 40,000/mm^3. Fluoride rinses are used as discussed in Chapter 12. Oral hygiene for children whose counts are below these parameters is limited to wiping the teeth with moistened gauze sponges or Toothettes.

Immunizations and Communicable Disease Exposure

Viral replication after the administration of live vaccine for polio, measles, rubella, and mumps can cause serious disease in immunocompromised children. The child receiving chemotherapy for cancer should not receive live, attenuated vaccines. Inactivated vaccines can be given to immunosuppressed children. Siblings and other family members can receive the live measles, mumps, and rubella vaccine and the varicella vaccine without risk to the child who is immunosuppressed. Guidelines for immunization of children receiving chemotherapy and HSCT patients have been published (Ardura & Koh, 2016).

An important indication for isolation is an outbreak of childhood communicable disease, such as rubella and varicella. Ideally, the school nurse should work with the treating practitioner to decide the optimum time for school attendance. Parents should be taught to work with the school or daycare staff to be sure they understand the risk to the child being treated for cancer and that they notify the parents immediately of any exposure. If the child has been exposed to the varicella virus, varicella-zoster immune globulin given within 96 hours may favorably alter the course of the disease. Antiviral agents, such as acyclovir, should be given if the child develops varicella. Without treatment, death from disseminated varicella can occur due to disease in the liver, lung, and CNS (Ardura & Koh, 2016) (see also Chapter 6, Immunizations).

NURSING ALERT

Children who were vaccinated 2 weeks before or during chemotherapy should be considered unimmunized and should be revaccinated or receive live virus vaccines 6 months after chemotherapy has stopped (American Academy of Pediatrics, 2018). Most institutions have individual guidelines regarding vaccinations in a child undergoing immunosuppressive therapy. The nurse should be aware of these guidelines and educate patients and families about the need for and timing of immunizations.

PATIENT AND FAMILY EDUCATION

Nurses working with children being treated for cancer have a significant role in helping the family understand the treatment plan, preventing or managing side effects, and transitioning to off-treatment and adult-focused health care. Little data to support evidence-based practices for patient and family education exist. Most children with cancer are enrolled in clinical trials through the Children's Oncology Group. The Children's Oncology Group Nursing Discipline has conducted several activities focusing on patient and family education during the new diagnosis period. They identified five broad principles with expert consensus recommendations: (1) patient and family education is family centered; (2) a diagnosis of childhood cancer is overwhelming, and the family needs time to process the diagnosis and develop a plan for managing ongoing life demands before they can successfully learn to care for the child; (3) patient and family education should be an interprofessional endeavor with three key areas of focus: (a) diagnosis and treatment, (b) psychosocial coping, and (c) care of the child; (4) patient and family education should occur across the continuum of care; and (5) a supportive environment is necessary to optimize learning (Landier, Ahern, Barakat, et al., 2016). According to the authors, "Dissemination and implementation of these recommendations will set the stage for future studies that aim to develop evidence to inform best practices, and ultimately to establish the standard of care for effective patient/family education in pediatric oncology" (Landier et al., 2016). In current practice, several excellent resources for teaching and learning are available. The National Cancer Institute (https://www.cancer.gov/) and the Children's Oncology Group (https://www.childrensoncologygroup.org/) websites are reliable sources of regularly updated information on childhood cancer research and care. The Association of Pediatric Hematology/Oncology Nurses[c] has developed a portfolio of educational materials for family education. The American Childhood Cancer Organization[d] is an international organization providing support, education, and advocacy programs for children with cancer and their families. Similarly, the Coalition Against Childhood Cancer (https://cac2.org/) is composed of numerous foundations that provide advocacy and resources focused on childhood cancer; it also hosts the HOPE Portal, an online guide to available information and support resources (https://cac2.org/family-resources/).

COMPLETION OF THERAPY

Care does not end when the child completes therapy. With the increasing awareness of late effects, nurses have an important role in the assessment of the child for problems such as delayed growth, subsequent malignancies, and disturbances in organ systems. The family needs to be aware of the importance of continued medical supervision, for both primary care and survivorship care. Other health care professionals caring for the child, such as school nurses, family physicians, and dentists, should be informed of the child's cancer diagnosis. As children reach young adulthood, transition services may be available in the treatment center to help ease the transfer of primary care to adult health care professionals in the community. If there is a survivorship program at the treating hospital or nearby, oncology follow-up care should be transferred there according to the program's criteria. Adolescents and young adults may benefit from genetic or genomic counseling that may affect their long-term health. If the possibility of infertility exists, fertility options should be discussed for pubertal males and females before the start of treatment and readdressed during survivorship care.

The Children's Oncology Group has developed guidelines for long-term follow-up care for pediatric cancer survivors.[e] Nurses involved with care of these children should be familiar with these guidelines and use all opportunities to help patients and families access needed survivorship and transition care.

CANCERS OF BLOOD AND LYMPH SYSTEMS

ACUTE LEUKEMIAS

Leukemia is a broad term given to a group of malignant diseases of the bone marrow, blood, and lymphatic system. In healthy children, the bone marrow makes blood stem cells that mature to become lymphoid or myeloid stem cells. Myeloid cells differentiate into red blood cells, platelets, and WBCs. Lymphoid stem cells become lymphoblasts that differentiate into B lymphocytes, T lymphocytes, and natural killer cells (National Institutes of Health, 2019c). In acute leukemias, immature cells that cannot function effectively predominate. Two types of leukemia are seen most often in children: acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML).

ACUTE LYMPHOBLASTIC LEUKEMIA

Older synonyms for ALL include acute lymphatic, lymphocytic, and lymphoid leukemia. ALL is the most common form of childhood cancer, with an annual incidence of approximately 4900 new cases annually in the United States (Rabin, Gramatges, Margolin, et al., 2016). It occurs more often in boys than in girls, and it is 20% more common in Hispanics than non-Hispanic whites; it is more common in whites than in African Americans (Rabin et al., 2016; Wiemels, Walsh, deSmith, et al., 2018). The peak age of onset is between 2 and 3 years old. Risk factors for ALL include prenatal exposure to x-rays, previous treatment with chemotherapy, and certain genetic conditions (e.g., Down syndrome, Bloom syndrome, Fanconi anemia, Li-Fraumeni syndrome) (National Institutes of Health, 2019c). Genetic predisposition also includes a number of germline polymorphisms (genetic variations) in common alleles found by GWAS, as well as rare germline variants (e.g., *PAX5, ETV6, TP53*). There is evidence to suggest that some ALL begins prenatally.

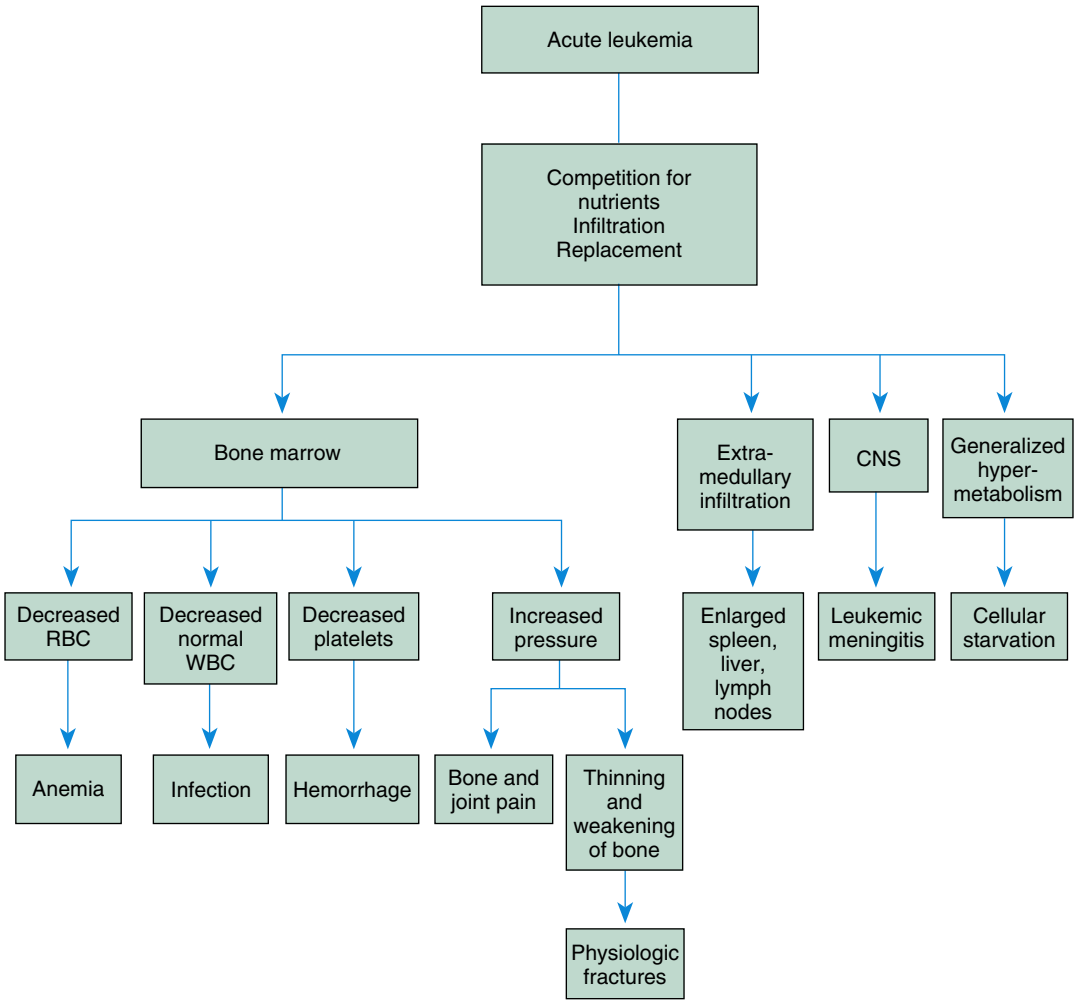

Fig. 25.3 Principal sites of tissue involvement in leukemia. *CNS,* Central nervous system; *RBC,* red blood cell; *WBC,* white blood cell.

Clinical Manifestations

The onset of leukemia varies from acute to insidious. In most instances the child displays remarkably few symptoms. For example, leukemia may be diagnosed when a minor infection, such as a cold, fails to disappear completely. The child continues to be pale, listless, irritable, febrile, and anorexic. Parents often suspect some underlying problem when they observe the child's weight loss, petechiae, bruising without cause, and continued complaints of bone and joint pain. At other times there may be an extended history of signs and symptoms mimicking such conditions as rheumatoid arthritis or mononucleosis. Sometimes leukemia is an incidental finding on a routine physical examination or during treatment for an injury. Fig. 25.3 displays the sites for tissue involvement in leukemia.

Signs and symptoms of ALL reflect infiltration of the bone marrow by nonfunctional leukemic cells ("blasts"). The three main consequences of bone marrow infiltration are (1) anemia from decreased erythrocytes, (2) infection from neutropenia, and (3) bleeding from decreased platelet production. Approximately half of patients have an elevated WBC count at presentation (>10,000/mm^3). Other signs and symptoms indicate leukemic cell infiltration of various organs; highly vascular organs, such as the spleen and liver, are most severely affected. Commonly seen are hepatosplenomegaly (68% of patients), splenomegaly (63%), fever (61%), lymphadenopathy (50%), bleeding (e.g., petechiae or purpura, 48%), and bone pain (23%) (Rabin et al., 2016).

Two important sites of extramedullary (outside the bone marrow) disease are the CNS and testes because they can serve as "sanctuaries" for leukemic cells; these sites require specific therapy.

Diagnostic Evaluation

Leukemia is usually suspected from the history, physical manifestations, and a peripheral blood smear that contains leukemic blasts, frequently in combination with low blood counts. The diagnostic evaluation includes a thorough history and physical examination, laboratory tests (CBC with differential, blood chemistries), and bone marrow aspiration or biopsy (cytogenetic analysis, immunophenotyping). A chest x-ray may be performed to determine whether there is a mass of leukemic cells in the chest. Definitive diagnosis is based on analysis of the bone marrow sample. Typically the bone marrow of a child with ALL shows a monotonous infiltrate of blast cells. Once the diagnosis is confirmed, an LP is performed to determine whether there is any CNS involvement. Only a small number of children have CNS involvement at diagnosis, and they are usually asymptomatic.

Clinical Staging and Prognosis

In the past, the standard ways to classify ALL were with the French-American-British (FAB) morphologic system and cytochemical stains. Now the standard accepted method is immunophenotyping, in which panels of monoclonal antibodies are used to determine

TABLE 25.3 Selected Prognostic Factors for Acute Lymphoblastic Leukemia

Factor	Relationship to Prognosis
Patient and Clinical Disease Characteristics	
Age at diagnosis	Favorable: >1 year or ≤10 years. Unfavorable: infants Note: Better outcomes are documented for adolescents when treated on pediatric (vs. adult) protocols.
White blood cell count at diagnosis	Favorable: ≤50,000/mm^3 (precursor B-cell ALL; association not seen in T-cell ALL).
CNS involvement at diagnosis	CNS3 has higher risk of treatment failure compared to CNS1 or CNS2. Patients with CNS2, CNS3, or traumatic LP have higher rates of unfavorable prognostic characteristics.
Testicular involvement at diagnosis	COG considers testicular involvement high risk; however, other large clinical trials groups do not.
Down syndrome (trisomy 21)	Outcomes somewhat inferior for children with Down syndrome compared to children who do not have Down syndrome.
Sex	Somewhat better prognosis for girls.
Race and ethnicity	Poorer outcomes associated with African American and Hispanic children than with Caucasian and Asian children. These differences likely reflect effects of multifactorial influences, such as ALL subtype predominance, treatment adherence, socioeconomic status, access to care, and ancestry-related genomic variations.
Weight at diagnosis and during treatment	Both obesity (weight >95th percentile for age and height) and underweight have been studied with variable results.
Leukemic Characteristics	
Morphology	At one time, treatment was partly based on morphology. ALL lymphoblasts were classified as L1, L2, or L3 morphology using the French-American-British (FAB) criteria. No longer used in prognostic classification.
Immunophenotype	Survival is somewhat better in B-cell ALL than in T-cell ALL.
Cytogenetics/genomic alterations	B-cell ALL: Favorable: high hyperdiploidy (51-65 chromosomes); *ETV6-RUNX1* gene fusion. Unfavorable: includes various gene rearrangements and numbers. Some formerly unfavorable characteristics are losing their unfavorability with newer, more effective treatment.
Treatment response	Favorable: rapid response to treatment (best prognosis associated with undetectable levels of minimal residual disease (MRD) or at least <10^{-4} at the end of standard induction).

ALL, Acute lymphoblastic leukemia.

Adapted from Rabin, K. R., Gramatges, M. M., Margolin, J. F., & Poplack, D. G. (2016). Acute lymphoblastic leukemia. In P. A. Pizzo & D. G. Poplack (Eds.), *Principles and practice of pediatric oncology* (7th ed.). Philadelphia, PA: Lippincott; National Institutes of Health, National Cancer Institute. (2017). Childhood acute lymphoblastic leukemia treatment. Retrieved from https://www.cancer.gov/types/leukemia/hp/child-all-treatment-pdq.

T-lineage, B-lineage, and myeloid antigens (Rabin et al., 2016). In addition, chromosomal number (ploidy) and structural rearrangements are evaluated using molecular genetic analyses. In 2016 the World Health Organization revised the classification of ALL into B-lymphoblastic leukemia subgroups characterized by specific chromosomal abnormalities, T-lymphoblastic leukemia, and acute leukemias of ambiguous lineage (having characteristics of both ALL and AML).

The most important prognostic factors in determining assignment to risk-based treatment for children with ALL (Table 25.3) include the child's age and WBC count at diagnosis, CNS involvement as indicated by cerebrospinal fluid sample (CNS1 = negative for blasts; CNS2 = fewer than 5 WBC/μL and positive for blasts; CNS3 = 5 or more WBC/μL and positive for blasts), testicular involvement, Down syndrome, sex, race and ethnicity, and nutritional status; leukemic cell characteristics, including immunophenotype and cytogenetics or genomic alterations such as ploidy and structural rearrangements; response to initial treatment; and minimal residual disease (MRD) determination (National Institutes of Health, 2019c).

Therapeutic Management

ALL has demonstrated dramatic improvements in survival rates such that current long-term disease-free survival rates for children with ALL approach 90% in major pediatric cancer treatment centers. Treatment is based on assignment to risk groups. Children with a higher risk of relapse or recurrence are treated with the most intensive therapy. Different research groups have similar but varying criteria for risk groups. Children's Oncology Group risk groups include age, WBC count at diagnosis, immunophenotype, cytogenetics or genomic alterations, presence of extramedullary disease, Down syndrome, and steroid pretreatment. With advances in treatment, refinement of risk groups is constantly under study.

Although specifics for various risk groups vary, treatment is generally divided into three phases: remission induction, consolidation/intensification, and maintenance (also called continuation). Four types of standard treatment are used: chemotherapy, radiation therapy, chemotherapy with stem cell transplant, and targeted therapy. Targeted therapy includes tyrosine kinase inhibitors (TKIs), monoclonal antibodies, and proteasome inhibitor therapy.

Almost immediately after confirmation of the diagnosis, induction therapy begins and lasts for 4 to 5 weeks (Rabin et al., 2016). The principal drugs are the corticosteroids (dexamethasone or prednisone), vincristine, and L-asparaginase or PEG-asparaginase, with or without an anthracycline. A complete remission (CR) is determined by the presence of less than 5% blast cells in the bone marrow and no detectable leukemia in extramedullary sites.

Because many of the drugs also cause myelosuppression of normal blood elements, the period immediately after a remission can be critical. The body is defenseless against invading organisms (especially normal bacterial flora) and susceptible to spontaneous hemorrhage. Consequently, supportive therapy during this time is essential. Supportive care consists of transfusion support and use of antibacterial and antifungal agents.

With achievement of CR, systemic treatment plus CNS-directed therapy begins. CNS-directed therapy is based on the understanding that leukemic cells could be present in the CNS where they are protected from many systemic chemotherapy drugs by the blood-brain barrier. For this reason, all children receive CNS prophylactic therapy. The combination of intrathecal chemotherapy (either methotrexate alone or in combination with cytarabine and hydrocortisone) plus CNS-directed systemic chemotherapy (dexamethasone, L-asparaginase, and high-dose methotrexate with leucovorin rescue) is standard; cranial radiation may be used for children at highest risk for CNS relapse (National Institutes of Health, 2019c).

Past clinical trials have shown that postinduction therapy is needed to maintain remission. Treatment regimens vary, but all patients receive consolidation/intensification after achieving CR. Most commonly used is the Berlin-Frankfurt-Münster (BFM) "backbone" (a very intensive chemotherapy regimen from the International BFM Study Group that greatly increases ALL survival). This backbone includes consolidation with cyclophosphamide, cytarabine, and mercaptopurine given initially, followed by interim maintenance with high-dose methotrexate with or without leucovorin rescue. Next, delayed intensification is given using drugs and schedules similar to those used in the induction and consolidation phases.

This is followed by maintenance therapy with daily mercaptopurine and weekly low-dose methotrexate; vincristine and a corticosteroid may be given, as well as continued intrathecal therapy (National Institutes of Health, 2019c; Rabin et al., 2016). A critical challenge during maintenance therapy is medication adherence because it has been shown that anything less than 95% adherence increases the risk of relapse (Bhatia, Landier, Shangguan, et al., 2012).

Nursing Care

Nursing care of the child with acute leukemia is directly related to the regimen of therapy. Myelosuppression, drug toxicity, and leukemic infiltration cause secondary complications that necessitate supportive physical care. This discussion focuses on supportive interventions for the child with leukemia and the family. General aspects of care appropriate for the child with leukemia are discussed earlier under General Nursing Care Management.

Prepare the Family for Diagnostic and Therapeutic Procedures

From the time before diagnosis to cessation of therapy, children must undergo several tests, the most traumatic of which are bone marrow aspiration or biopsy and LP. Finger sticks and venipunctures for blood analysis and drug infusion are common occurrences for several years after the diagnosis. Therefore children need an explanation of the rationale for each procedure, what can be expected, and what they can do to help (see Chapter 20, Preparation for Diagnostic and Therapeutic Procedures).

Depending on the child's age, one way of beginning diagnostic preparation is to explain the tests, procedures, and treatment plan. Using a drawing or letting the child look at a drop of blood under a microscope not only teaches but also fosters trust between the nurse and the child. It also allows the nurse to assess the child's level of understanding. An error many health professionals make is to overestimate children's knowledge about their bodies. For example, a bone marrow aspiration makes sense only when it is clarified that the center of a bone contains the cells that later become "working" blood cells or leukemic cells.

Provide Continued Emotional Support

Nursing care of the child with leukemia is based on typical problems the family confronts during the treatment phases and afterwards. Therefore the nurse's role is one of continual support, guidance, clarification, and clinical judgment. Parents need to know how to recognize symptoms that demand medical attention. Although some of the reactions discussed are expected, parents should still report them to their practitioner. Warning parents of their possible occurrence beforehand also allows parents to prepare themselves. At the same time, it reassures them that these reactions are not caused by a return of leukemic cells.

The nurse must also use judgment in recognizing which side effects are typical reactions and which indicate toxicity. Frequently it is the office or clinic nurse who screens such telephone calls and gives advice, when appropriate. Usually nausea and vomiting are not indications for drug cessation. However, severe vomiting or diarrhea may require immediate intervention to prevent dehydration. Signs of infection, mucosal ulceration, hemorrhagic cystitis, peripheral neuropathy, and constipation require medical evaluation.

Another aspect of continued emotional support involves prognosis. Leukemia is not invariably fatal, but present statistics must be interpreted correctly. Although almost 80% of children with ALL live for 5 years or longer, these are average estimates that apply to those children treated with the most successful protocols since diagnosis. For the high-risk child with ALL or the child with AML, the prognosis may be significantly poorer. Of those who do survive after completing therapy, some will experience recurrence of the leukemia.

LYMPHOMAS

The lymphomas, a group of malignant diseases that arise from the lymphoid and hematopoietic systems, are divided into Hodgkin lymphoma (HL) and NHL. These diseases are further subdivided according to tissue type and extent of disease. In children, NHL is more common than HL.

Hodgkin Lymphoma

Hodgkin lymphoma affects about 29 in 1 million children (National Institutes of Health, 2019e). Its incidence is age related. In the United States there is a striking increased incidence in adolescents 15 to 19 years of age. The Epstein-Barr virus (EBV) is thought to have a role in the causation of HL. Age cohorts vary in the predominant HL subtypes and in the association with EBV. The risk of HL is increased among individuals with immunodeficiency and those with a history of HL among immediate family members. Exposure to infections in early childhood may decrease HL risk (National Institutes of Health, 2019e).

Hodgkin lymphoma originates in the lymphoid system and primarily involves the lymph nodes. It predictably metastasizes to nonnodal or extralymphatic sites, especially the spleen, liver, bone marrow, lungs, and mediastinum (i.e., mass of tissues and organs separating the lungs, including the heart and its vessels, trachea, esophagus, thymus, and lymph nodes), although no tissue is exempt from involvement (Fig. 25.4).

Clinical Staging and Prognosis

Accurate clinical staging of the extent of disease is essential for assignment to treatment protocols based on expected prognosis. The four stages in the Ann Arbor Staging Classification are shown in Box 25.2.

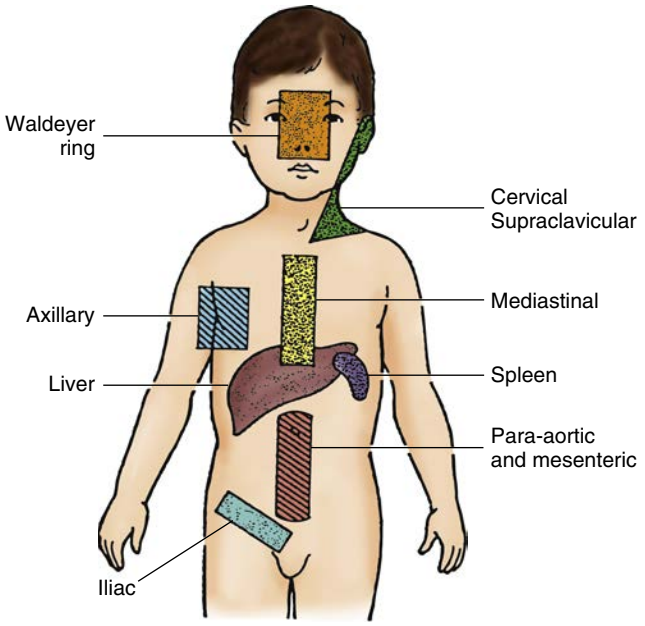

Fig. 25.4 Main areas of lymphadenopathy and organ involvement in Hodgkin disease.

BOX 25.2 Ann Arbor Staging of Hodgkin Disease

Stage I: Lesions are limited to one lymph node area or only one additional extralymphatic site (I_E), such as the liver, lungs, kidney, or intestines.

Stage II: Two or more lymph node regions on the same side of the diaphragm or one additional extralymphatic site or organ (II_E) on the same side of the diaphragm is involved.

Stage III: Lymph node regions on both sides of the diaphragm are involved with spread to one extralymphatic site (III_E), spleen (III_S), or both (III_{SE}).

Stage IV: Diffuse spread throughout the body to one or more extralymphatic sites with or without involvement of associated lymph nodes.

Each stage is further subdivided into A, B, E, or S. Stage A denotes absence of symptoms. Stage B indicates presence of symptoms, such as drenching night sweats, fever (100.4°F [38°C]), or weight loss of 10% or more during the preceding 6 months. Stage E represents involvement of a single extranodal site contiguous or proximal to the known nodal site. Stage S indicates splenic involvement.

The prognosis for patients with HL has improved dramatically, largely as a result of systematic staging, risk group stratification, and improved treatment protocols. The prognosis is excellent in children with localized disease. Overall survival rates for patients with HL are as high as 95%; however, survival rates vary with tumor histology and staging (Frew, Lewis, & Lucraft, 2013). Even in those with disseminated disease, long-term remissions are possible in more than half of patients. For relapses, CR may occur in 30% to 60% of patients undergoing autologous HSCT (Metzger, Krasin, Choi, et al., 2016).

Clinical Manifestations

Hodgkin lymphoma is characterized by painless enlargement of lymph nodes. The most common finding is enlarged, firm, nontender, movable nodes in the supraclavicular or cervical area. Other signs and symptoms depend on the extent and location of involvement. Mediastinal lymphadenopathy may cause a persistent, nonproductive cough. Enlarged retroperitoneal nodes may produce otherwise unexplained abdominal pain. Systemic symptoms include low-grade or intermittent fever, anorexia, nausea, weight loss, night sweats, and pruritus. Generally, such symptoms indicate advanced lymph node and extralymphatic involvement.

Diagnostic Evaluation

The history and physical examination often yield important clues to the disease, such as a history of systemic symptoms, presence of a mediastinal mass, and enlargement of lymph nodes, spleen, or liver. Enlarged nodes should be measured as baseline for later evaluation of treatment response. Because multiple organs can become involved, the diagnostic evaluation requires several tests to confirm the diagnosis and assess the extent of involvement for accurate staging. Laboratory tests include CBC and chemistry panel with albumin, erythrocyte sedimentation rate, and C-reactive protein. Imaging tests include chest x-ray; anatomic imaging with CT or MRI of neck, chest, abdomen, and pelvis; and functional imaging with PET scan (National Institutes of Health, 2019e).

Biopsy of one or more peripheral lymph nodes is used to establish histologic diagnosis. The presence of Hodgkin and Reed-Sternberg cells is considered diagnostic of Hodgkin disease because it is absent in the other lymphomas; however, it may occur in infectious mononucleosis. Hodgkin lymphoma is classified into one of four histologic types: (1) lymphocytic-rich HL, (2) nodular sclerosing HL, (3) mixed cellularity HL, and (4) lymphocytic-depleted HL. For some patients, the histologic subtype may determine therapy. A bone marrow aspiration or biopsy also may be performed.

Therapeutic Management

The primary treatment modalities for HL are chemotherapy and radiation. The length and intensity of therapy are based on disease-related factors (e.g., stage, number of involved nodal regions, tumor bulk, B symptoms, and early response); other factors that may be considered are age, sex, and histology (National Institutes of Health, 2019e). For treatment planning, patients are classified into favorable and unfavorable risk groups, indicating their risk of relapse or lack of response to treatment. Favorable clinical features include localized nodal involvement and no B symptoms or bulky disease. Unfavorable features include presence of B symptoms, bulky lymphadenopathy, extranodal extension, and advanced disease (stages IIIB to IV). Other features may be included in risk stratification (e.g., presence of a pleural effusion), depending on the treatment group or protocol.

The goal of treatment is cure; however, aggressive therapy increases the chances of complications that can seriously compromise quality of life. One of the major concerns with combined radiation and chemotherapy is the risk of serious late effects in children with an excellent prognosis. Consequently, treatment that is risk adapted and response based aims to minimize long-term complications. Because of the diversity of approaches to treatment, the following is an overview of general principles that may not apply to all children.

Most newly diagnosed children are treated with risk-adapted chemotherapy alone or in combination with radiation therapy. Radiation may entail involved field radiation or extended field radiation (involved areas plus adjacent nodes) depending on the extent of involvement. Combination chemotherapy, abbreviated as ABVE-PC, is used: doxorubicin (Adriamycin), bleomycin, vincristine (Oncovin), etoposide, prednisone, and cyclophosphamide. Monoclonal antibodies and other new agents/approaches are being studied in clinical trials for refractory/relapsed HL.

Nursing Care Management

Nursing care involves preparation for diagnostic and operative procedures, explanation of treatment side effects, and child and family support. When HL is suspected, a battery of diagnostic tests is

ordered. The family and child need an explanation of why each test is performed because many of them, such as bone marrow aspiration and lymph node biopsy, are invasive procedures (see Chapter 20).

Explanations of chemotherapeutic reactions are based on the specific drug regimen. The most common side effects, such as nausea and vomiting, body image changes, neuropathy, and mucosal ulceration, are discussed in the General Nursing Care Management section. Involved-field radiation results in few side effects, sometimes consisting only of a mild skin reaction. With extended-field radiation to the chest and abdomen, nausea and vomiting, weight loss, and mucosal ulceration (esophagitis, gastric ulcers) are common. The usual measures for providing relief are discussed earlier in the chapter and outlined in Table 25.2.

The most common side effect of extensive irradiation is fatigue, which may result from damage to the thyroid gland, causing hypothyroidism. Lack of energy is particularly difficult for adolescents because it prevents them from keeping up with their peers. Sometimes adolescents push themselves to the point of physical exhaustion rather than admit fatigue and give in to their decreased activity tolerance. Parents should observe for such behavior, such as extreme fatigue at the end of the day, falling asleep at the dinner table, inability to concentrate on homework, or an increased susceptibility to infection. Regular bedtimes and periodic rest times are important, especially during chemotherapy, when myelosuppression increases the risk of infection and debilitation. Before discharge (if the child has been hospitalized), the nurse should discuss a feasible school schedule with the parents and child; home schooling or tutoring may be an option. If alterations are necessary, such as elimination of strenuous physical education, they are discussed with the teacher, school nurse, and principal. If a central venous access device is in place, no gym or contact sports are permitted. Follow-up care is essential to diagnose hypothyroidism early and institute thyroid replacement.

An area of concern for adolescents is the risk of infertility from irradiation and chemotherapy. Both irradiation to the gonads and drugs, particularly procarbazine and alkylating agents, may lead to infertility. Younger females with a greater complement of oocytes are more likely to retain ovarian function. Adolescents should be informed of these side effects and offered options for fertility preservation early in the course of diagnosis and treatment. Although sexual function is not altered, the appearance of secondary sexual characteristics and menstruation may be delayed in the pubescent child. Delayed sexual maturation may be an extremely sensitive and painful area for children (see Chapter 16).

Non-Hodgkin Lymphoma

Approximately 800 new cases of NHL are diagnosed each year in the United States, with an incidence of 10 children per 1 million under the age of 20 years (Allen, Kamdar, Bollard, et al., 2016). Risk factors include infection with EBV, inherited or acquired immunodeficiency, DNA repair syndromes (e.g., ataxia-telangiectasia), and previous cancer (National Institutes of Health, 2019f).

Staging and Prognosis

NHL exhibits various morphologic, cytochemical, and immunologic features. The World Health Organization's histopathologic classification is based on immunophenotype, molecular biology, and clinical response to treatment. Most cases are categorized into one of three groups: mature B-cell NHL (including Burkitt lymphoma), lymphoblastic lymphoma, and anaplastic large cell lymphoma (National Institutes of Health, 2019f).

BOX 25.3 St. Jude Staging of Non-Hodgkin Lymphoma

Stage I: Disease limited to one lymph node area or only one additional extralymphatic site (excluding thoracic or abdomen).

Stage II: Single tumor with regional lymph node involvement; two or more lymph node regions on the same side of the diaphragm; two single tumors with or without regional involvement on the same side of the diaphragm; or primary resectable gastrointestinal tumor with or without involvement of adjacent mesenteric nodes.

Stage III: Two single tumors on opposite sides of the diaphragm; two nodal areas above or below the diaphragm; primary intrathoracic tumor or extensive intra-abdominal disease; or paraspinal or epidural tumors.

Stage IV: Tumor has spread into central nervous system and/or bone marrow

Prognostic staging is shown in Box 25.3. The St. Jude Children's Research Hospital Murphy Staging System is widely used for childhood NHL. A favorable prognosis is defined by young age, low stage without mediastinal involvement, low tumor burden, and good response to initial therapy (Allen et al., 2016). The use of aggressive combination chemotherapy has had a major impact on NHL survival rates in children. The most effective treatment regimens result in cure in 85% to 95% of children with limited disease involvement, and 70% to 90% of children with extensive disease are cured (Allen et al., 2016).

Clinical Manifestations

Many of the signs and symptoms seen in HL may be present in NHL, although it is rare for a single symptom to lead to the diagnosis. Rather, metastasis to the bone marrow or CNS may produce signs and symptoms typical of leukemia. Lymphoid tumors compressing various organs may cause intestinal or airway obstruction, cranial nerve palsies, or spinal paralysis. A large mediastinal mass and tumor lysis syndrome are medical emergencies requiring urgent attention because they may be life threatening.

The exception to the usual presentation of NHL is Burkitt lymphoma, a type of cancer that is rare in the United States but endemic in parts of Africa. It is a rapidly growing neoplasm that is most commonly seen as a mass in the jaw, abdomen, or orbit. However, no anatomic site appears exempt from involvement. Peripheral lymphadenopathy, hepatosplenomegaly, or signs of conversion to leukemia are rarely seen.

Diagnostic Evaluation

Current recommendations for diagnostic evaluation and staging include history and physical examination; blood chemistries; total body imaging (CT, PET, MRI); LP; bone marrow aspiration; and biopsy. Cancer cells are examined by immunophenotyping (immunohistochemistry, flow cytometry), cytogenetics, and/or FISH (National Institutes of Health, 2019f).

Therapeutic Management

Because NHL is generally considered to be widespread at diagnosis, most children are treated with combination chemotherapy. The role of radiation is limited, although it may be used in emergency situations at diagnosis, such as deviated trachea with impingement on the airway with associated respiratory compromise (National Institutes of Health, 2019f).

Treatment for NHL is based on histologic subtype. Lymphoblastic lymphoma therapy is similar to leukemia therapy; the protocols include induction, consolidation, and maintenance phases, some with intrathecal chemotherapy with or without cranial-spinal radiation therapy. The most commonly used chemotherapy regimens for

PATHOPHYSIOLOGY REVIEW

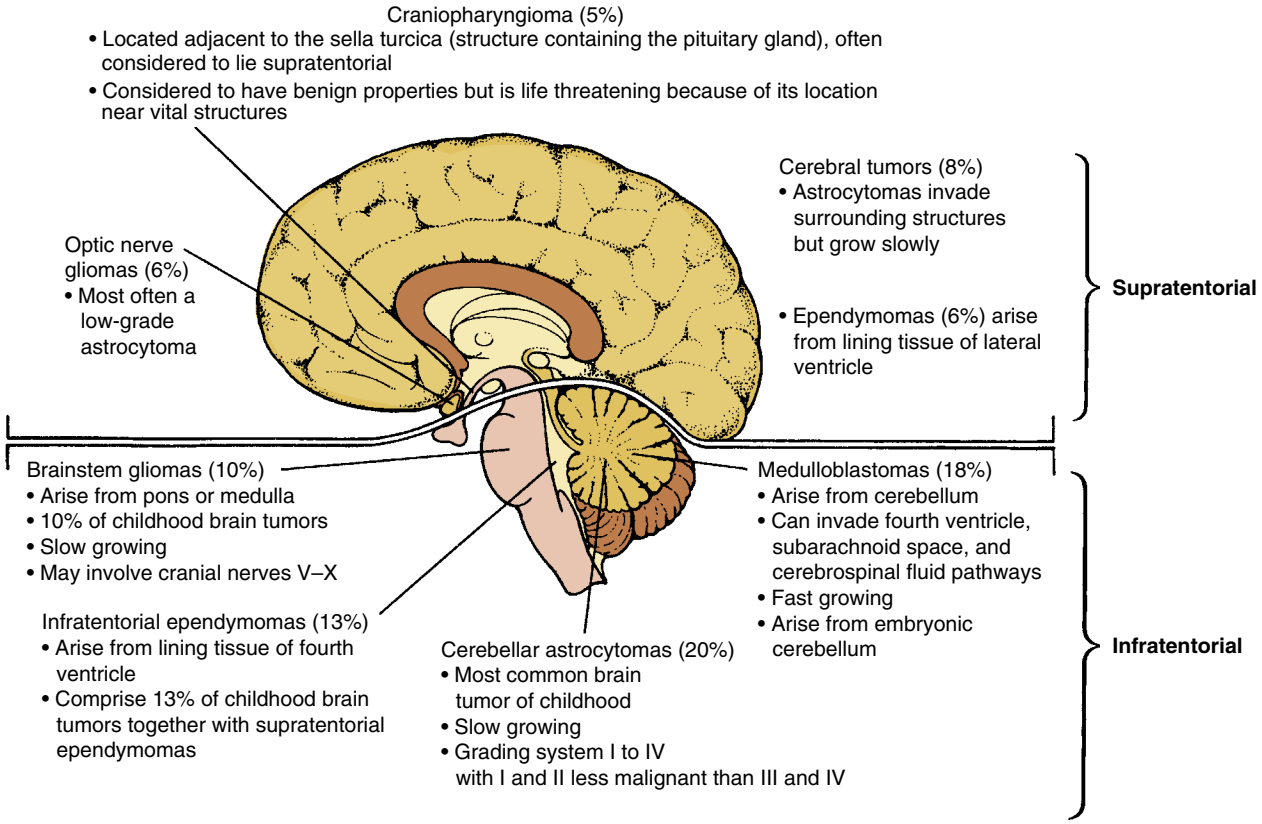

Fig. 25.5 Location of brain tumors in children. (From McCance KL, Huether SE. [2014]. *Pathophysiology: The biological basis for disease in adults and children* [7th ed.]. St. Louis, MO: Elsevier.)

newly diagnosed lymphoblastic lymphoma include prednisone, dexamethasone, vincristine, daunorubicin, doxorubicin, L-asparaginase, cyclophosphamide, cytarabine, methotrexate, 6-mercaptopurine, 6-thioguanine, and intrathecal treatments during maintenance. Newly diagnosed children with diffuse mature B-cell lymphoma are treated with surgery (stage I and II only) and chemotherapy with or without a monoclonal antibody; those with lymphoblastic lymphoma receive chemotherapy (plus cranial radiation for overt CNS disease); and patients with anaplastic large cell lymphoma are treated with surgery (stage I) and chemotherapy. These multiagent regimens are administered for 6 to 24 months.

Nursing Care Management

Nursing care of the child with NHL is similar to the care discussed under General Nursing Care Management. With intensive chemotherapy, nursing care is primarily directed toward managing the side effects of these agents.

NERVOUS SYSTEM TUMORS

BRAIN TUMORS

Primary tumors of the CNS, when grouped together, are the most common solid tumor in children and account for about 25% of all childhood cancers, with an annual incidence of 5 per 100,000 children younger than 20 years of age in the United States (Crawford, 2013). Brain tumors may be benign or malignant, although what matters the most is location, given the vital functions the brain controls. About 60% of the tumors are **infratentorial** (below the tentorium cerebelli), which means they occur in the posterior part of the brain, primarily in the cerebellum or brainstem. This anatomic distribution accounts for the frequency of symptoms resulting from increased intracranial pressure (ICP). The other tumors are **supratentorial** or lie within the midbrain structures. Fig. 25.5 shows the major brain tumors of childhood.

Because brain tumors can arise from any cell within the cranium, it is possible to have tumors originating from the glial cells, nerve cells, neuroepithelium, cranial nerves, blood vessels, pineal gland, and pituitary. Within each of these structures, specific cells may be involved that provide a histologic classification. For example, astrocytes, cells that form most of the supportive tissue for the neurons, may form astrocytomas, the most common glial tumor. Germline mutations are being increasingly recognized as cancer predisposing in childhood brain tumors (up to 8%); examples include Li-Fraumeni syndrome and neurofibromatosis. Other known risk factors include cranial irradiation and immunosuppression (Parsons, Pollack, Hass-Kogan, et al., 2016). Molecular or genomic studies of brain tumors are an active area of research and are changing traditional concepts of histology-based risk classification.

Clinical Manifestations

The signs and symptoms of brain tumors are directly related to their anatomic location, tumor size, rate of tumor growth, and the child's chronological and developmental age. For instance, in infants whose sutures are still open, a bulging fontanel indicates hydrocephalus. Head circumference measurements allow for detection of increased head size. Even in older children, clinical manifestations may be nonspecific.

However, the most common symptoms of infratentorial brain tumors are headache, especially on awakening, and vomiting that is not related to feeding. Tumors in this area of the brain often obstruct the flow of cerebrospinal fluid, causing increased ICP and the symptoms mentioned earlier. In addition, patients may have symptoms related to the specific structure involved. Tumors of the cerebellum often cause nystagmus, ataxia, dysarthria, and dysmetria. Supratentorial tumor symptoms more commonly include seizures, personality or behavioral changes, visual disturbances, and hemiparesis. Tumors involving the structures of the midbrain, including the hypothalamus and pituitary gland, may cause endocrinopathies such as diabetes insipidus, delayed or precocious puberty, and growth failure. Table 25.4 shows common presenting symptoms of brain tumors.

Diagnostic Evaluation

Diagnosis of a brain tumor is initially based on presenting clinical signs and diagnostic imaging. Because the signs and symptoms may be vague and easily overlooked, early diagnosis requires a high index of suspicion during history taking. A number of tests may be used in the neurologic evaluation, but the gold standard diagnostic procedure is MRI, which permits early diagnosis of brain tumors and assessment of tumor growth during or after treatment. Diffusion-weighted imaging, spectroscopy, and perfusion imaging are other MRI tools used to investigate and diagnose tumor types (Poussaint, Panigrahy, & Huisman, 2015). The CT scan permits direct visualization of the brain parenchyma, ventricles, and surrounding subarachnoid space, and it is commonly used in urgent cases of suspected tumors when MRI is not available. Other tests may include an MRI of the spine and electroencephalography. In the presence of increased ICP, LP is avoided due to the danger of possible brainstem herniation after sudden release of pressure.

Definitive diagnosis is based on tissue specimens obtained during surgery. Classification of pediatric brain tumors is evolving, and it is important that the diagnostic tissue be examined by a neuropathologist with special expertise in this area (National Institutes of Health, 2019g). Occasionally, special techniques are required for determining the cell type. The location of some brain tumors, such as brainstem tumors, may mean biopsy is avoided and the diagnosis is made by imaging findings alone; however, this is changing with recognition that postoperative complications of biopsy are mostly transient.

Therapeutic Management

Treatment depends on the type of brain tumor and may involve the use of surgery, radiation therapy, and chemotherapy (as well as targeted therapy). All three may or may not be used, depending on the type of tumor. The treatment of choice is total removal of the tumor without residual neurologic damage. Patients with the most complete tumor removal have the greatest chance of survival. Several surgical advances have allowed the biopsy and removal of tumors in areas previously considered too dangerous for traditional operative techniques. Stereotactic surgery involves the use of CT and MRI in conjunction with other special computer techniques to reconstruct the tumor in three dimensions. With computer-assisted instruments, total resection of the tumor is sometimes possible. Stereotactic biopsy is performed with CT or MRI computer guidance for inserting the biopsy needle. This procedure has the benefit of a shorter hospital stay and a lower morbidity and mortality rate in comparison with an open craniotomy (Parsons et al., 2016). Other procedures include the use of lasers to vaporize tumor tissue and brain mapping to determine the precise location of critical brain areas to avoid during surgery.

Radiation therapy is used to treat most tumors and to shrink the size of the tumor before attempting surgical removal. The use of chemotherapy has had an increasingly important role, either in combination with surgery and/or radiation or alone. All three modes of therapy are associated with serious late effects. Surgery can cause injury to important areas of the brain, especially when the surgeon is attempting to remove invasive tumors. The long-term consequences of radiation therapy include tissue necrosis, subsequent malignancies, endocrine dysfunction, and behavioral or intellectual deficits. For these reasons, the use of irradiation is deferred for as long as possible in young children. Chemotherapy may allow a delay or reduction in radiation therapy. Targeted therapy is being used in some types of brain tumors. Proton beam radiation therapy, available at some sites, is being studied to learn whether it offers greater efficacy and less long-term toxicity (Parsons et al., 2016).

Nursing Care

Nursing care of the child with a brain tumor is similar regardless of the type of intracranial lesion. Because a brain tumor is potentially fatal, the reader is urged to incorporate the psychologic interventions discussed in Chapter 19 with those elaborated on in this section. However, it is important to remember that many brain tumors are curable. Medulloblastoma, for instance, has a survival rate of approximately 80% in those patients without metastatic disease. Despite the grave nature of some brain tumors, new and emerging therapies are bringing hope to the families of many pediatric patients with brain tumor.

Assess for Signs and Symptoms

A child admitted to the hospital with neurologic dysfunction is often suspected of having a brain tumor, even though the actual diagnosis is not yet confirmed. Establishing baseline data for comparing preoperative and postoperative changes is an essential step toward planning physical care and preventing complications. It also allows the nurse to assess the degree of physical incapacity and the family's emotional response to the diagnosis. For example, children with cerebellar astrocytoma may have displayed vague cerebellar symptoms for several years before a tumor is suspected. For these parents the revelation of a neoplasm may be as shocking as for those who witnessed a rapid deterioration in their child's abilities. Table 25.4 summarizes common presenting signs and assessment procedures to document significant changes in the child's condition.

Prepare the Family for Diagnostic and Operative Procedures

The suspected diagnosis of a brain tumor is always a crisis. Although some tumors are removed with excellent results, the physician can rarely give definitive answers regarding prognosis until after surgery. Therefore parents, the child, and other family members require excellent emotional support to face the diagnostic procedures and a craniotomy.

How the child is prepared for the diagnostic tests depends on the child's age and experience. Chapter 20 discusses preparing children for an MRI or a CT scan. Once surgery is scheduled, the child needs an explanation of what to expect. By the time most children are late preschoolers, they know that the head and brain are important parts of their body. It may be helpful to have children draw their concept of the brain to clarify misconceptions and base the explanation on their level of understanding. Although it may be tempting to justify the surgery by stating that removing the tumor will take away various symptoms, the nurse should refrain from emphasizing this point too strenuously. Postsurgical headaches and cerebellar symptoms, such as ataxia, may be aggravated rather than improved. Surgery may not improve vision. With optic gliomas, the child will be blind in one eye even if the tumor is fully resected. Finally, surgical removal of the mass may

TABLE 25.4 Clinical Manifestations and Assessment of Brain Tumors

Signs and Symptoms	Assessment
Headache	
Recurrent and progressive In frontal or occipital areas Usually dull and throbbing Worse on arising, less during day Intensified by lowering head and straining, such as during bowel movement, coughing, sneezing	Record description of pain, location, severity, and duration. Use pain rating scale to assess severity of pain (see Chapter 5). Note changes in relation to time of day and activity. Observe changes in behavior in infants (e.g., persistent irritability, crying, head rolling).
Vomiting	
With or without nausea or feeding Progressively more projectile More severe in morning on arising Relieved by moving about and changing position	Record time, amount, and relationship to feeding, nausea, and activity.
Neuromuscular Changes	
Incoordination or clumsiness Loss of balance (e.g., use of wide-based stance, falling, tripping, banging into objects) Poor fine motor control Weakness Hyporeflexia or hyperreflexia Positive Babinski sign Spasticity Paralysis	Test muscle strength, gait, coordination, and reflexes (see Chapter 4).
Behavioral Changes	
Irritability Decreased appetite Failure to thrive Fatigue (frequent naps) Lethargy Coma Bizarre behavior (e.g., staring, automatic movements)	Observe behavior regularly. Compare observations with parental reports of normal behavioral patterns. Monitor growth and food intake. Monitor activity and sleep.
Cranial Nerve Neuropathy	
Cranial nerve involvement varied according to tumor location Most common signs: • Head tilt • Visual defects (e.g., nystagmus, diplopia, strabismus, episodic "graying out" of vision, visual field defect)	Assess cranial nerves especially VII (facial), IX (glossopharyngeal), X (vagus), V (trigeminal sensory roots), and VI (abducens see Chapter 4). Assess visual acuity binocularity and peripheral vision (see Chapter 4).
Vital Sign Disturbances	
Decreased pulse and respiration Increased blood pressure Decreased pulse pressure Hypothermia or hyperthermia	Measure vital signs frequently. Monitor pulse and respirations for 1 full minute. Record pulse pressure (difference between systolic and diastolic blood pressure).
Other Signs	
Seizures Cranial enlargement[a] Tense, bulging fontanel at rest[a] Nuchal rigidity Papilledema (edema of optic nerve)	Record seizure activity (see Chapter 27). Measure head circumference daily (infant and child). Perform funduscopic examination if skilled in procedure.

[a]Present only in infants and young children.

be impossible, and after surgery functioning may temporarily deteriorate or result in permanent damage. Being honest before surgery most often makes honesty after the procedure easier because no false hopes were created.

The hair is usually shaved in the operating room just before surgery or sometimes in the child's room, typically on the night before surgery. When shaving is done with the child awake, the procedure is approached in a sensitive, positive way. If the child's hair is long, braid it so that the long swatch can be saved. Showing children how they look at different stages of the process helps them prepare for their changed appearance.

Once the hair is clipped short or shaved, give the child a cap or scarf to camouflage the baldness. Take every precaution to provide privacy during the procedure and to protect the child from teasing or ridicule by other children before surgery. Also emphasize that the hair will regrow shortly after surgery. Depending on the child's immediate adjustment to the hair loss, the nurse may introduce the idea of wearing a wig until the hair grows in, particularly if additional irradiation or chemotherapy is anticipated.

Also tell children about the size of the dressing. Usually the entire scalp is covered to maintain tight wound closure, even if a small incision is made. Infratentorial head dressings may be attached to the upper back and extend forward to the neck to maintain slight extension and alignment as a precaution against wound rupture. Applying a similar dressing or "special hat" to a doll is often a less traumatic way of demonstrating the physical appearance.

Children also need a brief explanation of how they will feel after surgery and where they will be. Ordinarily they will return to a special intensive care unit, which they may visit beforehand, depending on hospital policy. They should be aware that they may be sleepy for some time after surgery and that a headache is likely and may last for a few days.

Parents need similar explanations before surgery, especially in terms of special equipment used in the intensive care unit, dressings, and their child's behavior. For example, they should know that it is not unusual for the child to be lethargic for a few days after surgery. The nurse may wish to encourage less frequent visiting during this period so that parents can rest and be able to support their child when the child is awake. The nurse should participate in preoperative conferences with the physician and parents. The nurse needs to know what information the parents have been given in order to provide further explanations or emotional support as needed.

! NURSING ALERT

Report sluggish, dilated, or unequal pupils immediately because they may indicate increased intracranial pressure (ICP) and potential brainstem herniation—a medical emergency.

Prevent Postoperative Complications

After surgery the surgeon prescribes specific orders for taking vital signs, positioning, regulating fluids, and administering medication. These vary somewhat, depending on the location of the craniotomy. The following are general principles of care for patients undergoing infratentorial or supratentorial surgery. Chapter 27 discusses additional aspects of care, such as care of the child with seizures and care of the unconscious child in terms of respiratory status and neurologic assessment.

Assessment

Vital signs are taken as often as every 15 to 30 minutes until the patient is stable. Temperature measurement is particularly important because of hyperthermia resulting from surgical intervention in the hypothalamus or brainstem and from some types of general anesthesia. To prepare for this reaction, a cooling blanket may be placed on the bed before the child returns to the unit, or it may be used when needed. Because the temperature control centers are affected and hypothermia can occur suddenly, the nurse monitors body temperature often when any cooling measures are used.

! NURSING ALERT

To keep an accurate account of drainage, circle the soiled area with a pen and monitor for signs of continuous bleeding. The presence of colorless drainage is reported immediately because it most likely is cerebrospinal fluid leaking from the incisional area. A foul odor from the dressing may indicate an infection. Such a finding is reported, and a culture is taken.

The most likely types of infection are meningitis and respiratory tract infection. The probable cause of meningitis is wound contamination. The risk of respiratory tract infections is high because of the imposed immobility, danger of aspiration, and possible respiratory depression from the brainstem. The usual precautions of deep breathing and turning as allowed are instituted. Regular pulmonary assessments are performed to identify adventitious sounds or any areas of diminished or absent breath sounds. Blood pressure is also taken at frequent intervals. The deflated cuff is left on the arm between readings to allow for the least movement and disturbance of the child. Ocular signs are recorded at least every hour.

As soon as possible, the nurse should begin testing reflexes, hand grip, and functioning of the cranial nerves. Muscle strength is usually reduced after surgery because of general weakness but should improve daily. Ataxia may be significantly worse with cerebellar intervention, but it slowly improves. Edema near the cranial nerves may depress important functions such as the gag, blink, or swallowing reflex.

Neurologic checks are an essential aspect of care and include pupillary reaction to light, level of consciousness, sleep patterns, and response to stimuli. Although children may be comatose for a few days, once they regain consciousness there should be a steady increase in alertness. Regression to a lethargic, irritable state indicates increasing pressure, possibly caused by meningitis, hemorrhage, or edema.

Dressings are observed for evidence of drainage. If soiled, the dressing is not removed but reinforced with dry sterile gauze. The approximate amount of drainage is estimated and recorded.

Once the younger child is alert, the arms may need to be restrained to preserve the dressing. Even a child who has been cooperative before surgery must be closely supervised during the initial stages of regaining consciousness, when disorientation and restlessness are common. Elbow restraints are satisfactory to prevent the hands from reaching the head, although additional restraint may be necessary to preserve an infusion line and maintain a specific position.

Positioning

Correct positioning after surgery is critical to prevent pressure against the operative site, reduce ICP, and avoid the danger of aspiration. If a large tumor was removed, the child is not placed on the operative side because the brain may suddenly shift to that cavity, causing trauma to the blood vessels, linings, and the brain itself. The nurse confers with the surgeon to be certain of the correct position, including the degree of neck flexion. The first 24 to 48 hours after brain surgery are critical.

If positioning is restricted, notice of this is posted above the head of the bed. When the child is turned, every precaution is used to prevent jarring or misalignment to prevent undue strain on the sutures. Two nurses, one supporting the head and the other supporting the body, are needed. The use of a turning sheet may facilitate turning a heavy child.

! NURSING ALERT

The Trendelenburg position is contraindicated in both infratentorial and supratentorial surgeries because it increases intracranial pressure (ICP) and the risk of hemorrhage. If shock is impending, the practitioner is notified immediately, before the head is lowered.

The child with an infratentorial craniotomy is usually positioned flat and on either side. Pillows should be placed against the child's back, not head, to maintain the desired position. Ordinarily the head and neck are kept in midline with the body and slightly extended. After a supratentorial craniotomy the head is usually elevated above the heart to facilitate cerebrospinal fluid drainage and decrease excessive blood flow to the brain to prevent hemorrhage.

Fluid Regulation

With an infratentorial craniotomy the child is allowed nothing by mouth for at least 24 hours or longer if the gag and swallowing reflexes are depressed or the child is comatose. With a supratentorial procedure, feeding may be resumed soon after the child is alert, sometimes within 24 hours. Clear water is always started first because of the danger of aspiration. If the child vomits, stop oral liquids. Vomiting not only predisposes the child to aspiration but also increases ICP and the risk for incisional rupture.

IV fluids are continued until fluids are well tolerated by mouth. Because of cerebral edema postoperatively and the danger of increased ICP, fluids are carefully monitored and usually infused less than the maintenance rate. If drugs such as prophylactic antibiotics are given intravenously, the medication amount is calculated as part of the IV fluid. For example, if the child is to receive 20 ml/h and the diluted drug is 5 ml, the IV solution is reduced to 15 ml for that hour.

A hypertonic solution such as mannitol may be necessary to remove excess fluid. These drugs cause rapid diuresis. After surgery the child may have a Foley catheter in place. Urinary output is monitored after administration of these drugs to evaluate their effectiveness.

When able to take fluids, the child should be fed to conserve strength and minimize movement. If there is any sign of facial paralysis, the child is fed slowly to prevent choking or aspiration. Scrupulous mouth care is essential to prevent oral infection. Sometimes gavage feeding is necessary when body functions are too depressed to permit safe oral feedings or the child refuses to eat or drink. In the latter instance the nurse should use every measure to encourage acceptance of fluids or solids (see Chapter 20 for nursing interventions).

Comfort Measures

Headache may be severe and is largely the result of cerebral edema. Measures to relieve some of the discomfort include providing a quiet, dimly lit environment; restricting visitors; preventing any sudden jarring movement, such as banging into the bed; and preventing an increase in ICP. The last is most effectively achieved by proper positioning and prevention of straining, such as during coughing, vomiting, or defecating. The use of opioids, such as morphine, to relieve pain has been controversial because it is thought that they may mask signs of altered consciousness or depress respirations. However, opioids are considered safe because naloxone can be used to reverse opioid effects, such as sedation or respiratory depression. Acetaminophen and codeine are also effective analgesics. Regardless of the drugs used, adequate dosage and regular administration are essential to provide optimum pain relief (see Chapter 5, Pain Assessment and Pain Management).

Monitor bowel movements to prevent constipation. Stool softeners may be given as soon as liquids are tolerated to facilitate easy passage of stool.

Brain edema may severely depress the gag reflex, necessitating suctioning of oral secretions. Facial edema may also be present, necessitating eye care if the lids remain partially open. Ice compresses applied to the eyes for short periods help relieve the edema. A depressed blink reflex also predisposes the corneas to ulceration. Irrigating the eyes with saline drops and covering them with eye dressings are important steps in preventing this complication.

Support the Family

The family's informational and support needs are great when the diagnosis is a brain tumor and are influenced by the extent of surgery, any neurologic deficits, the prognosis, and additional therapy. Because few definitive answers can be given before surgery, the surgeon's report is a significant finding that can vary from a completely benign, resected neoplasm to a highly malignant, invasive, and only partially removed tumor. Although parents try to prepare themselves for a potentially fatal diagnosis, it is understandably a shock for them.

Ideally, a nurse who will be involved in the continuing care of this child should be with the family when the physician discusses the prognosis and plan of therapy. Although parents may absorb only a fraction of what they are told, they can begin to put the future into perspective. Regardless of the future prospects, direct the parents' thinking toward helping the child recover and resume a normal life to his or her fullest potential. Providing the opportunity for the family to share their concerns and questions with other families who have a child with a brain tumor may help the family cope, and the nurse can direct them to resources.[f]

It is also a time to encourage parents to verbalize their feelings about the diagnosis. Often they express guilt for attributing the insidious onset of symptoms, such as ataxia, visual difficulty, or headache, to minor "complaints" by the child. Parents may have punished their child for clumsiness, mistaking it for carelessness, or for their declining performance in school. The nurse listens to such statements and emphasizes the normality of the parents' reactions. Sometimes it may be helpful to start a discussion with a statement such as "It is difficult to know when a child's complaints are significant because so often they are caused by minor ailments and you would never have imagined they were the result of a brain tumor." The nurse avoids any comments that insinuate the parents should have sought medical advice sooner because such remarks only add to the parents' feelings of guilt.

During this period the nurse should also discuss with parents what they plan to tell the child. If the child was prepared honestly, as described previously, the diagnosis can be expressed in a similar manner, such as "The surgeon removed most of the tumor, and the rest will be treated with special drugs and x-ray treatments." During recovery the child needs additional explanation about the treatment and the reason for residual neurologic effects, such as ataxia or blindness.

[f]Information about support groups is available from the National Brain Tumor Society, 22 Battery St., Suite 612, San Francisco, CA 94111; 800-934-CURE; email: info@braintumor.org; http://www.braintumor.org; and the Pediatric Brain Tumor Foundation, 302 Ridgefield Court, Asheville, NC 28806; 800-253-6530; email: info@curethekids.org; http://www.curethekids.org.

Hair loss is a normal concern for the child, and hair regrowth will be delayed, depending on the length of therapy. This is an appropriate time to reintroduce the idea of a wig, scarf, or hat.

Promote Return to Optimum Functioning

The ultimate goal is a cured child who has optimum functioning. As soon as possible, the child should resume usual activities within tolerable limits, especially returning to school.[g] Until the skull is completely healed, the child may need to wear a helmet when engaging in any active sport. This decision is made by the child's neurosurgeon. The school nurse and teacher should confer with the parents on activity restrictions, such as physical education, as well as the reactions of schoolmates to the child's appearance.

After discharge the family needs continuing medical and emotional support from health personnel. Children who are long-term survivors after treatment for a brain tumor require ongoing follow-up due to residual disabilities, such as short stature, cranial nerve palsies, sensory defects, motor abnormalities (especially ataxia), intellectual deficits, dysphagia, dysgraphia, and behavioral problems (Parsons et al., 2016).

The realm of all possible consequences after the diagnosis of a brain tumor is not discussed here. The reader is referred to other sections of the text that deal with possible outcomes, such as the paralyzed, visually impaired, or unconscious child or the child with a ventricular shunt, seizure disorder, or meningitis. Numerous physical problems can occur with progression of the tumor, and these may necessitate additional procedures. For example, frequent vomiting, anorexia, and nausea may require nonoral routes of feeding, such as gastrostomy or parenteral alimentation. Trials with chemotherapy may necessitate the use of central venous access devices. Whenever these procedures are instituted, the nurse may be responsible for teaching the family appropriate home care to allow the child the highest quality of life for the longest time (see discussion of discharge planning and home care in Chapter 19).

NEUROBLASTOMA

With approximately 650 new cases of neuroblastoma diagnosed every year in the United States, neuroblastoma is the most common extracranial childhood solid tumor (National Institutes of Health, 2019h). It is a disease of infancy and early childhood, with a median age at diagnosis of about 19 months (Brodeur, Hogarty, Bagatell, et al., 2016). Neuroblastoma sometimes occurs in a hereditary form, although this is rare. Three genes or mutations that play a part in hereditary neuroblastoma have been identified (*ALK* and *PHOX2B*, deletion at 1p36 or 11q14-23 locus). Also, several syndromes contribute to neuroblastoma predisposition, including Costello and Noonan syndromes, and neurofibromatosis (Brodeur et al., 2016). Genomic studies (GWAS) are an active area of research. Within the tumor cells, a hallmark is amplification of an oncogene, *MYCN*, a variation seen in 16% to 25% of neuroblastoma tumors and mainly associated with high-risk disease.

Neuroblastomas originate from embryonic neural crest cells (neuroblasts) that normally give rise to the adrenal medulla and the sympathetic nervous system. Consequently, the majority of the tumors arise from the adrenal gland or in the neck, chest, or spinal cord.

[g]The American Brain Tumor Association has information on returning to school: 8550 W. Bryn Mawr Ave. Suite 550, Chicago, IL 60631; 1-800-886-2282; email: info@abta.org; http://www.abta.org/returning-to-school/.

Clinical Manifestations

The signs and symptoms of neuroblastoma depend on the location and extent of disease (National Institutes of Health, 2019h). The most common primary site is within the abdomen; other sites include the head and neck region, chest, and pelvis. With abdominal tumors, the most common presenting sign is a firm, nontender, irregular mass in the abdomen that crosses the midline (in contrast to Wilms tumor, which is usually confined to one side). Other signs related to abdominal location include pain or discomfort, vomiting, anorexia, and respiratory compromise; compression of the kidney, ureter, or bladder may cause urinary frequency or retention. Tumors in the thoracic or cervical region can involve dyspnea, Horner syndrome (ptosis, miosis, anhidrosis), neck mass, stridor, and dysphagia. Spinal cord and brain sites can present with neurologic deficits, difficulty breathing, bladder and bowel dysfunction, paraparesis, paraplegia, or seizures. Neuroblastoma that infiltrates the bone marrow can produce anemia, thrombocytopenia, and neutropenia. Tumors in the orbit or optic nerves can produce exophthalmos, periorbital ecchymosis, and impaired vision. Tumors in bone can result in pain or limping. Metastases to the skin can appear as subcutaneous skin nodules, described as "blueberry muffin lesions" due to their color; this is usually only seen in infants.

Diagnostic Evaluation

Diagnostic evaluation is aimed at determining the primary site and extent of disease. Physical exam and history, blood chemistry studies, and neurologic exam are performed. Tumor imaging by CT or MRI is used to locate the primary tumor in neck, chest, abdomen, and pelvis. Evaluation for metastases includes examination of the bone marrow with bilateral aspirates and biopsies and of the bony skeleton with MIBG scanning.

Neuroblastomas, particularly those arising on the adrenal glands or from a sympathetic chain, excrete the catecholamines epinephrine and norepinephrine. Urinary excretion of catecholamine metabolites (vanillylmandelic acid [VMA] and homovanillic acid [HVA]) is measured before therapy; these markers can be used to monitor response to therapy and detection of relapse after therapy (National Institutes of Health, 2019h).

Diagnosis is based on the presence of tumor cells in a biopsy of tumor tissue (biopsy also provides tissue for determining *MYCN* copy number [amplification] and other chromosomal or genetic tests) or the presence of tumor cells in bone marrow plus increased urinary catecholamine metabolites (National Institutes of Health, 2019h).

Staging and Prognosis

Neuroblastoma is a "silent" tumor. In more than 70% of cases, diagnosis is made after metastasis occurs, with the first signs caused by involvement in a nonprimary site, usually the lymph nodes, bone marrow, skeletal system, or liver. Accurate clinical staging is important for establishing initial treatment. The International Neuroblastoma Risk Group staging system is used to classify neuroblastoma patients to a pretreatment risk group based on International Neuroblastoma Risk Group image-defined risk factors, age, histologic category, grade of tumor differentiation, *MYCN* amplification, 11q aberration, and ploidy (National Institutes of Health, 2019h). Future versions of the International Neuroblastoma Risk Group staging system are expected to include more tumor genomic criteria as new biomarkers that affect outcomes are identified. The International Neuroblastoma Risk Group staging system is shown in Box 25.4.

Therapeutic Management

For patients considered to be low risk, treatment may include surgery followed by observation or chemotherapy (carboplatin, cyclophosphamide, doxorubicin, etoposide) with or without surgery for those with

BOX 25.4 Staging of Neuroblastoma by International Neuroblastoma Risk Group

Stage L1: Localized tumor not involving vital structures as defined by the list of image-defined risk factors and confined to one body compartment

Stage L2: Local-regional tumor with presence of one or more image-defined risk factors

Stage M: Distant metastatic disease (except stage MS)

Stage MS: Metastatic disease in children younger than 18 months with metastases confined to skin, liver, and/or bone marrow

Note: Patients with multifocal primary disease should be staged according to the greatest extent of disease. Image-defined risk factors are grouped by anatomic location and include multiple body compartments, neck, cervicothoracic junction, thorax, thoracoabdominal junction, abdomen and pelvis, and intraspinal tumor extension.

Data from Monclair, T., Brodeur, G. M., Ambros, P., et al. (2009). The International Neuroblastoma Risk Group (INRG) staging system: An INRG task force report. Journal of Clinical Oncology, 27(2), 298–303; and Chen, A. M., Trout, A. T., & Towbin, A. J. (2018). A review of image-defined risk factors on magnetic resonance imaging. Pediatric Radiology, 48, 1337–1347.

symptomatic disease or unresectable disease after surgery. For certain low-risk patients, observation without biopsy is being studied.

For intermediate-risk patients, treatment may include chemotherapy (carboplatin, cyclophosphamide, doxorubicin, etoposide) with or without surgery, surgery, and observation (infants). Radiation therapy is used for patients with progressive disease during chemotherapy or progressive unresectable disease after chemotherapy.

Patients with high-risk neuroblastoma are treated with chemotherapy (cisplatin, etoposide, vincristine, cyclophosphamide, doxorubicin, topotecan), surgery, tandem cycles of myeloablative therapy and HSCT, radiation therapy, immunotherapy, and retinoid therapy. This treatment is usually divided into three phases. Induction includes chemotherapy and surgery; consolidation includes tandem cycles of myeloablative therapy and HSCT; and postconsolidation includes radiation to the primary tumor site and residual metastatic sites, immunotherapy, and retinoid therapy. Treatment plans are actively being studied in order to improve response rates and reduce long-term complications.

Nursing Care

Nursing care is similar to that discussed under General Nursing Care Management, including psychologic and physical preparation for diagnostic and operative procedures; prevention of postoperative surgical complications; and explanation of chemotherapy, immunotherapy, HSCT, and radiation therapy, as well as their side effects as appropriate for the patient.

Because this tumor carries a poor prognosis for many children, the nurse evaluates and addresses the needs of the family in terms of coping with a life-threatening illness (see Chapter 17). Because of the high frequency of metastasis at the time of diagnosis, many parents suffer guilt for not having recognized signs earlier. Parents need skilled support in dealing with these feelings and expressing them to the appropriate members of the health care team. In addition, many neuroblastoma patients will go home with tube feedings, and the family will need relevant education and skills training.

BONE TUMORS

Osteosarcoma (OS) and Ewing sarcoma (EWS) are the primary bone tumors that occur most often in young people. Although both are bone tumors, they are different in many ways. OS is the most common bone tumor in adolescents and young adults, with approximately 400 new cases annually in the United States (National Institutes of Health, 2019i). EWS is less common, with about 200 cases diagnosed annually among children under the age of 20 years in the United States (Hawkins, Brennan, Bolling, et al., 2016). EWS occurs predominantly in whites, and more than half of affected patients are adolescents (National Institutes of Health, 2019j). Risk factors for OS include ionizing radiation exposure, genetic predisposition syndromes, and a history of retinoblastoma, particularly the hereditary form (Gorlick, Janeway, & Marina, 2016).

CLINICAL MANIFESTATIONS

Most malignant bone tumors produce localized pain in the affected site, which may be severe or dull and may be attributed to trauma or the vague complaint of "growing pains." The pain is often relieved by a flexed position, which relaxes the muscles overlying the stretched periosteum. Frequently a bone tumor draws attention when the child limps, curtails physical activity, or is unable to hold heavy objects. A palpable mass is also a common manifestation of bone tumors. Systemic symptoms (such as fever) and other clinical symptoms (such as spinal cord compression and respiratory distress) are more frequent in patients with Ewing sarcoma.

DIAGNOSTIC EVALUATION

Diagnosis begins with a thorough history and physical examination. A primary objective is to rule out causes such as trauma or infection. Careful questioning regarding pain is essential in attempting to determine the duration and rate of tumor growth. Physical assessment focuses on functional status of the affected area; signs of inflammation; size of the mass; and any systemic indication of generalized malignancy, such as anemia, weight loss, and frequent infection.

Definitive diagnosis is based on imaging studies, such as plain films and CT or MRI scan of the primary site, CT scan of the chest, and PET scan to evaluate metastasis. Because EWS may be found in bone marrow, a bone marrow examination is performed; this is not the case in patients with OS. A needle or surgical biopsy is necessary to establish the diagnosis. EWS most commonly involves the pelvis, long bones of the lower extremities, and chest wall; imaging reveals involvement of the diaphysis with detachment of the periosteum from the bone (Codman triangle). In OS, lesions are most commonly located in the metaphyseal region of the bone, often involving the long bones. Radial ossification in the soft tissue gives the tumor a "sunburst" appearance on plain radiograph. It should be noted that the particular radiology findings associated with bone tumors are not themselves diagnostic of either OS or EWS.

PROGNOSIS

A better understanding of the biology of neoplastic growth has resulted in more aggressive treatment and improved prognosis. The natural history of OS and EWS suggests that multiple submicroscopic foci of metastatic disease are present at the time of diagnosis despite clinical evidence indicating only localized involvement. The lungs, distant bones, and bone marrow are the most common sites for metastatic bone tumor disease. With current therapies that include surgery and chemotherapy for OS and surgery, radiation therapy, and chemotherapy for EWS, the majority of patients with localized disease can be cured.

Pretreatment factors that influence OS outcome include primary tumor site and initial treatment, size of the primary tumor, and presence of clinically detectable metastatic disease; postchemotherapy treatment factors that influence outcome include surgical resectability of the tumor and degree of tumor necrosis assessed by the pathologist. Greater tumor necrosis has been associated with better prognosis in OS (National Institutes of Health, 2019i). Older adolescents and young adults with OS tend to have a worse prognosis than do younger patients.

For patients with EWS, the pretreatment factors that are associated with better prognosis are distal site of tumor, extraskeletal primary tumor, smaller tumor size or volume (larger tumors tend to occur in unfavorable sites), younger age, female sex, lactic acid dehydrogenase (LDH) levels not increased, and absence of metastases. Adverse prognostic factors include pathologic fracture, previous cancer treatment, certain chromosomal abnormalities, and other biologic factors (National Institutes of Health, 2019j). A key feature of EWS (in 85% of cases) is the translocation between chromosomes 11 and 22, fusing the *EWS* gene of chromosome 22 to the *FLLI1* gene of chromosome 11.

OSTEOSARCOMA

Osteosarcoma occurs most often in adolescents and young adults, coinciding with the period of rapid bone growth (Gorlick et al., 2016; National Institutes of Health, 2019i). It presumably arises from bone-forming mesenchyme, which gives rise to malignant osteoid tissue. Most primary tumor sites are in the diametaphyseal region (wider part of the shaft, adjacent to the epiphyseal growth plate) of long bones, especially in the lower extremities. More than half occur in the femur, particularly the distal portion, with the rest involving the humerus, tibia, pelvis, jaw, and phalanges.

Therapeutic Management

Optimum treatment of OS includes surgery and chemotherapy. The surgical approach consists of surgical biopsy followed by either limb salvage or amputation. Biopsy and surgery should be performed by an orthopedic oncology surgeon. To ensure local control, all gross and microscopic tumors must be resected. A limb salvage procedure has become the standard approach to surgical intervention and involves resection of the primary tumor with prosthetic replacement of the involved bone (Gorlick et al., 2016). For example, with OS of the distal femur, a total femur and joint replacement is performed. Frequently children undergoing a limb salvage procedure receive preoperative chemotherapy in an attempt to decrease the tumor size and make surgery more manageable (Gorlick et al., 2016).

Treatment for OS with few exceptions is preoperative chemotherapy, local control, and postoperative chemotherapy. The standard of care for localized OS is three-drug treatment with cisplatin, doxorubicin, and methotrexate with citrovorum. These combined-modality approaches have significantly improved the prognosis in OS to approximately 70% for patients with nonmetastatic disease (Gorlick et al., 2016). OS is not a very radiation-sensitive tumor. Thus radiation is used only in palliative situations for unresectable tumors of the axial skeleton.

Nursing Care

Nursing care depends on the type of surgical approach. The family may or may not have more difficulty adjusting to an amputation than a limb salvage procedure. In either instance, preparation of the child and family is critical. Straightforward honesty is essential in gaining the child's cooperation and trust. The emphasis is on early preparation and planning with the child and family. This is done with the multidisciplinary treating team, including the oncologist, surgeon, advanced practice registered nurse (APRN), physical therapist, psychologist, and social worker, as well as the staff nurse. It is a process, not a one-time discussion, in order to allow time to think about the diagnosis and consequent treatment and to ask questions.

Sometimes children have many questions about the prosthesis, limitations on physical ability, and prognosis in terms of cure. At other times they react with silence or with a calm manner that belies their concern and fear. Either response must be accepted because it is part of grieving the loss of an aspect of their physical appearance and function. For those who desire information, it may be helpful to introduce them to another amputee or survivor with a limb salvage procedure before surgery or to show them pictures of the prosthesis.[h] However, the nurse must be careful not to overwhelm children with information. A sound approach is to answer questions without offering additional information. For those who do not pursue additional information, the nurse expresses a willingness to talk.

Children are informed of the need for chemotherapy from the beginning of the treatment process through surgery and beyond. Children have a variety of responses to side effects of chemotherapy. The nurse should be aware of expected side effects, normalize the patient's responses, and be aware of resources within the hospital and outside the hospital for patients.

If an amputation is performed, the child may be fitted with a temporary prosthesis immediately after surgery, which permits early functioning and fosters psychologic adjustment. Stump care is provided the same as for any amputee. A permanent prosthesis is typically fitted within 6 to 8 weeks. During hospitalization the child begins physical therapy to become proficient in the use and care of the device. Wound healing is a significant issue for patients with OS, and they may have a significant delay in getting their prosthesis if they do not have complete surgical incisional healing. This can be frustrating and difficult for patients who are actively receiving chemotherapy and likely to have delayed healing.

Phantom limb pain may develop in 60% to 80% of patients after amputation. The exact pathophysiology is still unclear but may include a combination of physical and psychologic factors that need to be further clarified by research (Luo & Anderson, 2016). This symptom is characterized by sensations such as tingling, itching, and, more frequently, pain felt in the amputated limb. The child and family need to know that the sensations are real, not imagined. Although various pharmacologic and nonpharmacologic techniques have been used for phantom limb pain, none provides complete relief or is curative (Luo & Anderson, 2016). A study of pediatric patients with cancer-related amputation found that 76% had phantom limb pain during the first year after amputation, but only 10% still had phantom limb pain more than 1 year after amputation (Burgoyne, Billups, Jirón, et al., 2012). The nurse works with the institution's pain team to address the problem of phantom limb pain.

Discharge planning begins early in the postoperative period. Once the child has begun physical therapy, the nurse consults with the therapist and oncology team to evaluate the child's physical and emotional readiness to reenter school. However, patients with OS often do not attend school until their intense chemotherapy is complete and efforts are made to maintain school work until the end of treatment. Every effort is made to promote normality and gradual resumption of realistic presurgery activities. Role playing in anticipation of such

[h]Information about prostheses can be obtained from the National Amputation Foundation, 40 Church St., Malverne, NY 11565; 516-887-3600; http://www.nationalamputation.org.

experiences is beneficial in preparing the child for inevitable confrontations by others. Environmental barriers, such as stairs, are assessed in terms of accessibility in the school and home, especially because the child may need to use crutches or a wheelchair before complete healing and prosthetic competency are achieved. Information about special programs for children with amputations is available from the American Childhood Cancer Organization (see footnote earlier in the chapter).

The nurse encourages the child to select from among the many options available for personalization of prosthetics and sleeves. Well-fitted prostheses are so natural looking that girls usually can wear sheer stockings without revealing the device if that is their desire. The key is that the child can personalize the prosthetic device and apparel according to personal preference.

The family and child need much support in adjusting not only to a life-threatening diagnosis but also to alteration in body form and function. Because loss of a limb entails a grieving process, those caring for the child need to recognize that reactions of anger and depression are normal and necessary. Often parents view anger as a direct affront to them for allowing the amputation to occur, or they see the depression as rejection. These are not personal attacks but the child's attempts to cope with a loss. Psychosocial support programs (or members of the health care team such as psychologists, social workers, and child life specialists) at the institution may be particularly helpful in supporting the patient's and family's strengths in coping.

EWING SARCOMA (PRIMITIVE NEUROECTODERMAL TUMOR OF THE BONE)

Ewing sarcomas, or the EWS family of tumors, which includes primitive neuroectodermal tumor of the bone, are the second most common malignant bone tumor (after OS) in childhood (Hawkins et al., 2016). EWS arises in the marrow spaces of the bone rather than from osseous tissue. The tumor originates in the shaft of long and trunk bones, most often affecting the pelvis, femur, tibia, fibula, humerus, ulna, vertebra, scapula, ribs, and skull (Hawkins et al., 2016).

Therapeutic Management

Surgery is the main local therapy for EWS. However, radiation may be used for patients with unresectable disease or for patients who would have functional compromise by surgery (National Institutes of Health, 2019j). Limb salvage procedures may be feasible in extremity lesions, although amputation may be considered if the results of radiation therapy would render the extremity useless or deformed (e.g., from growth retardation in young children). Patients with EWS are encouraged to have surgical resection when possible, however, because it is associated with a slight survival advantage and fewer long-term morbidities.

The treatment of choice for most localized lesions is involved-field radiation therapy and chemotherapy. The standard chemotherapy protocol includes vincristine, doxorubicin, ifosfamide, and etoposide; cyclophosphamide and dactinomycin may also be used. High-dose chemotherapy with stem cell rescue may be used for patients at high risk of relapse.

Approximately two-thirds of patients with localized EWS can expect to be cured (Hawkins et al., 2016). Improving survival, especially for patients with metastatic or recurrent disease, is a focus of ongoing research.

Nursing Care Management

Ewing sarcoma differs from OS because preservation of the affected limb is more likely. Families may accept the diagnosis with some relief in knowing that this type of bone cancer does not necessitate amputation. They need preparation for the various diagnostic tests, including bone marrow aspiration and surgical biopsy, and adequate explanation of the treatment regimen.

High-dose radiation therapy often causes a skin reaction of dry or moist desquamation followed by hyperpigmentation. The child should wear loose-fitting clothes over the irradiated area to minimize additional skin irritation. Because of increased sensitivity, the area should be protected from sunlight and sudden changes in temperature, such as from heating pads or ice packs. Encourage the child to use the extremity as tolerated. The physical therapist may plan an active exercise program to preserve maximum function.

The child needs the same considerations for adjusting to the effects of chemotherapy as any other patient with cancer. The drug regimen usually results in hair loss, severe nausea and vomiting, peripheral neuropathy, and possible cardiotoxicity. Make every effort to outline a treatment plan that allows the child maximum resumption of a normal lifestyle and activities.

OTHER SOLID TUMORS

In addition to the cancers already discussed, several other types of solid tumors may occur in children. This section covers Wilms tumor, rhabdomyosarcoma, and retinoblastoma. These tumors tend to be diagnosed early, typically before 5 years of age. Wilms tumor and retinoblastoma are unusual in that they are among the few types of cancer that may occur in both hereditary and nonhereditary forms.

WILMS TUMOR

Of the many types of childhood kidney tumors, Wilms tumor (nephroblastoma) is the most common, with approximately 650 new cases per year in the United States (National Institutes of Health, 2019k). The average age at diagnosis is 44 months in children with tumor in one kidney but younger (31 months) in those with tumor in both kidneys. Although the specific cause is unknown, certain genetic syndromes or conditions increase the risk of Wilms tumor, such as WAGR (**W**ilms tumor, **a**niridia, **g**enitourinary anomalies, and cognitive impairment [mental **r**etardation]), Denys-Drash, and Beckwith-Wiedemann syndromes (hemihypertrophy, macroglossia, omphalocele, and visceromegaly) (National Institutes of Health, 2019k). Approximately 10% of children with Wilms tumor have congenital anomalies, such as cryptorchidism or hypospadias.

A number of genes and chromosomal alterations have been implicated in the biology of Wilms tumor, including *WT1, CTNNB1*, *WTX* on the X chromosome, imprinting cluster regions on chromosome 11p15 (*WT2),* and other genes or chromosomal alterations (National Institutes of Health, 2019k). Families of children at significantly increased risk of developing Wilms tumor are referred for genetic or genomic testing and counseling. In addition, children at increased risk are usually screened with ultrasound every 3 months until they are 8 years of age (National Institutes of Health, 2019k).

Clinical Manifestations

The most common presenting sign is swelling or mass within the abdomen; pain is present in about 40% of patients (Fernandez, Geller, Ehrlich, et al., 2016). The mass is characteristically firm, nontender, confined to one side, and deep within the flank. If it is on the right side, it may be difficult to distinguish from the liver, although unlike that organ, it does not move with respiration. The mass is typically discovered during routine bathing or dressing of the child.

Other clinical manifestations may result from compression by the tumor mass, metabolic alterations secondary to the tumor, or metastases. Hematuria occurs in less than one-fourth of children with Wilms tumor. Anemia, usually secondary to hemorrhage within the tumor, results in pallor, anorexia, and lethargy. Hypertension, probably caused by secretion of excess amounts of renin by the tumor, occurs in about 25% of children. Other effects of malignancy include anorexia, weight loss, and fever (10%). If pulmonary metastasis has occurred, symptoms of lung involvement, such as dyspnea, cough, shortness of breath, and pain in the chest, may be evident.

Diagnostic Evaluation

In a child suspected of having Wilms tumor, special emphasis is placed on the history and physical examination for the presence of congenital anomalies (e.g., aniridia, developmental delay, hypospadias, cryptorchidism); a family history of cancer; and clinical signs of Wilms tumor. The diagnostic workup includes abdominal imaging studies (abdominal x-ray, ultrasound, CT or MRI of the abdomen); chest x-ray; CT of the chest to look for lung metastases; and von Willebrand disease workup. Laboratory studies should include a CBC (polycythemia is sometimes present if the tumor secretes excess erythropoietin), biochemical studies, and urinalysis. Studies to assess intravascular extension of the tumor and tumor rupture also are performed.

Staging and Prognosis

There are two main staging systems for Wilms tumor, one used by the Children's Oncology Group and the other used by the European group SIOP. In the Children's Oncology Group system, disease staging (ranging from stage I to V) is determined by results of imaging studies and pathologic findings at nephrectomy (Box 25.5), with stage I being localized to one kidney and stage V indicating bilateral involvement by tumor (National Institutes of Health, 2019k). The histology of the tumor cells is classified into two groups: favorable histology (FH) and anaplastic (unfavorable) histology; the anaplastic group is further subdivided into diffuse and focal (Fernandez et al., 2016).

Prognosis depends on histology of the tumor (FH versus anaplastic), stage of disease at diagnosis, molecular features of the tumor, and age. Five-year survival rates for Wilms tumor with FH are above 90%. Anaplastic histology, disseminated disease, 1q gain, and older age confer a worse prognosis (National Institutes of Health, 2019k).

Therapeutic Management

The standard of care is combined treatment with surgery and chemotherapy; radiation therapy may be used, based on clinical stage and tumor histology. In unilateral disease, nephrectomy and lymph node sampling are performed; a transabdominal or thoracoabdominal incision is used for greatest visibility of the kidney. Great care is taken to keep the encapsulated tumor intact because intraoperative spill can seed cancer cells throughout the abdomen, lymph channel, and bloodstream. If imaging studies do not indicate bilateral kidney involvement, exploration of the contralateral kidney is not necessary during the operative procedure (National Institutes of Health, 2019k).

In the United States, the standard approach to treatment is immediate surgery followed by postoperative chemotherapy, except for selected cases who do not receive chemotherapy; in advanced stages, radiation therapy is used in a risk-adapted approach. Standard chemotherapy regimens for Wilms tumor include some or all of the following: vincristine, dactinomycin, doxorubicin, cyclophosphamide, and etoposide. Postoperative radiation therapy is indicated for children with tumors classified as stage II focal or diffuse anaplastic histology, stage III, and stage IV (National Institutes of Health, 2019k). Options for stage V tumors may include preoperative chemotherapy and surgery and/or renal transplantation.

The child may be treated with chemotherapy preoperatively under some circumstances (e.g., tumor is bilateral or child has a single kidney) after biopsy confirmation of the diagnosis. The rationale is that preoperative chemotherapy reduces the size and vascular supply of the tumor, thereby making tumor removal easier (National Institutes of Health, 2019k).

BOX 25.5 Children's Oncology Group Staging of Wilms Tumor

Stage I: Tumor is limited to one kidney and completely resected without rupture or previous biopsy. All sampled lymph nodes negative for tumor.
Stage II: Tumor extends beyond kidney but is completely resected; lymph nodes do not contain tumor cells.
Stage III: There is postoperative residual tumor confined to abdomen. Lymph nodes in abdomen or pelvis contain tumor cells.
Stage IV: Hematogenous metastases with disease spread to the lung, liver, bone, brain, or distant lymph nodes.
Stage V: Bilateral renal involvement is present at diagnosis.

Nursing Care

The nursing care of the child with Wilms tumor is similar to that of other cancers treated with surgery and chemotherapy and possibly radiation therapy. However, some significant differences are discussed for each phase of nursing intervention.

Preoperative Care

As with most cancers, the diagnosis of Wilms tumor is a shock for the family. Frequently the child has no physical indication of the seriousness of the disorder other than a palpable abdominal mass. The nurse needs to take particular account the parents' feelings, since parents are often the ones who discover the mass. Whereas some parents are grateful for detecting the tumor so that it can be treated, others feel guilty for not finding it sooner or feel angry toward the health care professional, believing it was missed on earlier examinations.

The preoperative period is one of swift diagnostic workup. Typically, surgery is scheduled within 24 to 48 hours of admission. The nurse is faced with the challenge of preparing the child and parents for all laboratory and operative procedures. Explanations should be simple and repeated, with attention to what the child will experience. In addition to usual preoperative observations, blood pressure is monitored because hypertension from excess renin production is possible.

There are several special preoperative concerns, the most important of which is not to palpate the tumor unless absolutely necessary because manipulation of the mass may cause dissemination of cancer cells to adjacent and distant sites.

! NURSING ALERT

To reinforce the need for caution, it may be necessary to post a sign on the bed that reads "Do not palpate abdomen." Careful bathing and handling are also important in preventing trauma to the tumor site.

Because chemotherapy and radiation therapy (if used) are usually begun immediately after surgery, parents need an explanation of what to expect, such as major benefits and side effects, although the timing of the information should be considered to avoid overwhelming the family. Ideally the nurse should be present during physician-parent conferences to answer questions as they arise afterwards.

Postoperative Care

Despite the extensive surgical intervention necessary in many children with Wilms tumor, the recovery period is usually rapid. The major nursing responsibilities are those after any abdominal surgery. Because of the risk for intestinal obstruction from vincristine-induced adynamic ileus, radiation-induced edema, and postsurgical adhesion formation, the nurse monitors gastrointestinal activity, such as bowel movements, bowel sounds, distention, and vomiting. Other considerations are frequent evaluation of blood pressure and observation for signs of infection, especially during chemotherapy.

Support the Family

The postoperative period may be difficult for parents. The shock of seeing their child immediately after surgery may be the first realization of the seriousness of the diagnosis. From surgery, the stage and pathology of the tumor are determined. The physician discusses this information with the parents. The nurse's presence during this conversation is important to provide additional support and assess the parents' understanding of the information.

Children need an opportunity to deal with their feelings concerning the many procedures to which they have been subjected in rapid succession. Therapeutic play can be beneficial in helping children understand what they have undergone and express their feelings.

RHABDOMYOSARCOMA

Sarcomas, including rhabdomyosarcoma (*rhabdo* means striated), are tumors arising from mesenchymal cells, which normally develop into muscle and other tissues (Wexler, Skapek, & Helman, 2016). Approximately 400 new cases are diagnosed in the United States each year, with almost two-thirds occurring in children younger than 10 years of age; a smaller peak in incidence occurs in early to middle adolescence (Wexler et al., 2016).

Rhabdomyosarcomas originate from undifferentiated mesenchymal cells in muscles, tendons, bursae, and fascia or in fibrous, connective, lymphatic, or vascular tissue. The most common primary sites are the head and neck (especially the orbit), the genitourinary tract, and the extremities, but these tumors can occur in other sites as well.

Rhabdomyosarcoma is classified into histologic subtypes (Box 25.6): embryonal, alveolar, and pleomorphic. More than half are embryonal. Risk factors for rhabdomyosarcoma include high birth weight (embryonal rhabdomyosarcoma) and several genetic conditions, including Li-Fraumeni syndrome, neurofibromatosis type 1, Costello syndrome, and Beckwith-Wiedemann syndrome. At the molecular level, embryonal and alveolar histologies are associated with characteristic genetic abnormalities. As one example, translocations between the *FOXO1* gene on chromosome 13 and either the *PAX3* gene on chromosome 2 or the *PAX7* gene on chromosome 1 are seen in 70% to 80% of alveolar tumors (National Institutes of Health, 2019l).

Clinical Manifestations

The initial signs and symptoms are related to the site of the tumor and compression of adjacent organs (Table 25.5). Some tumor locations, such as the orbit, manifest early in the course of the illness. Other tumors, such as those of the retroperitoneal area, produce symptoms only when they are large enough to cause organ compression. Unfortunately, many of the signs and symptoms attributable to rhabdomyosarcoma are vague and frequently suggest a common childhood illness, such as "earache" or "runny nose." Often it is not possible to identify the site of the primary tumor.

BOX 25.6 Subtypes of Rhabdomyosarcoma

- **Embryonal**—Most common type; most frequently found in the head, neck, abdomen, and genitourinary tract
- **Alveolar**—Second most common type; most often seen in deep tissues of the extremities and trunk
- **Pleomorphic**—Rare in children (adult form); most often occurs in soft parts of extremities and trunk

TABLE 25.5 Clinical Manifestations of Rhabdomyosarcoma According to Tumor Site

Location	Signs and Symptoms
Orbit	Rapidly developing unilateral proptosis Ecchymosis of conjunctiva Loss of extraocular movements (strabismus)
Nasopharynx	Stuffy nose (earliest sign) Nasal obstruction—dysphagia, nasal voice (obstruction of posterior nasal conches), serous otitis media (obstruction of eustachian tube) Pain (sore throat and ear) Epistaxis Palpable neck nodes Visible mass in oropharynx (late sign)
Paranasal sinuses	Nasal obstruction Local pain Discharge Sinusitis Swelling
Middle ear	Signs of chronic serous otitis media Pain Sanguinopurulent drainage Facial nerve palsy
Retroperitoneal area (usually a "silent" tumor)	Abdominal mass Pain Signs of intestinal or genitourinary obstruction
Perineum	Visible superficial mass Bowel or bladder dysfunction (from tumor compression)

Diagnostic Evaluation

Diagnosis begins with a careful history and physical examination, imaging studies, and baseline laboratory studies. An extensive evaluation is then performed to determine the extent of disease. Metastatic evaluation includes chest x-ray and CT scan, CT or MRI for abdominal or pelvic tumors, MRI of the skull and brain for parameningeal tumors, imaging of regional lymph nodes, bilateral bone marrow aspirates and biopsies, and bone scan for selected patients. An excisional biopsy or surgical resection of the tumor, when possible, is done to confirm the diagnosis.

Staging and Prognosis

Careful staging is extremely important for planning treatment and determining the prognosis. Two staging systems are used in

BOX 25.7 Surgicopathologic Staging of Rhabdomyosarcoma

Group I: Localized disease; tumor completely resected and regional nodes not involved
Group II: Localized disease; tumor completely removed; microscopic residual that may have spread into nearby lymph nodes
Group III: Incomplete resection with gross residual disease
Group IV: Metastatic disease present at diagnosis

combination: a surgicopathologic staging system (Box 25.7) and a modified tumor, node, metastasis (TNM) pretreatment staging system. A stage is assigned, based on primary site, tumor size, and whether there is regional lymph node involvement or distant metastasis. A group is assigned based on the status of the surgical resection or biopsy, pathologic assessment of the tumor margin, and lymph node involvement before therapy. Then a risk group is assigned, based on stage, group, and histology (National Institutes of Health, 2019l). Risk refers to the risk of disease recurrence.

Prognosis is related to age, with children ages 1 to 9 years having the best prognosis; primary tumor site, size, and resectability; whether there is lymph node involvement or metastasis at diagnosis; and histologic subtype. The alveolar histologic subtype is associated with worse outcomes. Most rhabdomyosarcomas are curable with the use of contemporary multimodal therapy. More than 70% of patients with localized disease are expected to survive (Wexler et al., 2016). However, if relapse occurs, the prognosis for long-term survival is poor.

Therapeutic Management

Rhabdomyosarcoma is treated with multimodality therapy that includes chemotherapy plus surgery or radiation therapy, or both modalities. The intensity and duration of chemotherapy are based on risk group. Some or all of the following chemotherapeutic drugs are used: vincristine, dactinomycin, cyclophosphamide, ifosfamide, irinotecan, vinorelbine, and doxorubicin. Complete resection of the primary tumor before chemotherapy is advocated whenever possible, if it will not result in disfigurement, functional compromise, or organ dysfunction (National Institutes of Health, 2019l). Otherwise, only an initial biopsy is performed. Radiation therapy is based on risk group and tailored to the primary site and the sites of metastatic disease.

Nursing Care

The nursing responsibilities in caring for a child with rhabdomyosarcoma are similar to those for other types of cancer, especially the other solid tumors for which surgery is used. Specific objectives include careful assessment for signs of tumor, especially during well-child examinations; preparation of the child and family for the multiple diagnostic tests; and supportive care during each stage of multimodal therapy. The reader is urged to review the General Nursing Care Management section earlier in the chapter and Chapter 17 for emotional support of the family in the event of a poor prognosis.

RETINOBLASTOMA

Retinoblastoma, so named because it arises from the retina, is the most common intraocular malignancy of childhood, with approximately 300 new cases diagnosed annually in the United States (Hurwitz, Shields, Shields, et al., 2016). Retinoblastoma can be present at birth, can have single or multiple foci in one or both eyes, and occurs in a heritable form. Of all cases of retinoblastoma, 60% are unilateral and nonhereditary (also called sporadic), 25% are bilateral and hereditary, and 15% are unilateral and hereditary (Hurwitz et al., 2016). Retinoblastoma occurs predominantly in very young children; most cases are diagnosed before 2 years of age (National Institutes of Health, 2019m).

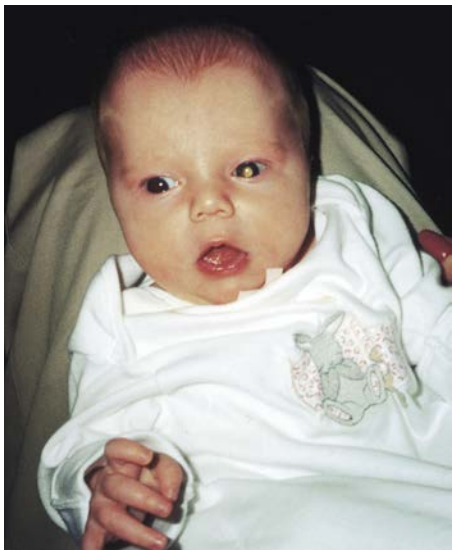

Fig. 25.6 Cat's eye reflex. Whitish appearance of lens is produced as light falls on tumor mass in left eye.

Children with hereditary retinoblastoma tend to be diagnosed at a younger age. In the hereditary form of retinoblastoma, germline mutation of the *RB1* gene is present. The mutation may have been inherited, occurred in a germ cell before conception, or occurred in utero during embryogenesis (Hurwitz et al., 2016). The "two-hit model" was developed to explain hereditary and sporadic retinoblastoma. According to the model, as few as two mutation events can lead to tumor formation; in the hereditary form, the "first hit" occurs in the germline, whereas both hits occur somatically in the sporadic form.

Clinical Manifestations

Retinoblastoma has few grossly obvious signs. Typically parents or relatives are the ones who first observe a whitish "glow" in the pupil, known as the **cat's eye reflex**, or **leukocoria** (Fig. 25.6), which prompts ophthalmoscopic examination. The reflex represents visualization of the tumor as light momentarily falls on the mass. When a tumor arises in the macular region (area directly at the back of the retina when the eye is focused straight ahead), a white reflex may be visible when the tumor is small. It is best observed when a bright light is shining toward the child as the child looks forward, which is why it may be discovered when a flash photograph is taken.

When the tumor arises in the periphery of the retina, it must grow to a considerable size before light can strike it sufficiently to produce the cat's eye reflex. In this situation it is visible only when the child looks sideways or if the observer stands at an oblique angle to the child's face as the child looks straight ahead. The fleeting nature of the reflex often results in a delayed diagnosis because health care professionals fail to appreciate the ominous significance of the parents' observation.

The next most common sign is strabismus resulting from poor fixation of the visually impaired eye, particularly if the tumor develops in the macula, the area of sharpest visual acuity. Blindness is usually a late sign, but it may not be obvious unless the parent or other caregiver consciously observes for behaviors indicating loss of sight, such as bumping into objects, slowed motor development, or turning of

BOX 25.8 International Classification of Retinoblastoma

Group A: Small (3 mm or less) intraretinal tumors away from the optic disc and foveola

Group B: All remaining tumors that are larger than 3 mm and/or close to the optic disc or foveola but remain confined to the retina

Group C: Discrete local disease with minimal disease under the retina (subretinal seeding) or in the gelatinous material of the eye (vitreous seeding)

Group D: Large or poorly defined tumors with significant vitreous or subretinal seeding; retina may have become detached from the back of the eye

Group E: Tumor is very large, extending near the front of the eye; is bleeding or causing glaucoma; or has other features that indicate it is not possible to save the eye

the head to see objects lateral to the affected eye. Other late signs and symptoms include pain, orbital cellulitis, and glaucoma.

Diagnostic Evaluation

A detailed family history and recording of eye signs and symptoms are essential. Children suspected of having retinoblastoma are referred to an ophthalmologist; the diagnosis usually is based on indirect ophthalmoscopy (under anesthesia), ultrasound, CT, and MRI scans. Blood and tumor samples can be tested for *RB1* gene mutations.

Metastatic disease at the time of retinoblastoma diagnosis is rare. For patients with suspected metastatic disease, bone marrow aspirates and biopsies, bone scan, and LP may be performed.

Staging and Prognosis

Staging of retinoblastomas is done under indirect ophthalmoscopy before surgery to accurately determine the tumor size (measured in disc diameter [DD]) and location (according to an imaginary line called the equator drawn on the midplane of the eye) (Hurwitz et al., 2016).

Various classification systems have been used to stage or group retinoblastomas. The Reese-Ellsworth system classifies tumors according to five groups and is used to compare therapeutic results in patients treated with methods other than enucleation (i.e., radiation therapy). A revised classification system, the International Classification of Retinoblastoma, is based on the extent and location of the intraocular tumor; it better predicts globe salvage using contemporary treatments (Box 25.8). The overall 10-year survival rate is nearly 90% for unilateral and bilateral tumors (Hurwitz et al., 2016). Like neuroblastoma, retinoblastoma may spontaneously regress.

A major concern for long-term survivors is the development of SNs. Children with bilateral disease (hereditary form) are more likely to develop subsequent cancers than are children with unilateral disease, and radiation therapy increases their risk.

Therapeutic Management

Treatment of retinoblastoma is complex. Enucleation may be used to treat advanced disease with optic nerve invasion in which vision cannot be salvaged. Radiation therapy can be used when there is vitreous seeding. Chemotherapy has been used to decrease the tumor size to allow treatment with local therapies such as plaque brachytherapy (surgical implantation of an iodine-125 applicator on the sclera until the maximum radiation dose has been delivered to the tumor), photocoagulation (use of a laser beam to destroy retinal blood vessels that supply nutrition to the tumor), and cryotherapy (freezing of the tumor, which destroys the microcirculation to the tumor and the cells themselves through microcrystal formation). Chemotherapy, along with radiation or high-dose chemotherapy with autologous stem cell rescue, is used to treat metastatic disease (Hurwitz et al., 2016).

Fig. 25.7 Infant with left prosthetic eye.

Nursing Care

Prepare the Family for Diagnostic and Therapeutic Procedures and Home Care

Because the tumor is usually diagnosed in infants or very young children, most of the preparation for diagnostic tests and treatment involves parents. Once the disease is staged, the treating team confers with the parents regarding the plan of care. In most cases, enucleation can be avoided. If enucleation is performed, the procedure and the benefits of a prosthesis are explained. Showing parents pictures of another child with an artificial eye may help with adjustment to the procedure (Fig. 25.7). Although the loss of vision is distressing, acknowledging the significance of the loss and emphasizing that the unaffected eye retains normal vision and that the affected eye is probably already blind may be helpful in promoting acceptance of the imposed impairment.

After surgery the parents need to be prepared for the child's facial appearance. An eye patch is in place, and the child's face may be edematous and ecchymotic. Parents often fear seeing the surgical site because they imagine a cavity in the skull. On the contrary, the lids are usually closed, and the area does not appear sunken because a surgically implanted sphere maintains the shape of the eyeball. The implant is covered with conjunctiva, and when the lids are open, the exposed area resembles the mucosal lining of the mouth. Once the child is fitted for a prosthesis, usually within 3 weeks, the facial appearance returns to normal.

After an uneventful recovery from enucleation, plans can be made for discharge from the hospital, usually within 3 to 4 days postoperatively. Parents need instruction on care of the surgical site and preparation for any additional therapy. They should be given the opportunity to see the socket as soon after surgery as possible. A good time to do this without unduly pressuring them is during dressing changes. They should then be encouraged to participate in the dressing changes.

Care of the socket is minimal and easily accomplished. The wound itself is clean and has little or no drainage. If an antibiotic ointment is prescribed, it is applied in a thin line on the surface of the tissues of the socket. The dressing consists of an eye pad changed daily. Once the socket has healed completely, a dressing is no longer necessary, although there are several reasons for having the child continue to wear an eye patch. Infants and toddlers explore their environment with their hands, and without an eye patch in place, the socket is available to

exploring fingers. Although there is little danger of the child injuring the socket, parents may feel more secure with the socket covered. This also helps prevent infection.

The ocularist, who fits and manufactures the prosthesis, gives initial instructions for care of the device. Once in place, the prosthesis need not be removed unless cleaning is necessary, in which case it is taken out by gently pulling down on the lower lid, which frees the lower edge of the prosthesis, and applying pressure to the upper lid. The prosthesis is cleaned by placing it in hot water and soaking it for several minutes. Reinsertion is easier if the prosthesis remains wet. To reinsert the prosthesis, the lids are separated, and with the prosthesis held in the correct position (it should be marked to indicate the nasal side), it is pushed up under the upper lid, allowing the lower lid to cover its lower edge.

Safety is a major concern to prevent damage to the unaffected eye. Safety measures should be practiced at all times, and children should avoid rough contact sports or wear protective eyewear.

Support the Family

The diagnosis of retinoblastoma presents some special concerns in addition to those raised by cancer in general. Families with a history of retinoblastoma may feel guilt for transmitting the mutation to their offspring, especially if they knowingly "played the odds" in conceiving an affected child. Conversely, when parents are aware of the probability and have an affected child, early treatment results in such favorable outcomes that parental adjustment may be rapid. In families with no history of retinoblastoma, the diagnosis is a shock, frequently complicated by guilt for not having discovered it sooner. Because parents often are the first to observe the cat's eye reflex, they may be angry at themselves or others, especially health care professionals, if a more thorough examination was delayed. The nurse should consider each of these variables while offering supportive care to the family. Active listening is helpful.

Other concerns also relate to the hereditary aspects of the disease. Of great importance to parents is the risk of retinoblastoma in their subsequent offspring and in the offspring of the surviving affected child. With improving prognoses for these children, genetic counseling is assuming greater importance (see Chapter 3 for a discussion of the nurse's role in genetic counseling).

Encourage these families to seek regular follow-up care for the affected child for early identification of possible SNs. Offspring of unaffected parents and survivors should undergo regular ophthalmoscopy to detect retinoblastoma at its earliest stage.

GERM CELL TUMORS

Germ cell tumors (GCTs) account for approximately 3% of cancers in children younger than 15 years and 14% of cancers in adolescents 15 to 19 years (National Institutes of Health, 2019n). They can arise in gonadal and extragonadal sites and are broadly classified as teratomas (mature and immature) or malignant germ cell tumors (National Institutes of Health, 2019n). GCTs can appear in various body sites, including the testicles (e.g., yolk sac tumor, teratoma), ovaries (e.g., teratoma, germinoma, yolk sac tumor), sacrococcyx, mediastinum, and retroperitoneum (Frazier, Olson, Schneider, et al., 2016; National Institutes of Health, 2019n). In general, most children with teratomas and localized gonadal tumors that are surgically resected can be observed without the need for further therapy. For patients with more advanced disease, chemotherapy has produced excellent results.

LIVER TUMORS

Primary liver tumors are rare in childhood; they are divided into two main histologic subtypes, hepatoblastoma (infants and young children) and hepatocellular carcinoma (individuals ages 5 to 15 years), with hepatoblastoma being most common (National Institutes of Health, 2019o). Surgical resection is the treatment of choice for liver tumors, usually performed after the administration of platinum-based chemotherapy to increase the likelihood of complete resection (Meyers, Trobaugh-Lotrario, Malogolowkin, et al., 2016). Liver transplant should be used for unresectable tumors. Survival rates for patients with hepatoblastoma can be as high as 90% with current therapies (Aronson & Meyers, 2016).

THE CHILDHOOD CANCER SURVIVOR

Survival rates for children with cancer have greatly improved over the past decades, so that long-term survival is expected for more than 80% of children with access to contemporary therapy for cancer (National Institutes of Health, 2019p). Curative therapy can also produce adverse health outcomes, referred to as late effects, which may become apparent months to years after cancer treatment is completed. Survivorship research has demonstrated that 60% to 90% of adult survivors of childhood cancer develop chronic health conditions; of these, 20% to 80% experience severe or life-threatening complications (Landier et al., 2016). Late effects are related to therapeutic exposures (chemotherapy, surgery, radiation therapy, HSCT) and are also influenced by host factors such as genetic predisposition, age at diagnosis or treatment, comorbid health conditions, and health habits (National Institutes of Health, 2019p).

All survivors should have risk-based medical follow-up that includes a survivorship care plan for lifelong screening, surveillance, and health promotion. Because nurses in pediatric and adult primary care settings may encounter childhood cancer survivors, they should be aware of the risk-based, exposure-based guidelines developed by the Children's Oncology Group (2013) and endorsed by the American Academy of Pediatrics (2009). The Children's Oncology Group long-term follow-up guidelines include patient education materials ("Health Links") on guideline-specific topics that can be downloaded for use (Landier et al., 2016). The current fifth edition can be retrieved from http://www.survivorshipguidelines.org/.

Childhood cancer survivors have an elevated risk for disease and treatment-related morbidity and mortality that persists long after disease cure (Landier et al., 2016). Survivorship research has contributed to better characterization of late effects, as well as to modification of treatment regimens to minimize the risk of late effects. As therapeutic options evolve, nurses will need to stay current with ongoing research to determine best practices for continued improvement in both the duration and the quality of survival after childhood cancer.

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

The Child With Acute Lymphoblastic Leukemia

Tadala Mulemba

Day 1, 8:00 am

1. A 7-year-old male developed bilateral neck swelling 1 month ago and is being seen in the Emergency Department. His mother had taken him to a nearby health center twice because the swelling is increasing in size; oral antibiotics were prescribed. Two-weeks later, he now has hoarseness when speaking and his mother also reports that he is sleeping most of the time. On presentation to the hospital this morning, the complete blood count revealed a hemoglobin of 6.0 g/dl, white blood cell (WBC) of 85,000/mm^3 and a platelet count of 60,000/mm^3. On examination, the child has bilateral parotid gland enlargement, submental nodes and axillary nodes, and hepatomegaly approximately 6cm below the right subcostal margin. Leukemia is suspected and the child is admitted for further evaluation. Based on the list below, what are the most common signs and symptoms of leukemia the nurse would look for? **Select all that apply.**

A. Fever
B. Seizure
C. Fatigue
D. Infection
E. Bone pain
F. Short stature
G. Shortness of breath
H. Lymphadenopathy
I. Hepatosplenomegaly
J. Bruising and bleeding

Day 1, 8:00 am Continued

2. It is important for the nurse to be aware of the pathophysiology associated with the signs and symptoms of childhood leukemia. Symptoms are caused by bone marrow dysfunction that cause the rapidly proliferating leukemia cells to depress bone marrow production of the formed elements of the blood. **Choose the most likely options for the information missing from the table below by selecting from the lists of options provided.**

Symptom	Pathophysiology	Assessment Finding
Anemia	2	Pale, tired, listless
Infection	Decreased production of WBCs	3
1	Decreased production of platelets	Nosebleed, bruising
Bone pain	Increased pressure	Unable to bear weight on legs

Option 1	Option 2	Option 3
Seizure	Decreased production of RBCs	Lack of appetite and weight loss
Blindness	Increased production of plasma cells	Headache and seizure
Hemorrhage	Decreased production of CNS fluid	Enlarged spleen
Hearing loss	Increased production of bilirubin	Fever and infection

Day 1, 4:00 pm

3. This afternoon a diagnostic work-up was completed and the child underwent a bone marrow aspiration and biopsy. Flow cytometry revealed 70% B-cell leukemia blast cells and the diagnosis of acute lymphoblastic leukemia (ALL) is confirmed. He is to start chemotherapy tomorrow as part of the initial therapy for ALL. The child's WBC is extremely high, 85,000/mm^3 this morning and he is at risk for tumor lysis syndrome. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.** Children who present with a high WBC caused by leukemia are at risk for _____1_____ abnormalities that are a direct result of the _____2_____ release of intracellular contents during the _____3_____ of malignant cells, in this child's case- leukemia cells.

Options for 1	Options for 2	Options for 3
cardiac	rapid	production
cellular	slow	growth
metabolic	intermittent	lysis
neurologic	prolonged	mitosis

Day 1, 5:00 pm

4. A 7-year-old male was diagnosed with acute lymphocytic leukemia and has done well overnight. He continues on IV fluids and medication to reduce uric acid formation and prevent tumor lysis syndrome. He is due to start chemotherapy today and will undergo a lumbar puncture with intrathecal chemotherapy administered to prevent invasion of leukemia cells into the CNS. The nurse is preparing the child and family for the lumbar puncture procedure. **For each nursing action, use an X to indicate whether it was Effective (helped to meet expected quality patient outcomes), Ineffective (did not help to meet expected quality patient outcomes), or Unrelated (not related to the quality patient outcomes).**

Nursing Action	Effective	Ineffective	Unrelated
Explain the procedure to the patient and family and obtain informed consent.			
Monitor vital signs during the procedure (pulse rate, oxygen saturation, respirations, blood pressure).			
Administer a bolus of IV fluids before the procedure begins.			
Administer sedation during the procedure to provide optimal comfort and minimize pain.			
Provide comfort and reassure the patient and family throughout the procedure.			
Allow the child to watch a favorite show before the procedure.			
Watch for signs of bleeding from the puncture site.			

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—cont'd

The Child With Acute Lymphoblastic Leukemia

Day 2, 8:00 am

25.5. A 7-year-old male was diagnosed today with Acute Lymphocytic Leukemia confirmed by bone marrow examination and a complete diagnostic work up. He will begin chemotherapy tomorrow. Orders are written for preventing tumor lysis syndrome since his WBC is 85,000mm^3. Which of the following actions would the nurse take? **Select all that apply.**

A. Restrict IV fluids
B. Monitor WBC
C. Check urine pH with each void
D. Administer aggressive IV fluids
E. Monitor serum chemistries frequently
F. Maintain strict record of intake and output
G. Administer medication to prevent heart failure
H. Administer medication to reduce uric acid formation

Day 5, 8:00 am

6. A 7-year-old male was diagnosed with acute lymphocytic leukemia five days ago and has no complications from starting chemotherapy. He remains afebrile and the blood count today reveals a hemoglobin of 8.0 g/dl, white blood cell (WBC) of 10,000/mm^3 and a platelet count of 65,000/mm^3. Packed red blood cells were given on day 3 due to decreasing hemoglobin. The WBC count has decreased dramatically from 85,000/mm^3 to 10,000/mm^3. Chemistries are without evidence of tumor lysis syndrome. Plans are for the child to be discharged in the next 2 days if he does not develop fever and there are no signs of tumor lysis. The nurse begins preparing the child and family for discharge.

Indicate which nursing action listed in the far-left column is appropriate for potential complications following the start of leukemia treatment listed in the middle column, indicate the nursing action number in the far-right column.

Note that ONLY one nursing action can be used for each potential complication and that NOT all nursing actions will be used.

Nursing Action	Potential Complication	Nursing Action to prevent Complication
1. Explain the disease course of treatment and adverse effects to the family.	Skin as an entry point for infection	
2. Teach the patient and family ways to prevent infection through hand washing, bathing frequently, and not using cups and utensils used by another person.	Lack of recognition of infection	
3. Teach the family how to recognize symptoms of infection such as fever, chills, cough, and sore throat and report these to the health care worker immediately.	Lack of understanding of leukemia treatment	
4. Provide skin care to patient by keeping the skin and perianal area clean and apply mild lotion.	Mouth ulceration	
5. Provide a high-protein and high-calorie diet.	Lack of knowledge on how to prevent infection in the home	
6. Provide adequate hydration and encourage a high-fiber diet and stool softeners.	Bleeding	
7. Educate family and patient on how to recognize and report abnormal bleeding through bruising and petechiae.		
8. Provide frequent mouth care and saline rinses and check for ulcers in the mouth and gum swelling.		
9. Instruct patient and family to avoid contact sports.		

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A new nurse is in orientation on the pediatric cancer ward. She is working with her preceptor to administer chemotherapy to a newly diagnosed child with leukemia. The child is to receive intravenous Vincristine today. Which nursing actions are appropriate for the nurse to perform? **Select all that apply.**
   - **A.** Wear disposable gloves and protective clothing
   - **B.** Make sure drugs are prepared in a properly ventilated room
   - **C.** Use strict aseptic technique when administering chemotherapy agents
   - **D.** Use a sterile gauze pad when connecting the syringe to the IV tubing
   - **E.** Make sure air is out of the chemotherapy syringe by slowly injecting into the air
   - **F.** Dispose of all contaminated materials in a leak-proof and puncture-resistant contained
   - **G.** Wear face and eye protection that includes a respirator at all times when handling the agent

2. A 5-year-old boy with cancer is experiencing mucositis from receiving methotrexate a week ago. He had a fever and since his blood count shows the WBCs are less than 1,000,/mm ^{3} he is admitted for antibiotics and observation. The nurse is to provide mouth care this morning. Which of the following principles would be followed when providing oral care for a child with mucositis? **Use an X for the nursing action statement below that is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Nursing Action	Indicated	Contraindicated	Non-Essential
Viscous lidocaine should be used to swish the mouth three times per day			
Perform mouth care routinely before and after feeding			
Lemon glycerin swabs are helpful because they remind children of lemon drops.			
Allowing the child to sleep 8 hours will help recovery			
Using a soft sponge–type toothbrush will decrease the tendency of gums to bleed.			
Sodium bicarbonate and saltwater rinses can be used			

3. Infection prevention is a major goal during treatment for childhood cancer. The nurse is caring for a family who has a newly diagnosed child with lymphoma. The doctor has told them that their child's blood counts will be extremely low after receiving chemotherapy. Their child is a 6-year-old boy who just finished his first treatment cycle. When considering the need for the family to understand the importance of the white blood cell count, complete the following statements. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**

   Children receiving treatment for cancer experience low white blood cell counts and for this reason, they are closely monitored. The _____1_____ cell count reflects the risk for infection and is determined by _____2_____ the white blood cell count by percentage of _____3_____.

Options for 1	Options for 2	Options for 3
absolute red blood	subtracting	platelets
absolute platelet	multiplying	monocytes
absolute neutrophil	dividing	neutrophils
absolute white blood	adding	eosinophils

4. The parents of a child with a possible cancer diagnosis ask how the physician will know what type of cancer their child has. Their son is 14 years of age and presented with an enlarged subclavian lymph node. He completed the diagnostic evaluation and the diagnosis is confirmed as Hodgkin lymphoma. What teaching would the nurse present at this time on Hodgkin lymphoma to answer the parent's question? **Select all that apply.**
   - **A.** Radiographic tests are used to determine the extent of disease.
   - **B.** A lymph node biopsy is essential to establish the histologic diagnosis.
   - **C.** Hodgkin lymphoma is staged to determine the extent of spread throughout the body.
   - **D.** The presence of lymphoblastic cells is considered diagnostic of Hodgkin lymphoma.
   - **E.** Hodgkin lymphoma often presents with an enlarged, firm, nontender, movable nodes in the supraclavicular or cervical area.
   - **F.** Tests used to confirm the diagnosis include a complete blood count, prothrombin time and
   - **G.** glucose-6-phosphate dehydrogenase (G6PD), erythropoietin, and sedimentation rate.
   - **H.** The presence of a white reflection as opposed to the normal red pupillary reflex in the pupil of a child's eye is a classic sign.

The Child With Genitourinary Dysfunction

Maryellen S. Kelly

http://evolve.elsevier.com/wong/essentials

CONCEPTS

- Infection
- Acid-Base Balance
- Fluid Reflection

GENITOURINARY DYSFUNCTION

Assessment of kidney and urinary tract integrity and diagnosis of renal or urinary tract disease are based on several evaluative tools. Physical examination, history taking, and observation of symptoms are the initial procedures. In suspected urinary tract diseases or disorders, further assessment by laboratory, radiologic, and other evaluative methods is carried out. Fig. 26.1 provides a review of the kidney and nephron structures.

CLINICAL MANIFESTATIONS

As in most disorders of childhood, the incidence and type of kidney or urinary tract dysfunction will change with the age and maturation of the child. In addition, the presenting complaints and the significance of these complaints vary with age. For example, a complaint of enuresis has greater significance at 8 years old than at 4 years old. In newborns, renal abnormalities may be associated with a number of other malformations—for example, obvious neural tube defects to the subtle abnormal shape or position of the outer ear. Failure to thrive in children may be a sign of impaired renal function.

Many of the clinical manifestations of renal disease are common to a variety of childhood disorders, but their presence is an indication to obtain further information from the child's history, family history, and laboratory studies as part of a complete physical examination. Suspected renal disease can be further evaluated by means of radiographic studies and renal biopsy (Table 26.1).

LABORATORY TESTS

Both urine and blood studies contribute vital information for detection of renal problems. The single most important test is probably routine urinalysis. Specific urine and blood tests provide additional information. Because nurses are usually the individuals who collect the specimens for examination and who often perform many of the screening tests, they should be familiar with the test, its function, and factors that can alter or distort the results of the test. The major urine and blood tests are outlined in Tables 26.2 and 26.3.

NURSING CARE MANAGEMENT

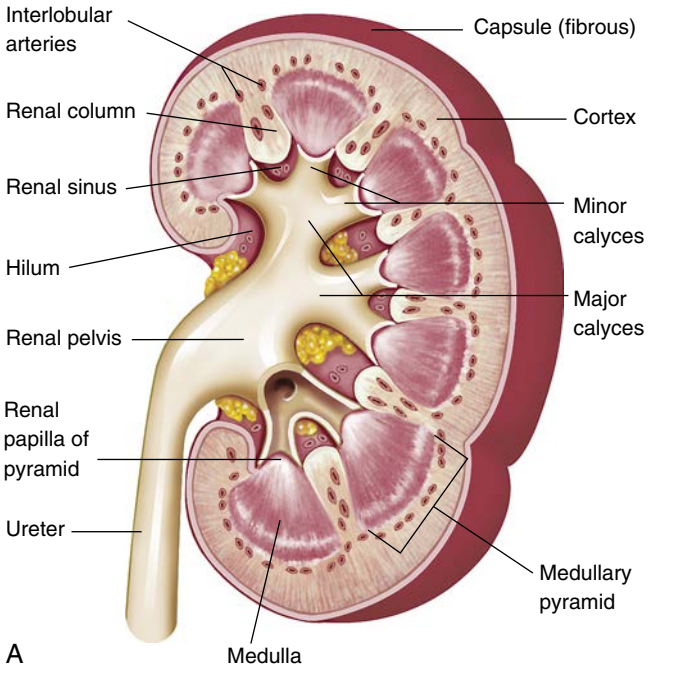
Nursing responsibilities in the assessment of genitourinary disorders or diseases begin with observation of the child for any manifestations that might indicate dysfunction. Many conditions have specific characteristics that distinguish them from other disorders. These are discussed as appropriate throughout the chapter.

The nurse is generally responsible for preparing infants, children, and parents for tests and for collection of urine and (sometimes) blood specimens for observation and laboratory analysis (see Chapter 20, Preparation for Diagnostic and Therapeutic Procedures and Collection of Specimens). An important nursing responsibility is to maintain careful intake and output measurements and blood pressure for most children with genitourinary dysfunction and those who might be at risk for developing renal complications (e.g., children in shock, postoperative patients). For example, any significant degree of renal disease can diminish the glomerular filtration rate (GFR), a measure of the amount of plasma from which a given substance is totally cleared in 1 minute. A number of substances can be used, but the most useful clinical estimation of glomerular filtration is the clearance of **creatinine**, an end product of protein metabolism in muscle and a substance that is freely filtered by the glomerulus and secreted by renal tubular cells. The nurse's responsibility in this test is collection of urine, usually a 12- or 24-hour specimen.

GENITOURINARY TRACT DISORDERS AND DEFECTS

Urinary Tract Infection

Urinary tract infection (UTI) is a common and potentially serious problem in children. The overall prevalence is approximately 7% in infants and young children, although there is some variability based on age,



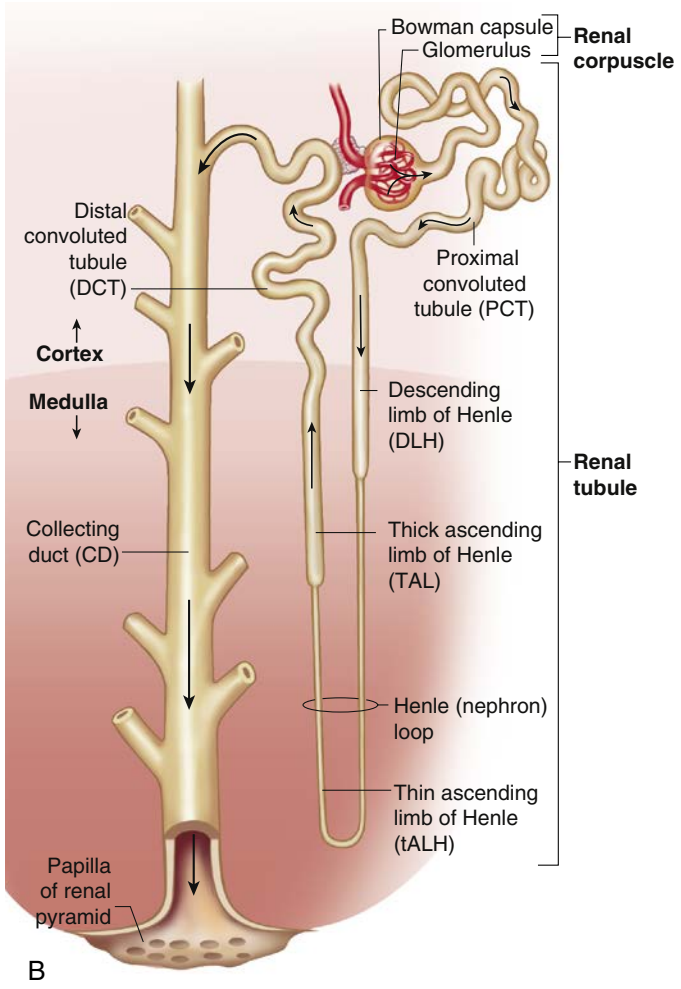


Fig. 26.1 A, Kidney structure. B, Components of the nephron. (From Patton, K. T., & Thibodeau, G. A. [2010]. *Anatomy and physiology* [7th ed.]. St. Louis, MO: Mosby.)

gender, race, and circumcision status (Shaikh, Morone, Bost, et al., 2008). Whites, females, and uncircumcised boys have the highest rates. Specifically, girls have a twofold to fourfold higher prevalence than do circumcised boys. Uncircumcised males younger than 3 months old and females younger than 12 months old have the highest baseline prevalence of UTI (Shaikh et al., 2008). UTI is an umbrella term for infections of either the upper or the lower urinary tract. UTIs may involve the urethra and bladder (lower urinary tract) or the ureters, renal pelvis, calyces, and renal parenchyma (upper urinary tract). Because of the difficulty in distinguishing upper from lower tract infection, particularly in young children, UTI is often broadly defined. Lower UTIs are often characterized by symptoms of irritation to the bladder, such as hesitancy to void, dysuria, frequency of voiding, and urine incontinence. Upper UTIs or kidney infections (pyelonephritis) tend to present with fever and may lead to renal scarring that may be associated with decreased kidney function, hypertension, and renal disease over time. Upper UTIs may also present with additional symptoms of flank pain, nausea, or vomiting. Diagnosis of UTI is made based on the presence of both pyuria and at least 50,000 colonies/ml of a single uropathic organism in an appropriately collected specimen (Roberts, 2011).

Classification

Infection of the urinary tract may be present with or without clinical symptoms. As a result, the site of infection is often difficult to pinpoint with any degree of accuracy. Various terms used to describe urinary tract disorders include:

Bacteriuria: Presence of bacteria in the urine

Pyuria: Presence of white blood cells in the urine

Asymptomatic bacteriuria: Significant bacteriuria (usually defined as >100,000 colony-forming units [CFUs]) with no clinical symptoms

Symptomatic bacteriuria: Bacteriuria accompanied by physical signs of UTI (dysuria, suprapubic discomfort, hematuria, fever)

Recurrent UTI: Repeated episode of bacteriuria or symptomatic UTI with the same strain of bacteria

Frequent UTI: More than three UTIs within a 6-month period; they do not have to be infections characterized by the same strain of bacteria

Persistent UTI: Persistence of bacteriuria despite antibiotic treatment

Febrile UTI: Bacteriuria accompanied by fever and other physical signs of UTI; presence of a fever typically implies pyelonephritis

Cystitis: Inflammation of the bladder

Urethritis: Inflammation of the urethra

Pyelonephritis: Inflammation of the upper urinary tract and kidneys; kidney infection, usually characterized by presence of bacteriuria and clinical symptoms that include fever

Urosepsis: Febrile UTI coexisting with systemic signs of bacterial illness; blood culture reveals presence of urinary pathogen

Etiology

A variety of organisms can be responsible for UTI. *Escherichia coli* remains the most common uropathogen overall, but the prevalence is higher in females (83%) than males (50%) (Edlin, Shapiro, Hersh, et al., 2013). Other gram-negative organisms associated with UTI include *Proteus mirabilis, Pseudomonas aeruginosa, Klebsiella,* and *Enterobacter.* Gram-positive bacterial pathogens include *Enterococcus, Staphylococcus saprophyticus,* and, rarely, *Staphylococcus aureus.* Viruses and fungi are uncommon causes of UTI in children. Most uropathogens originate in the gastrointestinal tract, migrate to the periurethral area, and ascend to the bladder. Organ cross-talk between the bladder and the colon can also contribute to pathologic changes that may increase risks for UTI (Malykhina, Wyndaele, Andersson, et al., 2012). A number of factors contribute to the development of UTI, including anatomic, physical, and chemical conditions or properties of the host's urinary tract.

TABLE 26.1 Radiologic and Other Tests of Urinary System Function

Test	Procedure	Purpose	Comments and Nursing Responsibilities
Urine culture and sensitivity	Collection of sterile specimen	Determines presence of pathogens and the drugs to which they are sensitive	Send specimen to laboratory immediately after collection Catheterization, clean-catch, or suprapubic specimen
Renal and bladder ultrasonography	Transmission of ultrasonic waves through renal parenchyma, along ureteral course, and over bladder	Allows visualization of renal parenchyma and renal pelvis without exposure to external-beam radiation or radioactive isotopes Visualization of dilated ureters and bladder wall also possible Can show renal cysts and stones, though less sensitive than CT Doppler ultrasonography can be used to evaluate renal vascular flow	Noninvasive procedure
Testicular (scrotal) ultrasonography	Transmission of ultrasonic waves through scrotal contents and testis	Allows visualization of scrotal contents, including testis Testicular ultrasonography is used to identify masses, and Doppler-enhanced ultrasonography is used to differentiate hyperemia of epididymo-orchitis from ischemia or torsion	Noninvasive procedure
Plain film of the abdomen	Flat plate radiograph of abdomen and pelvis for KUB	Can identify certain types of stones that are calcium containing as well as calculi or opaque foreign bodies in bladder (diagnostic test of choice for nephrolithiasis is noncontrast helical CT)	Prepare as for routine x-ray film
Voiding cystourethrography	Contrast medium injected into bladder through urethral catheter until bladder is full; films taken before, during, and after voiding	Visualizes bladder outline and urethra, reveals VUR Provides information on bladder emptying and is also used to diagnosis PUV	Prepare child for catheterization Should not be done at time of active UTI
Radionuclide (nuclear) cystogram	Radionuclide-containing fluid injected through urethral catheter until bladder is full; images generated before, during, and after voiding	Alternative to voiding cystourethrography to evaluate reflux, although visualization of anatomic details is relatively poor Used in some institutions for follow-up due to less radiation	Prepare child for catheterization
Radioisotope imaging studies (renal scans)	Contrast medium injected intravenously; computer analysis to measure uptake or washout (excretion) for analysis of organ function	DMSA radioisotope used to visualize renal scars and differential renal function; does not visualize ureters and bladder MAG3 radioisotope assesses obstruction and differential function between the two kidneys DTPA is an alternative to MAG3, but imaging is limited because it is only filtered at the glomerulus	Insert or assist with insertion of IV infusion Monitor IV infusion Urethral catheterization may accompany MAG3 scan; prepare child for catheterization when indicated
MRI	Uses strong magnetic fields and radio waves to form images	MRI of kidneys used to evaluate renal mass Magnetic resonance angiography used to evaluate renovascular hypertension and has reduced need for renal angiography Magnetic resonance urogram used to detect specific urologic abnormalities, such as ectopic ureter	MRI often requires sedation in infants and children due to need to stay still, typically in an enclosed space; follow NPO guidelines depending on timing of study Assist with IV access if indicated Magnetic devices or implants may be unsafe for MRI, including cochlear implants and permanent pacemakers
CT	Narrow-beam x-rays and computer analysis provide precise reconstruction of area	Visualizes vertical or horizontal cross-section of kidney Especially valuable to distinguish tumors, cysts, and stones Noncontrast helical CT is gold standard for radiologic diagnosis of renal stone disease Renal CT angiogram used to evaluate blood flow in hypertensive patients and is now used more commonly than renal arteriography	Noncontrast scan is noninvasive Contrast-enhanced CT scan preparation may require child be NPO for a few hours With speed of newer scans, the need for sedation is decreased but if required will also require NPO Assist with IV access if needed *Used selectively due to higher radiation exposure*

Continued

TABLE 26.1 Radiologic and Other Tests of Urinary System Function—cont'd

Test	Procedure	Purpose	Comments and Nursing Responsibilities
Cystoscopy	Direct visualization of bladder and lower urinary tract through small scope inserted via urethra	Investigation of bladder and lower tract lesions; visualizes ureteral openings, bladder wall, trigone, and urethra	NPO orders per protocol, typically no solid food after midnight, liquids until 4-6 h before procedure Carry out preoperative preparations; cystoscopy is done under anesthesia in children
Renal biopsy	Removal of kidney tissue by open or percutaneous technique for study by light, electron, or immunofluorescent microscopy	Yields histologic and microscopic information about glomeruli and tubules; helps distinguish among types of nephritic syndromes Distinguishes other renal disorders	Nothing orally 4-6 h before test Premedicate as ordered Prepare setup for procedure Assist with procedure Take vital signs Apply pressure to area with pressure dressing and, if feasible, a sandbag Bed rest for 24 h Observe for abdominal pain, tenderness Monitor input and output Surgical incision may be required in infants
Urodynamics	Set of tests designed to measure bladder filling, storage, and evacuation functions: **Uroflowmetry:** Test to determine efficiency of urination **Cystometrography:** Graphic comparison of bladder pressure as a function of volume **Voiding pressure study:** Comparison of detrusor contraction pressure, sphincter electromyelogram, and urinary flow	Determine characteristic of voiding dysfunction Used to identify type (cause) of incontinence or urinary retention Especially valuable for voiding dysfunction complicated by urinary infection, urinary retention, or neurogenic bladder dysfunction	Prepare child for urinary catheterization The bladder will be filled with contrast, sterile water, or saline solution, and filling pressures will be recorded; the child may experience fullness, coolness from the fluid, and urine leakage during the study Insertion of needles may be required for sphincter EMG (institution specific, often use electrode patches)

CT, Computed tomography; *DMSA,* dimercaptosuccinic acid; *DTPA,* diethylenetriamine pentaacetic acid; *EMG,* electromyography; *IV,* intravenous; *KUB,* kidney, ureters, and bladder; *MAG3,* mercaptoacetyltriglycine; *MRI,* magnetic resonance imaging; *NPO,* nothing by mouth; *PUV,* posterior urethral valve; *UTI,* urinary tract infection; *VUR,* vesicoureteral reflux.

TABLE 26.2 Urine Tests of Renal Function

Test	Normal Range	Deviations	Significance of Deviations
Physical Tests			
Volume	Age related Newborn: 30-60 ml Children: Bladder capacity (oz) = Age (years) + 2	Polyuria Oliguria	Osmotic factors (urinary glucose level in diabetes mellitus) Retention caused by obstructive disease Inadequate bladder emptying caused by neurogenic bladder or obstructive disorder
		Anuria	Obstruction of urinary tract; AKI
Specific gravity	With normal fluid intake: 1.016-1.022 Newborn: 1.001-1.020 Others: 1.001-1.030	High	Dehydration Presence of protein or glucose Presence of radiopaque contrast medium after radiologic examinations
		Low	Excessive fluid intake Distal tubular dysfunction Insufficient ADH Diuresis

TABLE 26.2 Urine Tests of Renal Function—cont'd

Test	Normal Range	Deviations	Significance of Deviations
Osmolality	Newborn: 50-600 mOsm/L	Fixed at 1.010	Chronic glomerular disease
	Thereafter: 50-1400 mOsm/L	High or low	Same as for specific gravity More sensitive index than specific gravity
Appearance	Clear pale yellow to deep gold	Cloudy	Contains sediment
		Cloudy reddish-pink to reddish-brown	Blood from trauma or disease Myoglobin after severe muscle destruction
		Light	Dilute
		Dark	Concentrated
		Red	Trauma
Chemical Tests			
pH	Newborn: 5-7 Thereafter: 4.8-7.8 Average: 6	Weak acid or neutral Alkaline	If associated with metabolic acidosis, suggests tubular acidosis If associated with metabolic alkalosis, suggests potassium deficiency Urinary infection Metabolic alkalosis
Protein level	Absent	Present	Abnormal glomerular permeability (e.g., glomerular disease, changes in blood pressure) Most kidney disease Orthostatic in some individuals
Glucose level	Absent	Present	Diabetes mellitus Infusion of concentrated glucose-containing fluids Glomerulonephritis Impaired tubular reabsorption
Ketone levels	Absent	Present	Conditions of acute metabolic demand (stress) Diabetic ketoacidosis
Leukocyte esterase	Absent	Present	Can identify both lysed and intact WBCs via enzyme detection
Nitrites	Absent	Present	Most species of bacteria convert nitrates to nitrites in the urine
Microscopic Tests			
WBC count	<1 or 2	>5 polymorphonuclear leukocytes/field	Urinary tract inflammatory process
		Lymphocytes	Allograft rejection Malignancy
RBC count	<1 or 2	4-6/field in centrifuged specimen	Trauma Stones Glomerular injury Infection Neoplasms
Presence of bacteria	Absent to a few	>100,000 organisms/ml in centrifuged specimen	UTI
Presence of casts	Occasional	Granular casts	Tubular or glomerular disorders
		Cellular casts	Degenerative process in advanced renal disease
		WBC	Pyelonephritis
		RBC	Glomerulonephritis
		Hyaline casts	Proteinuria; usually transient

ADH, Antidiuretic hormone; *AKI,* acute kidney injury; *RBC,* red blood cell; *UTI,* urinary tract infection; *WBC,* white blood cell.

Anatomic and Physical Factors

The structure of the lower urinary tract has traditionally been thought to account for the increased incidence of bacteriuria in females. The short urethra, which measures about 2 cm in young girls and 4 cm in women, provides a ready pathway for invasion of organisms. In addition, the closure of the urethra at the end of micturition may return contaminated bacteria to the bladder. The longer male urethra (as long as 20 cm in an adult male) and the antibacterial properties of prostatic secretions inhibit the entry and growth of pathogens. The importance of the length of the urethra in the pathogenesis of UTI has been questioned because of the high incidence of UTI in male neonates. The presence or absence of the foreskin has been shown to be a significant factor, with prevalence of UTI in infant males younger than 3 months old being 2.4% in circumcised and 20.1% in uncircumcised males (Shaikh et al., 2008). The presence of a foreskin is associated with a preputial colonization of uropathic bacteria that

TABLE 26.3 Blood Tests of Renal Function

Test	Normal Range (mg/dl)	Deviations	Significance of Deviations
BUN	Newborn: 4-18 Infant, child: 5-18	Elevated	Renal disease: Acute or chronic (the higher the BUN, the more severe the disease) Increased protein catabolism Dehydration Hemorrhage High protein intake Corticosteroid therapy
Uric acid	Child: 2.0-5.5	Increased	Severe renal disease
Creatinine	Infant: 0.2-0.4 Child: 0.3-0.7 Adolescent: 0.5-1.0	Increased	Renal impairment

BUN, Blood urea nitrogen.

can ascend the urethra easily (Balat, Karakok, Guler, et al., 2008). Virulence factors are important in the pathogenesis, and these, coupled with the propensity of bacteria to adhere to the female periurethral mucosa, may explain the increased incidence of UTI in females.

NURSING TIP: Considerable evidence shows significant reductions in the risk of urinary tract infection (UTI) in the first year of life in circumcised male infants. Current evidence indicates that the health benefits of circumcision outweigh the risks and that the benefits of the procedure justify access for families who choose it but are not sufficient to recommend routine circumcision for all male newborns (American Academy of Pediatrics Task Force on Circumcision, 2012).

The single most important host factor influencing the occurrence of UTI is **urinary stasis**. Under normal conditions, the act of completely and repeatedly emptying the bladder flushes away any uropathogens before they have an opportunity to multiply and invade surrounding tissue. However, urine that remains in the bladder after voiding allows uropathogens to rapidly establish in bladder tissue and cause symptoms. Incomplete bladder emptying (stasis) may result from **reflux** (see Vesicoureteral Reflux later in the chapter), anatomic abnormalities, neurogenic bladder, voiding dysfunction, or extrinsic ureteral or bladder compression that may be caused by constipation. Overdistention of the bladder may increase risk of infection by decreasing host resistance, probably as a result of decreased blood flow to the mucosa. This occurs more often in a neurogenic bladder with increased bladder pressure, but it can be the result of voluntary urine holding (Vasudeva & Madersbacher, 2014).

Altered Urine and Bladder Chemistry

Increased fluid intake promotes flushing of the normal bladder and lowers the concentration of organisms in the infected bladder, thereby decreasing risk of UTI. Children with UTIs should be encouraged to have adequate water intake (generally accepted as one 8-oz cup of water per year of age until age 8) to aid in prevention of further infections. Diuresis also seems to enhance the antibacterial properties of the renal medulla.

Most pathogens favor an alkaline medium. Normally, urine is slightly acidic with a median pH of 6. A urine pH of 5 hampers but does not eliminate bacterial multiplication. Much has been reported about the use of cranberry products for prevention of UTI. Initially it was thought to alter the urine acidity, but studies have not shown that ingestion results in a lower pH; instead it appears to decrease the adherence of certain bacteria *(E. coli)* to the bladder wall. Recent review of the literature showed that cranberry products did not significantly reduce the occurrence of symptomatic UTI overall or in any of the subgroups, including children. Because the benefit is small, cranberry juice cannot currently be recommended for prevention of UTIs. Other cranberry preparations need to be quantified using standardized methods to ensure their potency before being evaluated in clinical studies or recommended for use (Jepson, Williams, & Craig, 2012; Ranfaing, Dunyach-Remy, Lavigne, et al., 2018; Sihra, Goodman, Zakri, et al., 2018).

Diagnostic Evaluation

The clinical manifestations of UTI depend on the child's age (Box 26.1). Diagnosis of UTI is confirmed by detection of bacteria in urine culture, but urine collection is often difficult, especially in infants and very small children. Several factors may alter a urine specimen, and contamination of a specimen by organisms from sources other than the urine, such as perineal and perianal flora in bag specimens or clean-catch specimens, is the most frequent cause of false-positive results. Unless the specimen is a first morning sample, a recent high fluid intake may indicate a falsely low organism count. Therefore children should not be encouraged to drink large volumes of water in an attempt to obtain a specimen quickly.

! NURSING ALERT

A child who exhibits the following should be evaluated for urinary tract infection (UTI):

- Incontinence in a toilet-trained child
- Frequency or urgency of voiding
- Dysuria
- Gross hematuria

The most accurate tests of bacterial content are **suprapubic aspiration** (for children younger than 2 years old) and properly performed **bladder catheterization** (as long as the first few milliliters are excluded from collection). The specimen must be fresh (<1 hour with storage at room temperature or <4 hours with refrigeration) to ensure sensitivity and specificity of the urinalysis and to prevent growth of organisms (Roberts, 2011). Clean catch and specimens collected by urine bags are prone to contamination, given the difficulty of obtaining a true midstream specimen with wiping of the meatus and retraction of the labia or foreskin or cleaning the perineum. In these instances, a negative specimen excludes infection and a positive culture is not necessarily diagnostic.

Predictive tests are used to direct therapy when UTI is suspected. Urine dipsticks indicate the presence of leukocyte esterase and nitrites and are quick and inexpensive. Leukocyte esterase is a surrogate marker for pyuria, and nitrite is converted from dietary nitrates in the presence of most gram-negative enteric bacteria in the urine. Because the conversion takes 4 hours in the bladder, it is not a sensitive marker for infants or children who empty their bladder frequently. Also, not all urinary pathogens reduce nitrate to nitrite (Roberts, 2011). Use of a microscopic urinalysis for pyuria should be used for confirmation and diagnosis.

Further radiographic evaluation, such as ultrasonography, voiding cystourethrogram (VCUG), and renal scans such as a dimercaptosuccinic acid (DMSA) scan, may be performed after the infection subsides to identify anatomic abnormalities contributing to the development of infection and existing kidney changes from recurrent infection.

Therapeutic Management

The objectives of treatment of children with UTI are to (1) eliminate current infection, (2) identify contributing factors to reduce the risk of recurrence, (3) prevent systemic spread of the infection, and (4) preserve renal function. Antibiotic therapy should be initiated on the

BOX 26.1 Clinical Manifestations of Urinary Tract Disorders or Disease

Neonatal Period (Birth to 1 Month Old)
Poor feeding
Vomiting
Failure to gain weight
Rapid respiration (acidosis)
Respiratory distress
Spontaneous pneumothorax or pneumomediastinum
Frequent urination
Screaming on urination
Poor urine stream
Jaundice
Seizures
Dehydration
Other anomalies or stigmata
Enlarged kidneys or bladder

Infancy (1 to 24 Months Old)
Poor feeding
Vomiting
Failure to gain weight
Excessive thirst
Frequent urination
Straining or screaming on urination
Foul-smelling urine
Pallor
Fever
Persistent diaper rash
Seizures (with or without fever)
Dehydration
Enlarged kidneys or bladder

Childhood (2 to 14 Years Old)
Poor appetite
Vomiting
Growth failure
Excessive thirst
Enuresis, incontinence, frequent urination
Painful urination
Swelling of face
Seizures
Pallor
Fatigue
Blood in urine
Abdominal or back pain
Edema
Hypertension
Tetany

basis of identification of the pathogen, the child's history of antibiotic use, and the location of the infection. Several antimicrobial drugs are available for treating UTI, but all of them can occasionally be ineffective because of resistance of organisms. Common anti-infective agents used for UTI include the penicillins, sulfonamide (including trimethoprim-sulfamethoxazole), the cephalosporins, and nitrofurantoin (not to be used if pyelonephritis is suspected or confirmed).

If anatomic defects such as primary reflux or bladder neck obstruction are present, surgical correction or urinary prophylaxis may be necessary to prevent further infections. The aim of therapy and careful follow-up is to reduce the chance of renal scarring.

Vesicoureteral Reflux

Vesicoureteral reflux (VUR) refers to the retrograde flow of urine from the bladder into the upper urinary tract. **Primary reflux** results from congenitally abnormal insertion of ureters into the bladder; **secondary reflux** occurs as a result of an acquired condition.

VUR does not cause UTIs but does increase the risk that a lower UTI will become an episode of pyelonephritis. When bladder pressure is high enough, refluxing urine can fill the ureter and the renal pelvis. The International Reflux Study Group developed a classification system that describes the degree of VUR, ranging from Grade I to V, which is important because higher grades are associated with increased renal abnormalities and renal damage. In addition, higher grades are less likely to spontaneously resolve than lower grades. Children with pyelonephritis are often very symptomatic with high fevers, vomiting, and chills. In most cases, conservative therapy is sufficient, with a high rate of spontaneous resolution of VUR over time: 51% at a mean duration of 2 years for all grades of VUR (Estrada, Passerotti, Graham, et al., 2009). Prevention of infection has been the goal with use of continuous antibiotic prophylaxis (CAP) common practice until resolution or correction of VUR. This practice was reviewed in a recent multisite trial and found to be associated with a substantially decreased risk of recurrence of UTI but not of renal scarring, leaving the use of CAP controversial (Hoberman & Chesney, 2014). Urine cultures are not recommended routinely for children with VUR but should be obtained if there are symptoms or unexplained fevers present, because breakthrough infections can occur despite CAP.

Surgical management of VUR corrects the anatomy at the insertion of the refluxing ureter into the bladder and consists of open or laparoscopic and robotic techniques or endoscopic correction. Surgical intervention is indicted in patients who are unlikely to resolve their VUR and are at risk for renal scarring, including those with Grade V reflux with scarring, those with Grade V reflux over 6 years of age, and children who fail medical therapy (have breakthrough infections).

Prognosis

With prompt and adequate treatment at the time of diagnosis, the long-term prognosis for UTI is usually excellent. However, the risk of progressive renal injury due to scarring from a first UTI has been found to be highest in children with an abnormal renal bladder ultrasound or with a combination of high fever (≥39°C) and an etiologic organism other than *E. coli* (Shaikh, Craig, Rovers, et al., 2014). The presence of VUR, particularly high grade (IV to V), is an important risk factor for the development of renal scarring.

QUALITY PATIENT OUTCOMES: Urinary Tract Infections
- Treatment based on culture and sensitivity
- Renal function maintained
- Appropriate diagnosis of renal abnormalities

Nursing Care Management

Nurses should instruct parents of those with VUR to observe for signs and symptoms suggestive of UTI. These are not always obvious, particularly in an infant, young child, or developmentally delayed child. A high fever without obvious cause should be a signal to check the urine. Because infants and young children often are unable to express their feelings and sensations verbally, it is difficult to detect discomfort they may be experiencing from dysuria. A careful history regarding voiding habits, stooling pattern, feeding tolerance, and episodes of unexplained irritability may assist in detecting less obvious cases of UTI.

NURSING TIP: Another strategy for obtaining a daily urine protein is to place cotton balls in the diaper at night before bedtime and then squeeze them out in the morning. This should not be used if looking for urinary tract infections (UTIs).

When infection is suspected, collecting an appropriate specimen is essential. It is the nurse's responsibility to take every precaution to obtain acceptable clean-voided specimens in a child who is able to void volitionally, taking care to cleanse the meatus and retract the foreskin in uncircumcised males or keep the labia separated in females. Having a young girl sit backwards on the toilet can facilitate this process, particularly the ability to obtain urine midstream, decreasing the risk of contamination. Because of the unreliability of a specimen obtained via a urine collection bag, sterile catheterization should be done in infants and young children whose illness warrants immediate antibiotic therapy, such as with high fever, vomiting, and lethargy.

Frequently, additional tests are performed to detect anatomic defects. Children are prepared for these tests as appropriate for their age. This includes an explanation of the procedure, its purpose, and what the children will experience (see Chapter 20, Preparation for Diagnostic and Therapeutic Procedures). Sometimes a simple description of the urinary system is helpful. For children younger than 3 to 4 years old, the procedure can be explained on a doll. For those who are older, a simple drawing of the bladder, urethra, ureters, and kidneys makes the procedure more understandable.

Handling actual equipment when feasible can be helpful in allaying anxiety in children of all ages. Anticipatory instruction on distraction techniques such as deep breathing, storytelling, and imagery may help the child relax and be more cooperative during the actual procedures.

Because antibacterial drugs are indicated in UTI, the nurse advises parents of proper dosage and administration. When used in low dose for prevention of UTI, parents need an explanation of the drug's continued necessity when no signs of infection are present. For all children, adequate fluid intake is encouraged.

Prevention

Prevention is the most important goal in both primary and recurrent infection, and many preventive measures are simple hygienic habits that should be a routine part of daily care (see Nursing Care Guidelines box). For example, parents are taught to cleanse their infant's genital areas from front to back to avoid contaminating the urethral area with fecal organisms. Girls are taught to wipe from front to back after voiding and defecating. Children should void as soon as they feel the urge and should not be encouraged to hold their urine for prolonged periods.

NURSING CARE GUIDELINES

Prevention of Urinary Tract Infection

Factors Predisposing to Development

Short female urethra close to vagina and anus
Incomplete emptying and overdistention of bladder
Concentrated urine
Constipation

Measures of Prevention

Practice perineal hygiene; wipe from front to back in females.
Avoid tight clothing or diapers; wear cotton panties rather than nylon.
Avoid "holding" urine; encourage child to void frequently.
Take time to empty bladder completely. This may be helped by relaxed toilet posture for girls, with feet supported on a stool and knees apart. Some children benefit from "double voiding" (void, wait a few minutes, and void again).
Avoid constipation.
Encourage adequate fluid intake.

Sexually active female adolescents are advised to urinate as soon as possible after they have intercourse to flush out any bacteria introduced. Children who have recurrent UTIs or neurogenic bladder are sometimes maintained on daily low-dose antibiotics. Giving the dose at bedtime in children who stay dry through the night allows the drug to remain in the bladder longer. The nurse should reinforce the importance of compliance to parents and older children.

Obstructive Uropathy

Structural or functional abnormalities of the urinary system that obstruct the normal flow of urine can result in renal dysfunction. The area above the obstruction may demonstrate increased pressure, dilation, and urinary stasis. If the blockage is low in the urinary tract, both ureters and kidneys may be affected; if one kidney or ureter is affected, the other may be normal. The renal pelvis and calyces typically show dilation called **hydronephrosis** from obstruction, although a kidney may have hydronephrosis and not be obstructed.

Obstruction may be congenital or acquired, unilateral or bilateral, and complete or incomplete with acute or chronic manifestations. The obstruction can occur at any level of the upper or lower urinary tract (Fig. 26.2). Partial obstruction may not be symptomatic, and changes caused may be partially or completely reversible if there is early intervention. Boys are affected more frequently than girls, and malformations should be suspected when patients have associated congenital defects (e.g., prune belly syndrome, chromosomal anomalies, anorectal malformations, neural tube defects). Prenatal diagnosis with ultrasonography has been a factor leading to early diagnosis and intervention with subsequent decrease in renal impairment.

Causes of obstructive uropathy include congenital problems, such as posterior urethral valves (PUVs), ureteropelvic junction (UPJ) and ureterovesical junction (UVJ) obstruction, and ureterocele. Acquired causes include renal or bladder stones, tumor, and trauma. PUVs are obstructing membranous folds within the lumen of the posterior urethra and are the most common cause of obstruction of the urinary

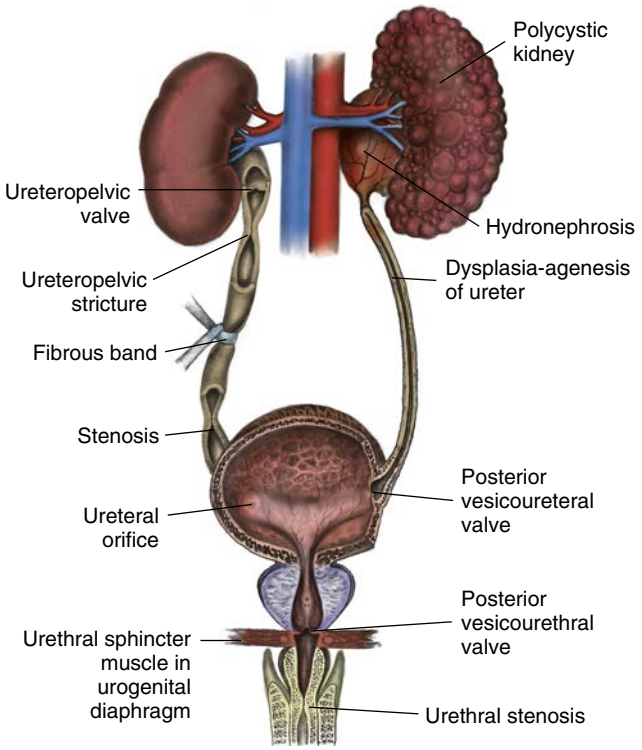

Fig. 26.2 Major sites of urinary tract obstruction.

tract in newborn males, as well as the most common cause of chronic renal injury from obstructive uropathy. Because the obstruction occurs in the urethra, the bladder and upper urinary tract are affected. Damage to distal nephrons in chronic uropathy may cause decreased glomerular filtration, which can lead to renal insufficiency (Chevalier, 2015). Damage to smooth muscle of the bladder and upper urinary tract also may occur with obstruction and can contribute to bladder dysfunction. Because stasis of urine serves as a medium for bacterial growth, infection can magnify destructive changes of obstruction and cause increased renal damage as well as increased morbidity.

Early diagnosis and surgical correction or procedures that divert the flow of urine to bypass the obstruction may prevent progressive renal damage. Medical complications of acute or chronic renal failure (CRF) or infection are managed as described for those disorders.

Nursing Care Management

Nursing goals in urinary tract obstruction include helping to identify cases, assisting with diagnostic procedures, and caring for children with complications (described elsewhere). Preparing parents and children for procedures is a major nursing responsibility (see Chapter 20, Preparation for Diagnostic and Therapeutic Procedures).

Parents and children need emotional support and counseling during the potentially lengthy management of these disorders. Children may be discharged with urinary drainage systems that require nursing education of the parents and older child to provide care and to recognize problems, such as obstruction of urine flow or infection. Drainage tubes should be observed for obstruction resulting from sediment, small blood clots, or kinking. If indicated, instructions on site care and drainage tube irrigation need to be provided, including observation for signs of infection or dislodgement.

Children with external diversional systems need psychologic support and guidance, especially as they reach adolescence and body image concerns assume more prominence. Those with progressive renal deterioration may face the prospect of dialysis or transplantation and the physical and psychologic challenges that accompany these procedures.

EXTERNAL DEFECTS OF THE GENITOURINARY TRACT

Defects of the external genitourinary tract have the potential to cause distortions of body image. Satisfactory surgical repair is successful for the more common disorders and is carried out or initiated as early as possible. The major anomalies of the lower genitourinary tract, their description, and their management are outlined in Table 26.4.

PHIMOSIS

Phimosis is a narrowing or stenosis of the preputial opening of the foreskin that prevents retraction of the foreskin over the glans penis.

TABLE 26.4 Defects of the Genitourinary Tract

Defect	Therapeutic Management
Inguinal hernia: Protrusion of abdominal contents through inguinal canal into scrotum	Detected as painless inguinal swelling of variable size Surgical closure of inguinal defect
Hydrocele: Fluid in scrotum	Surgical repair may be indicated if persists past 1 year old and symptomatic
Phimosis: Narrowing or stenosis of preputial opening of foreskin	**Mild cases:** May not require therapy if urine flow not obstructed; steroid cream may be prescribed, typically twice a day for 1 month **Severe cases:** Circumcision or dorsal slit in severe, rare cases
Hypospadias: Urethral opening located behind glans penis or anywhere along ventral surface of penile shaft	Objectives of surgical correction: • Enable child to void in standing position and direct stream voluntarily in usual manner • Improve physical appearance of genitalia • Produce a sexually adequate organ
Chordee: Ventral curvature of penis, often associated with hypospadias	Surgical release of fibrous band causing the deformity
Epispadias: Meatal opening located on dorsal surface of penis	Surgical correction, usually including penile and urethral lengthening and bladder neck reconstruction (if necessary)
Cryptorchidism: Failure of one or both testes to descend normally through inguinal canal	Detected by inability to palpate testes within scrotum **Medical:** Administration of hormonal therapy has historically been used in some centers to induce testicular descent but is controversial and not currently recommended **Surgical:** Orchiopexy Objectives of therapy: Place and fix viable undescended testes in a normal scrotal position or remove nonviable testicular remnants Allows for easier examination of the testis because there is an increased risk of testicular cancer in undescended testes; early surgical correction may reduce the risk of cancer as well as infertility Decrease risk of trauma and torsion Decrease risk of inguinal hernia by closing the inguinal canal Potential improved body satisfaction
Exstrophy of bladder: Eversion of posterior bladder through anterior bladder wall and lower abdominal wall; associated with open pubic arch (a severe defect)	Potential objectives of surgical correction: • Preserve renal function • Attain urinary control • Provide adequate reconstructive repair • Improve sexual function

It is a normal finding in infants and young boys and usually resolves as the child grows and the distal prepuce dilates. Occasionally the narrowing obstructs the flow of urine, resulting in a dribbling stream or even ballooning of the foreskin with accumulated urine during voiding. Phimosis causing urinary obstruction is often treated effectively by application of steroid cream twice a day for 1 month, with the option for surgical treatment with circumcision in severe cases.

Balanitis is an inflammation or infection of the phimotic foreskin, which occurs occasionally and is managed as any other inflammation or infection.

Nursing Care Management

Proper hygiene of the phimotic foreskin in infants and young boys consists of external cleansing during routine bathing. The foreskin should not be forcibly retracted because this may create scarring that can prevent future retraction. Furthermore, retraction of the tight foreskin can result in paraphimosis, a condition in which the retracted foreskin cannot be replaced in its normal position over the glans. This causes edema and venous congestion created by constriction by the tight band of foreskin—a urologic emergency that requires immediate evaluation.

HYDROCELE

A **hydrocele** is the presence of peritoneal fluid in the scrotum between the parietal and visceral layers of the tunica vaginalis and is the most common cause of painless scrotal swelling in children and adolescents, along with nonincarcerated inguinal hernia. Hydroceles may be communicating or noncommunicating. A communicating hydrocele usually develops when the processus vaginalis does not close during development, allowing for communication with the peritoneum. Noncommunicating hydroceles have no connection to the peritoneum, with fluid coming from the mesothelial lining of the tunica vaginalis. Hydroceles are common in newborns and often resolve spontaneously, usually by 1 to 3 years of age. In older children, noncommunicating hydroceles may be idiopathic or a result of trauma, epididymitis, orchitis, testicular torsion, torsion of the appendix testis or appendix epididymis, or tumor.

Communicating hydroceles may change in size during the day or with straining, whereas noncommunicating hydroceles are not reducible and so do not change size with crying or straining. Surgical repair is indicated for communicating hydroceles persisting past 1 year old because there is a risk for development of incarcerated inguinal hernia. Idiopathic hydroceles are repaired if symptomatic, and reactive hydroceles usually resolve with treatment of underlying cause, such as epididymitis.

Nursing Care Management

Surgical correction is an outpatient procedure. Advise parents that there may be temporary swelling and discoloration of the scrotum that resolves spontaneously. Straddle toys are avoided for 2 to 4 weeks, and strenuous activities in older boys may be avoided for 1 month. If a dressing is used, it is removed in 2 to 3 days, and typically the child can bathe in 3 days.

CRYPTORCHIDISM (CRYPTORCHISM)

Cryptorchidism, commonly referred to as undescended testicle(s), is failure of one or both testes to descend normally through the inguinal canal into the scrotum. It is the most common disorder of sexual development in boys. Absence of testes within the scrotum can be a result of undescended (cryptorchid) testes, retractile testes, or anorchism (absence of testes). Undescended testes can be categorized further according to location:

Abdominal: Proximal to the internal inguinal ring

Canalicular: Between the internal and external inguinal rings

Ectopic: Outside the normal pathways of descent between the abdominal cavity and the scrotum

The incidence of cryptorchidism is reported to be as high as 45% in preterm boys and less than 5% in full-term boys; by 1 year old, the incidence decreases to less than 2% and does not change thereafter (Sijstermans, Hack, Meijer, et al., 2008). Guidelines from the American Urological Association recommend that boys with cryptorchidism be referred to a surgeon by 6 months of age (Kolon, Herndon, Baker, et al., 2014).

Pathophysiology

Cryptorchidism occurs when one or both testes fail to descend through the inguinal canal and into the scrotum. Several processes may slow or arrest testicular descent, including endocrinologic abnormalities affecting the hypothalamic-pituitary-testicular axis, denervation of the genitofemoral nerve, traction of the gubernaculum, abnormal development of the epididymis, or preterm birth. Congenital hernias and abnormal testes often accompany cryptorchid testes, and they are at risk for subsequent torsion.

Anorchism is the complete absence of a testis. Anorchism is suspected whenever one or both testes cannot be palpated in the patient with apparent cryptorchidism. In some cases, bilateral anorchism is associated with disorders of sex development with genotypic and phenotypic abnormalities, specifically congenital adrenal hyperplasia (CAH). Although it is commonly associated with a normal karyotype (46, XY) and normal genital development, it is critical to rule out the possibility of CAH in the newborn because of the potential for serious harm due to inability to regulate electrolyte levels (Kolon et al., 2014). An absent testis may be due to atrophy from prenatal testicular torsion, also known as *vanishing testes* or *testicular regression syndrome.*

The cryptorchid or ectopic testis must be differentiated from anorchism because of the risk for malignant degeneration and subfertility when the testis is left in an extrascrotal location. This differentiation requires laparoscopic or direct surgical exploration (Kolon et al., 2014).

Retractile testes can be found at any level within the path of testicular descent, but they are most commonly identified in the groin. Fortunately, they are not truly cryptorchid. Instead, they are introverted to an inguinal or abdominal position because of an overactive cremasteric reflex. The cremasteric reflex, observed as withdrawal of the testis above the scrotum and into the inguinal canal in response to various stimuli, including exposure to cool temperatures, is active during infancy and peaks around 4 to 5 years old. Unlike the cryptorchid testis, the retractile testis can be gently moved into the scrotum without residual tension and does not require treatment. Retractile testes can become ascending testes and require annual monitoring. Retractile testicles do not require surgical intervention unless they do become ascended testicles that can no longer be brought into the scrotum.

Clinical Manifestations

A nonpalpable testis is typically observed by the parent or detected during routine physical examination by a nurse practitioner, physician assistant, or physician. If one testis is not palpable, the affected hemiscrotum will appear smaller than the other. With bilateral nonpalpable testes, both hemiscrota appear small. In the case of retractile testes, the parents may report intermittently observing the testes in the scrotum, interspersed with periods when they cannot be visualized or palpated. Frequently, the retractile testis will be observed in the scrotum when the child is being bathed in warm water.

Diagnostic Evaluation

It is important to differentiate the true undescended testis from the more common retractile testis. Retractile testes can be "milked" or pushed back into the scrotum, but truly undescended ones cannot. For examination, the nurse can obviate the cremasteric reflex by placing the child in a squatting or cross-legged sitting position prior to checking the position of the testes.

Therapeutic Management

Although primary hormonal therapy with luteinizing hormone–releasing hormone (nasal spray) and human chorionic gonadotropin (injection) has been used more commonly in Europe, it is no longer recommended to induce testicular descent (Kolon et al., 2014). Evidence shows low response rates and lack of long-term efficacy (Kolon et al., 2014). **Orchiopexy**, or surgical repositioning of the testis, is performed on palpable testes. Exploratory surgery may be required if the testis is not palpable. The goal of surgery is to place and fix viable undescended testes to a normal scrotal position or to remove nonviable testicular remnants. Scrotal positioning reduces the risk of torsion and trauma and permits easier examination of the testis because there is an increased risk of testicular cancer despite treatment of undescended testes. In the routine surgical procedure for undescended testes, the testes are brought down into the scrotum and secured in that position without tension or torsion. A simple orchiopexy for a palpable testis can usually be performed in an outpatient setting. If exploratory surgery is needed to determine whether a testis is present, an examination under anesthesia is the initial step. Depending on findings, a diagnostic laparoscopic procedure or an open inguinal approach may be performed. If an intra-abdominal testis is identified, this permits planning for a definitive procedure, which may be open or laparoscopic; some boys will require a planned two-stage surgical repair to bring an intra-abdominal testis into the scrotum. Approximately 10% of boys with nonpalpable testes are found to have an absent testicle at the time of surgery.

Nursing Care Management

Postoperative nursing care is directed toward preventing infection and instructing parents in home care of the child, including pain control. Observation of the wound for complications and activity restrictions are discussed. The child should avoid vigorous sports activities and use of toys that are straddled for 2 to 4 weeks postoperatively. General care is similar to that described for hydrocele repair.

Parents may be concerned about the child's future fertility, and recent studies show some decreased fertility in bilateral cryptorchidism, but in unilateral patients the fertility rate approximates that found in the general population. The risk of testicular cancer is a concern that is decreased if surgery is done before puberty, but all boys with cryptorchidism should be taught testicular self-examination at puberty to potentially facilitate early detection (Kolon et al., 2014). Surgical treatment is indicated as soon as possible after 6 months of age and definitely should be completed by 2 years old, because spontaneous descent rarely occurs after 6 months and treatment by 1 to 2 years old is associated with improved fertility and testicular growth (Kolon et al., 2014).

HYPOSPADIAS

Hypospadias is a congenital anomaly of the male urethra that results in abnormal ventral placement of the urethral opening on the underside of the penis, ranging from the glans to the perineum (Fig. 26.3). It is one of the most common congenital anomalies with an incidence report varied around the world, with 10% to 15% having a first-degree male relative (sibling or father) with the same condition (Gray, 2009; Springer, van den Heijkant, & Baumann, 2016). Both genetic and environmental factors have been associated with hypospadias. Severity of hypospadias is based on the position of the urethral opening and the degree of **chordee**, or ventral curvature of the penis. The more distant the opening from the normal position at the tip of the glans and the more marked curvature increases the severity and the need for more extensive surgical correction. In mild cases, the meatus is just below the tip of the penis. In the most severe malformation, the meatus is on the perineum between the halves of the bifid scrotum. In addition, the foreskin is usually absent ventrally and, when combined with chordee, gives the organ a hooded and crooked appearance. In severe cases the altered appearance may leave the infant's gender in doubt at birth because of the perineal position of the meatus and small penis. In any case of ambiguous genitalia, additional evaluation is essential. Cryptorchidism is present in about 10% of infants with hypospadias and increases with more proximal hypospadias with the meatus at the scrotum or perineum. There is an increased risk of disorders of sex development in patients with severe hypospadias, both with and without cryptorchidism.

Fig. 26.3 Hypospadias. (Courtesy H. Gil Rushton, MD, Children's National Medical Center, Washington, DC.)

Surgical Correction

The principal objectives of surgical correction are (1) to enhance the child's ability to void in the standing position with a straight stream, (2) to improve the physical appearance of the genitalia for psychologic reasons, and (3) to preserve a sexually adequate organ. The choice of surgical procedure is affected primarily by the severity of the defect and the presence of associated anomalies. Numerous techniques are used in repair of hypospadias and are performed under general anesthesia and typically as an outpatient procedure.

Hypospadias repair may be done by primary tubularization for milder forms in which a new urethra is made by rolling a ventral strip of penile shaft skin that normally would have formed the urethra. For more severe hypospadias, an onlay island flap is used to create the urethra, transferring a strip of inner foreskin onto the ventral urethral plate. In severe forms of hypospadias, including those with significant chordee, a two-stage repair is used to straighten the penis and create a new urethra. These are typically performed at least 6 months apart. There is no consensus on the best surgical approach for correcting severe hypospadias, and complication rates—specifically, development of urethrocutaneous fistula, urethral stricture or meatal stenosis, and urethral diverticulum—are high.

The preferred time for surgical repair is 6 to 12 months old, before the child has developed body image. Occasionally a short course of testosterone is administered preoperatively to achieve additional penile size to facilitate the surgery. If preoperative testosterone is used it does not have an effect on the eventual adult size of the phallus.

Nursing Care Management

Neonatal circumcision should be avoided in hypospadias where there is incomplete foreskin, because this is not conductive to a safe clamp

or Plastibell circumcision. In severe cases, the foreskin may be used in reconstruction. In mild hypospadias, the foreskin may not be incomplete and the abnormality may not be noted until after a circumcision is complete. This does not affect future successful reconstruction if it is needed. In most cases, the appearance after reconstruction will be of a circumcised normal penis. Preparation of parents for the type of procedure to be done and the expected cosmetic result helps avert problems.

Frequently parents are informed of what is to be surgically corrected but are not advised of what to expect as a reasonable consequence. More refined surgical techniques performed by surgeons specializing in pediatric urologic conditions have improved cosmetic and functional outcomes in these boys. If children are old enough to understand what is occurring, the nurse also prepares them for the operation and the expected outcome.

Hypospadias repair may require some type of urinary diversion with a silicone stent or feeding tube to promote optimum healing and to maintain the position and patency of the newly formed urethra. This is left in the bladder to drain urine for 5 to 10 days. In most infants and children who are not toilet trained, the catheter drains directly into the diaper. In older children, the catheter is connected to a leg bag or a larger bedside bag at night. Drainage bags should always be positioned below the bladder level for proper drainage. Tub baths are avoided until the catheter is removed. Most children will have a caudal or penile nerve block in addition to general anesthesia, which lasts 6 to 8 hours. Appropriate administration of prescribed pain medication for 48 to 72 hours after surgery will help control discomfort. When a catheter is left in place, bladder spasms are common and are very uncomfortable. Anticholinergic medications, such as oxybutynin, are typically used to prevent spasms. Parents should be advised of the possibility of bladder spasms, which are usually brief and intense and during which the child may arch his back and bring his knees up to his chest and urine may leak around the catheter. Oxybutynin is given every 8 hours typically and may require dosing adjustment, such as increasing frequency to every 6 hours to control spasms. Once the catheter is removed, the medication is no longer needed. Often a prophylactic antibiotic is given until shortly after catheter removal. Anticholinergic medication is constipating, and this is a problem that is common in the postoperative period and may be avoided with preventative measures, such as giving adequate fluid and a stool softener or laxative if needed. Preparing parents for these potential problems is an important nursing responsibility. Patients usually go home with a dressing that often comes off in 1 to 2 days and typically is removed in the bath in 3 days if there is no stent in place. If the dressing is soiled, it can be cleaned gently and removed once the parent is prepared that the appearance of the penis is often swollen, discolored, and/or bruised and that this is expected and will resolve with time. While healing, applying petroleum jelly or KY jelly to the diaper to prevent the penis from sticking can help prevent bleeding and increase comfort.

EXSTROPHY-EPISPADIAS COMPLEX

Bladder exstrophy is a severe defect involving the musculoskeletal system and the urinary, reproductive, and intestinal tracts. It is one of three anomalies that define the exstrophy-epispadias complex (EEC). **Epispadias** is an exposed or open dorsal urethra. Bladder exstrophy is a more severe defect characterized by an open, inside-out bladder with the inner surface exposed and the dorsal urethra on the lower abdominal wall (Figs. 26.4 and 26.5). The third disorder, **cloacal exstrophy**, is the most severe, and includes bladder exstrophy as well as exstrophy of the large intestine (hindgut) through an abdominal wall defect. In addition, there is anal atresia, omphalocele, hypoplasia of the colon, anomalous genitalia, and often spinal dysraphism. Fortunately,

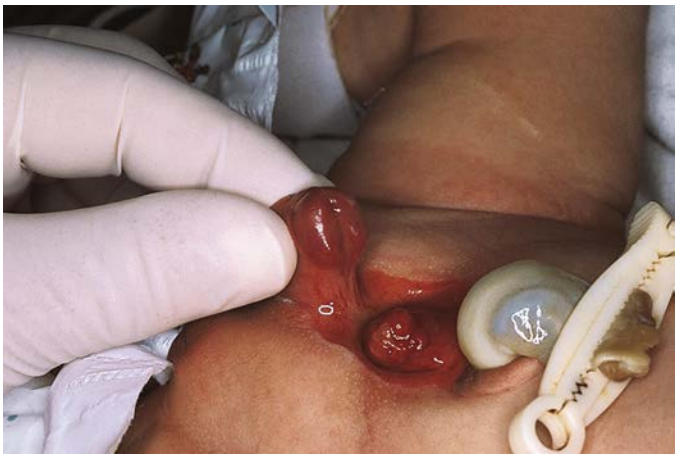

Fig. 26.4 Newborn with bladder exstrophy and epispadias. (Courtesy Tim Yankee, St. Francis Hospital, Tulsa, OK.)

Fig. 26.5 Exstrophy of bladder. (Courtesy H. Gil Rushton, MD, Children's National Medical Center, Washington, DC.)

incidence of cloacal exstrophy is low—less than 1 per 100,000 live births (Feldkamp, Botto, Amar, et al., 2011). Classic bladder exstrophy typically includes findings of diastasis (separation) of the symphysis pubis (pelvic bone), low-set umbilicus, anteriorly displaced anus, defects of the genitalia, and inguinal hernia. The incidence of bladder exstrophy ranges from 3.3 to 5 per 100,000 live births and is more common in males than females (Jayachandran, Bythell, Platt, et al., 2011).

Pathophysiology

Exstrophy results from failure of the abdominal wall and underlying structures, including the ventral wall of the bladder, to fuse in utero. As a result, the lower urinary tract is exposed, and the everted bladder appears bright red through the abdominal opening. This is accompanied by a constant seepage of urine from the exposed ureteral orifices, making the area malodorous and susceptible to infection. The constant accumulation of urine on the surrounding skin produces tissue ulceration and further infection. Progressive renal damage from infection and obstruction may cause renal failure if left untreated.

In males with bladder exstrophy, the defect of the genitalia includes epispadias and upward curvature of a shortened penis and may include other problems, such as undescended testes and inguinal hernias. In females, there is epispadias, a bifid clitoris, and small labia minora. The vagina is shortened compared with normal, and vaginal dilation may be needed to allow for sexual intercourse. In patients with cloacal exstrophy, there are often more severe anomalies, such as bifid

or duplicated uterus, split clitoris, completely separated labia, and a duplicate or absent vagina in females. Males may have a split penis and scrotum or a short, flat penis with hypospadias. In either sex, separation of the pubic bones is generally corrected by pelvic osteotomy, particularly if there is extreme diastasis to increase the likelihood of successful bladder closure. In patients with bladder exstrophy, the upper urinary tract is usually normal. Fertility is possible in females but decreased in males, possibly because of semen abnormalities, abnormal ejaculation, or both. Assisted reproductive techniques remain a viable option for patients with infertility. Recent studies indicate good long-term outcomes on erectile and general sexual function in both men and women with epispadias and bladder exstrophy (Suominen, Santtila, & Taskinen, 2015).

Therapeutic Management

The objectives of treatment are (1) preservation of renal function, (2) attainment of urinary control, (3) adequate reconstructive repair for acceptable appearance, (4) prevention of UTIs, and (5) preservation of optimum external genitalia with continence and sexual function. Two surgical approaches currently are used to correct bladder exstrophy. One is called *modern staged repair of exstrophy (MSRE),* typically involving three surgeries beginning with closure of the bladder and abdominal wall. Complete primary repair of bladder exstrophy (CPRE) is a single-stage surgical closure combining closure of the bladder and abdominal wall, partial tightening of the bladder neck, and bilateral ureteral reimplantation to correct reflux. Often pelvic osteotomies are performed at the time of primary closure to deepen the flattened pelvis, close the pubic diastasis, and release tension on the abdominal wall to improve success of primary closure (Inouye, Massanyi, Di Carlo, et al., 2013; Inouye, Tourchi, Di Carlo, et al., 2014; Kasprenski, Benz, Maruf, et al., 2018).

For the child with bladder exstrophy, CPRE may be performed within the first 72 hours of life or as a delayed procedure at about 2 months old. For the child with cloacal exstrophy, pelvic osteotomies are needed because of the wide pelvic diastasis, and surgery is done within 48 to 72 hours of life to close the bladder and omphalocele and perform intestinal diversion (Inouye et al., 2013, 2014; Kasprenski et al., 2018).

In some children, reconstruction (tightening) of the bladder neck may not provide sufficient resistance to achieve urinary continence. In these cases, suburethral collagen injections or implantation of an artificial urinary sphincter may be performed. Occasionally the bladder fails to achieve an adequate functional capacity, and augmentation enterocystoplasty is required. This procedure is typically combined with the creation of a Mitrofanoff appendiceal stoma, because catheterization is difficult after reconstruction of the proximal urethra. Abnormalities of the genitalia are addressed to ensure optimal sexual function. In boys, the testes are typically cryptorchid, and bilateral orchiopexy is combined with reconstruction of the bifid scrotum to preserve testicular function. In girls, surgical enlargement of the vaginal introitus may be needed to permit intercourse. In both genders, plastic surgery to reduce scarring of the genital area or to create an umbilicus may significantly improve the child's body image and emerging sexual identity.

Nursing Care Management

It is important to limit trauma to the exposed bladder mucosa, and the bladder is covered with a nonadherent film of plastic wrap or transparent dressing that will not stick to the bladder but can adhere to the surrounding skin. After bladder closure, the neonate is monitored for urinary output and for signs of urinary tract or wound infection. At the time of closure, the pelvic diastasis may be corrected with an osteotomy, but even if that is not performed, these patients typically require immobilization of the pelvis with traction for 2 to 4 weeks. A common form of traction for newborns is modified Bryant's traction, but spica casting and other alternatives are used. Monitoring of skin condition and circulation is critical, as is monitoring the incision for wound dehiscence. The focus of nursing care is pain management and maintenance of immobilization. Pain management may be achieved with continuous epidural therapy or patient-, parent-, or nurse-controlled intravenous analgesia and may involve the acute pain service working with the bedside nurse to provide optimal pain control (Kozlowski, 2008). Postoperative nursing care also includes monitoring of hemodynamic stability, maintaining patency and stability of tubes and drains, provision of intravenous (IV) fluids and nutrition, and inclusion of the family in care.

Postoperative nursing care after bladder neck reconstruction and antireflux surgery (ureteral reimplantation) includes routine wound care and careful monitoring of urinary output from the bladder and ureteral drainage tubes. Care after a penile lengthening, chordee release, and urethral reconstruction is similar to care after hypospadias repair.

Children who fail to attain urinary continence after bladder neck reconstruction are offered a continent diversion. In addition to routine postoperative care, nursing care after a continent diversion includes wound care, observation of nasogastric (NG) suction (surgery requires bowel resection), and measurement and observation of urinary output. Clean intermittent catheterization (CIC) is used to regularly empty the urinary reservoir. Most children are able to learn self-catheterization by 6 or 7 years old. Adult supervision is needed to ensure that the child is compliant.

Family Support and Home Care

Bladder exstrophy and the other disorders of the EEC are significant congenital abnormalities that require lifelong care by a team of specialists. Improvement in surgical techniques has helped achieve better outcomes, specifically that of the goal of continence. Parental stress is significant, and support services may be helpful for positive adaptation. Patients may also benefit from psychologic support, as adjustment problems are common, particularly in adolescents. Parents should receive teaching and practice on care of the infant or child at home and have access to resources to call if there are questions. Allowing time for the parent to voice concerns can facilitate evaluation of their understanding and help direct discharge needs. When the infant is discharged with an unrepaired defect, plastic wrap is placed over the defect, and diapers are changed frequently to prevent infection, ulceration, and odor. Parents are taught to recognize the signs of UTI and to report a suspected infection to the practitioner. General infant care remains unchanged—except for sponge baths rather than immersion in water.

DISORDERS OF SEX DEVELOPMENT

Infants born with a discrepancy between external genitalia, gonadal, and chromosomal sex are now referred to as having a **disorder of sex development (DSD)** (Lee, Nordenstrom, Houk, et al., 2016). The presentation at birth may be a genital appearance that does not permit gender declaration, and this is called **ambiguous genitalia**. These may include bilateral cryptorchidism, perineal hypospadias with bifid scrotum, clitoromegaly, posterior labial fusion, phenotypic female appearance with a palpable gonad, and hypospadias and unilateral nonpalpable gonad. Also included in the DSD category are infants with discordant genitalia and sex chromosomes. Turner syndrome (45, XO) and Klinefelter syndrome (47, XXY) are also DSDs that do not present with ambiguous genitalia.

Pathophysiology

Normal sexual differentiation starts at 7 weeks' gestation when fetuses with a Y chromosome begin developing testes. Early on, both female (XX) and male (XY) fetuses have a similar reproductive structure. Multiple genes contribute to this process, and mutations in these genes can lead to various DSDs. Congenital malformation of the genitalia are most frequently because of androgen deficiency in XY individuals and androgen excess in XX patients, though in many cases no endocrine etiology can be found (Grinspon & Rey, 2014).

Initial evaluation includes karyotype and assessment of adrenal and gonadal function, and this information can be used to categorize the infant into one of three categories:

- Virilized XX (XX DSD)
- Undervirilized XY (XY DSD)
- Mixed sex chromosome pattern

Therapeutic Management

The most common cause of ambiguous genitalia is **congenital adrenal hyperplasia (CAH)**, which can lead to life-threatening salt-wasting adrenal insufficiency in the first weeks of life. Though now a part of neonatal screening in the United States, any infant with genital ambiguity should be evaluated urgently. Laboratory testing includes a measurement of 17-hydroxyprogesterone in addition to karyotype with immediate probe for SRY (sex-determining region on the Y chromosome). Serum electrolytes are monitored, as signs and symptoms of adrenal insufficiency may include hypoglycemia, hypovolemia, hyponatremia, hyperkalemia, vomiting, and diarrhea. Fluids and electrolytes need to be replaced urgently, and the nurse plays a key role in assessing the infant and providing prescribed therapy. Additional laboratory testing may be indicated, as may be pelvic and abdominal ultrasonography to evaluate for gonads, uterus, and vagina.

Family Support

The birth of a child with ambiguous genitalia has been called a *psychosocial emergency for the family*. They require support because the answer to a seemingly simple question as to the sex of their child requires evaluation and time. Involvement in a multidisciplinary team that may include endocrinology, urology, genetics, surgeons, nurses, and social workers can make clear communication challenging, and the nurse may be instrumental in coordinating family meetings with the team.

The infant and child with DSD poses very complex and controversial management questions, including sex assignment and potential genital surgery. Traditional approaches are being questioned and continue to evolve. Referral to a specialized center for children with DSD is recommended.

Psychological Problems Related to Genital Surgery

Improved understanding of the psychologic implications of genitourinary surgery in children, improvements in technical aspects of surgery, and advances in pediatric anesthesia have resulted in modifications of the surgical approach to children requiring genitourinary surgery. Some of the problems of hospitalization, separation, and anxiety can be eased by hospital practices that are sensitive to the child's needs (see Chapter 19).

A child's body image is largely derived as a result of feedback from primary caregivers and peers, and parental anxiety regarding an acceptable physical appearance is readily communicated to an affected child. This subtle communication increases the risk of development of a distorted body image, and early repair may facilitate a positive body image. Sexual body image is another area that has been thought to be largely a function of socialization. In terms of disorders of sex development, this becomes a much more complex and multifaceted area.

The child's reaction to surgery is related to emotional and cognitive development. Separation of parent and child is important to minimize, particularly in the first 1 to 2 years of life. From about 3 to 6 years old, children are frightened of what they perceive to be threats to their body and bodily function. They are egocentric in their view of the world and may perceive surgery as punishment for real or imagined wrongdoing and require reassurance that they are not to blame. By age 7 years, they have more ability to understand but may still associate surgery with punishment. Surgical repair is ideally performed before these fears and anxieties develop. In terms of anesthesia risk, elective procedures are generally performed after 6 months of age. It is thought that children do not have memory of procedures performed by 18 to 24 months old. Age 24 to 36 months may be a time when trauma of surgery is relatively less, but in the case of an external defect this prolongs correction. The American Academy of Pediatrics Action Committee on Surgery first published recommendations on timing of elective surgery on the genitalia of male children as a review in 1996.

Nursing Care Management

Preparing children and their families for diagnostic and surgical procedures (see Chapter 20, Preparation for Diagnostic and Therapeutic Procedures) and for home care is a major nursing function. Most postoperative care involves care of the surgical site. Tub baths may be discouraged for a few days or longer, depending on procedure (if a stent or catheter is left in place) and surgeon preference. It is common practice to leave a urethral stent or catheter in place to drain directly into the diaper after some reconstructive procedures, such as hypospadias repair. The surgical site is kept clean and is inspected for signs of infection or bleeding. More complex surgeries require additional care and observation, such as drainage tube care and irrigation, dressing changes, and monitoring of collection devices.

Postoperative activity restrictions vary with age and type of surgery. Activity of infants and toddlers is not typically limited, with the exception of avoiding straddle toys following penile or scrotal surgery. Older children may need more restriction from strenuous activity for 1 month after these types of procedures. In the case of more extensive abdominal surgery, there may be restrictions on lifting and strenuous activity for a longer period. Swimming may be restricted, especially when any drains are still in place or until incisions are healed. Precise restrictions depend on the specific type of surgery and surgeon preference.

In most cases, the results of surgery are satisfactory. However, in some of the more severe defects, such as exstrophy and severe hypospadias, additional psychologic support may be needed to help adjust to concerns about penis size, appearance of the genitalia, potential ability to procreate, and rejection by peers (especially the opposite sex). Ongoing open discussion and support groups for parents and children are useful in promoting optimum emotional adjustment, particularly during adolescence.

GLOMERULAR DISEASE

NEPHROTIC SYNDROME

Nephrotic syndrome is a clinical state that includes massive proteinuria, hypoalbuminemia, hyperlipidemia, and edema. The disorder can occur as (1) a primary disease known as **idiopathic nephrosis**, **childhood nephrosis**, or **minimal-change nephrotic syndrome (MCNS)**; (2) a secondary disorder that occurs as a clinical manifestation after or in association with glomerular damage that has a known or presumed cause; or (3) a congenital form inherited as an autosomal recessive disorder. The disorder is characterized by increased glomerular permeability to plasma protein, which results in massive urinary protein

loss. This discussion is devoted to MCNS because it constitutes 80% of nephrotic syndrome cases.

Pathophysiology

The onset of MCNS can occur at any age but predominantly occurs in children between 2 and 7 years old. It is rare in children younger than 6 months old, uncommon in infants younger than 1 year old, and unusual after 8 years old. Patients with MCNS are twice as likely to be male.

The pathogenesis of MCNS is not fully understood. There may be a metabolic, biochemical, physiochemical, or immune-mediated disturbance that causes the basement membrane of the glomeruli to become increasingly permeable to protein, but the cause and mechanisms are only speculative.

The glomerular membrane, normally impermeable to albumin and other proteins, becomes permeable to proteins, especially albumin, that leak through the membrane and are lost in urine (**hyperalbuminuria**). This reduces the serum albumin level (**hypoalbuminemia**), decreasing the colloidal osmotic pressure in the capillaries. As a result, the vascular hydrostatic pressure exceeds the pull of the colloidal osmotic pressure, causing fluid to accumulate in the interstitial spaces (**edema**) and body cavities, particularly in the abdominal cavity (**ascites**). The shift of fluid from the plasma to the interstitial spaces reduces the vascular fluid volume (**hypovolemia**), which in turn stimulates the renin-angiotensin system and the secretion of antidiuretic hormone and aldosterone. Tubular reabsorption of sodium and water is increased in an attempt to increase intravascular volume. The elevation of serum lipids is not fully understood. The sequence of events in nephrotic syndrome is diagrammed in Fig. 26.6.

Diagnostic Evaluation

The disease is suspected based on clinical manifestations (Box 26.2). The generalized edema may develop rapidly or gradually but eventually prompts the family to seek medical attention. Parents usually give a history of the child being well but steadily gaining weight; appearing edematous; and then becoming anorexic, irritable, and less active.

The diagnosis of MCNS is suspected on the basis of the history and clinical manifestations (edema, proteinuria, hypoalbuminemia, and hypercholesterolemia in the absence of hematuria and hypertension) in children between 2 and 8 years old. The hallmark of MCNS is massive proteinuria (higher than 2+ on urine dipstick). Hyaline casts, oval fat bodies, and a few red blood cells (RBCs) can be found in the urine of some affected children, although there is seldom gross hematuria. The GFR is usually normal or high. Kidney function must be monitored, however, because acute kidney injury (AKI) may occur due to intravascular volume depletion, interstitial nephritis, acute tubular necrosis, or other factors (Rheault, Wei, Hains, et al., 2014).

Total serum protein concentration is low, with the serum albumin significantly reduced and plasma lipids elevated. Hemoglobin and hematocrit are usually normal or elevated as a result of hemoconcentration. The platelet count may be elevated. Serum sodium concentration may be low. If the patient does not respond to an 8-week course of daily steroids, a renal biopsy may be needed to distinguish among other types of nephrotic syndrome. The biopsy results of children with MCNS are remarkable for effacement of the foot processes of the epithelial cells lining the basement membrane, but otherwise the kidney tissue is normal.

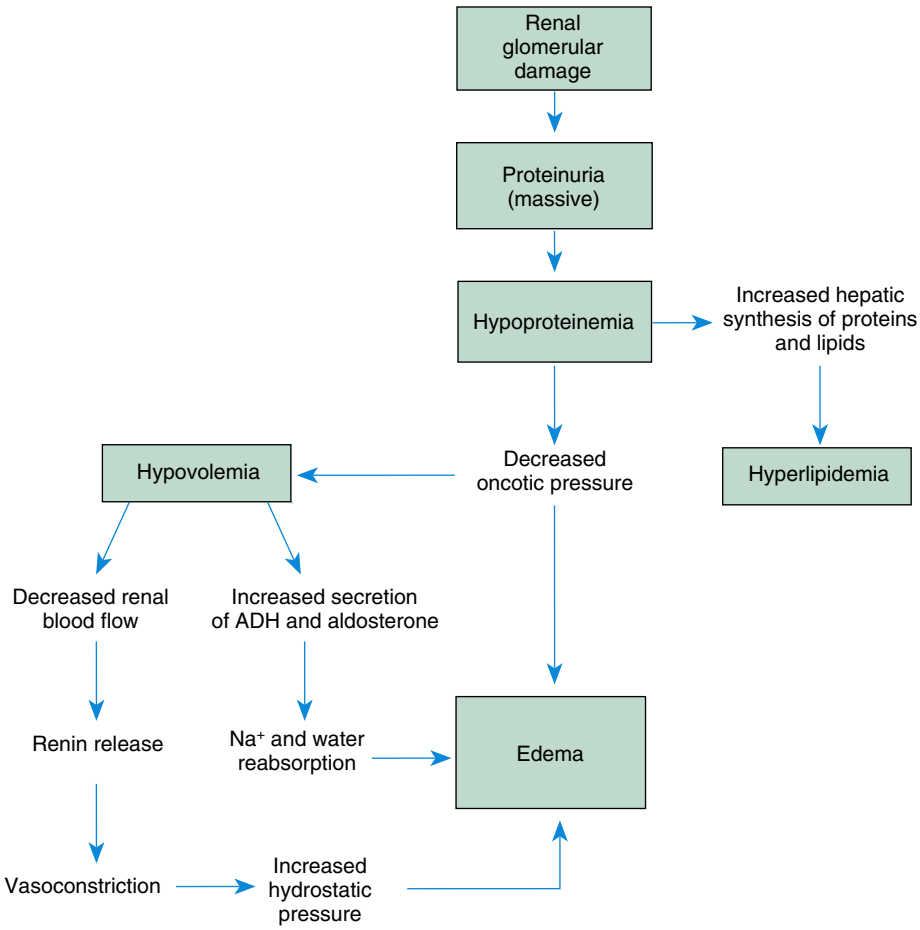

Fig. 26.6 Sequence of events in nephrotic syndrome. *ADH,* Antidiuretic hormone.

BOX 26.2 Clinical Manifestations of Nephrotic Syndrome

Weight gain
Puffiness of face (facial edema):
- Especially around the eyes
- Apparent on arising in the morning
- Subsides during the day

Abdominal swelling (ascites)
Pleural effusion
Labial or scrotal swelling
Edema of intestinal mucosal, possibly causing:
- Diarrhea
- Anorexia
- Poor intestinal absorption

Ankle or leg swelling
Irritability
Easily fatigued
Lethargic
Blood pressure normal or slightly decreased
Susceptibility to infection
Urine alterations:
- Decreased volume
- Frothy

Therapeutic Management

Objectives of therapeutic management include (1) reducing excretion of urinary protein, (2) reducing fluid retention in the tissues, (3) preventing infection, and (4) minimizing complications related to therapies. Dietary restrictions include a low-salt diet and, in more severe cases, fluid restriction. If complications of edema develop, diuretic therapy may be initiated to provide temporary relief from edema. Sometimes infusions of 25% albumin are used. Acute infections are treated with appropriate antibiotics.

Corticosteroids are the first line of therapy for MCNS. The starting dosage for prednisone is usually 2 mg/kg body weight/day for 6 weeks followed by 1.5 mg/kg every other day for 6 weeks (Lombel, Gipson, & Hodson, 2013). About two-thirds of children with MCNS have a relapse, heralded first by increased urine protein. Relapses can be diagnosed early if parents are taught routine home monitoring of urine protein by dipstick. Relapses are treated with a repeated, but usually shorter, course of high-dose steroid therapy. Side effects of the steroids include increased appetite, weight gain, rounding of the face, and behavior changes. Long-term therapy may result in hirsutism, growth retardation, cataracts, hypertension, gastrointestinal bleeding, bone demineralization, infection, and hyperglycemia. Children who do not respond to steroid therapy, those who have frequent relapses, and those in whom the side effects threaten their growth and general health may be considered for a course of therapy using other immunosuppressant medications (cyclophosphamide, chlorambucil, or cyclosporine).

Episodes of MCNS, both the first episode and relapse, often happen in conjunction with a viral or bacterial infection. Relapses can also be triggered by allergies and immunizations. Relapses in children with MCNS may continue over many years.

Complications of nephrotic syndrome include infection, circulatory insufficiency secondary to hypovolemia, and thromboembolism. Infections that may be seen in children with nephrotic syndrome include peritonitis, cellulitis, and pneumonia and require prompt recognition and vigorous treatment with appropriate antibiotic therapy.

Prognosis

The prognosis for ultimate recovery in most cases is good. In children who respond to steroid therapy, the tendency to relapse decreases with time. With early detection and prompt implementation of therapy to eradicate proteinuria, progressive basement membrane damage is minimized so that when the tendency to relapse is past, renal function is usually normal or near normal. It is estimated that approximately 80% of affected children have this favorable prognosis.

QUALITY PATIENT OUTCOMES: Nephrotic Syndrome
- Protein-free urine
- Acute infections prevented
- Edema absent or minimal
- Nutrition maintained
- Metabolic abnormalities controlled

Nursing Care Management

Continuous monitoring of fluid retention or excretion is an important nursing function. Strict intake and output records are essential but may be difficult to obtain from very young children. Application of collection bags is irritating to edematous skin that is readily subject to breakdown. Applying diapers or weighing wet pads may be necessary.

Other methods of monitoring progress include urine examination for albumin, daily weight, and measurement of abdominal girth. Assessment of edema (e.g., increased or decreased swelling around the eyes and dependent areas), the degree of pitting, and the color and texture of skin are part of nursing care. Vital signs are monitored to detect any early signs of complications, such as shock or an infective process.

Infection is a constant source of danger to edematous children and those receiving corticosteroid therapy. These children are particularly vulnerable to upper respiratory tract infection; therefore they must be kept warm and dry, active, and protected from contact with infected individuals (e.g., roommates, visitors, personnel). The Centers for Disease Control and Prevention recommend the pneumococcal conjugate vaccine (13-valent) and pneumococcal polysaccharide vaccine (PPSV, 23-valent) for children with nephrotic syndrome.

Loss of appetite accompanying relapse creates a perplexing problem for nurses. The combined efforts of nurse, dietitian, parents, and child are needed to formulate a nutritionally adequate and attractive diet. Salt is restricted (but not eliminated) during the edema phase and while the child is on steroid therapy. Fluid restriction (if prescribed) is limited to short-term use during massive edema. Every effort should be made to serve attractive meals with preferred foods and a minimum of fuss, but it usually requires considerable ingenuity to entice the child to eat (see Chapter 20, Feeding the Sick Child). Once the child feels better, the appetite (enhanced by steroids) returns. At this point, care must be taken to prevent excessive caloric intake and weight gain.

Children usually adjust activities according to their tolerance level. However, they may require guidance in selecting play activities. Suitable recreational and diversional activities are an important part of their care. Irritability and mood swings that accompany steroid therapy are not unusual in these children and may create an additional challenge for the nurse and family.

Family Support and Home Care

Continuous support of the child and family is one of the major nursing considerations. Parents are taught to detect signs of relapse and to call for changes in treatment at the earliest indication. Unless the edema and proteinuria are severe or the parents, for some reason, are unable to care for the ill child, *home care is preferred.* Parents are instructed in testing urine for albumin, administering medications, and providing

general care. Parents are also instructed on avoiding contact with infected playmates, but the child should attend school.

The prolonged course of the relapsing form of nephrotic syndrome is taxing to both the child and the family. The up-and-down course of remissions and exacerbations with periodic disruption of family life by hospitalization places a severe strain on the child and the family, both psychologically and financially. Reassurance regarding this characteristic of the course of the disease, with emphasis on the importance of long-term care, needs to be provided to parents and children. A satisfactory response is more likely when relapses are detected and therapy is instituted early, and remissions are prolonged when instructions are carried out faithfully. Continuous support of the child and family is one of the major nursing considerations (see Chapter 17).

ACUTE GLOMERULONEPHRITIS

Acute glomerulonephritis (AGN) may be a primary event or a manifestation of a systemic disorder that can range from minimal to severe. Common features include oliguria, edema, hypertension and circulatory congestion, hematuria, and proteinuria. Most cases are postinfectious and have been associated with pneumococcal, streptococcal, and viral infections. **Acute poststreptococcal glomerulonephritis (APSGN)** is the most common of the postinfectious renal diseases in childhood and the one for which a cause can be established in most cases. APSGN can occur at any age but affects primarily early school-age children, with a peak age of onset of 6 to 7 years old. It is uncommon in children younger than 2 years old, and boys outnumber girls 2 to 1.

Etiology

APSGN is an immune-complex disease that occurs after an antecedent streptococcal infection with certain strains of the group A beta-hemolytic streptococci (GABHS). Most streptococcal infections *do not* cause APSGN. A latent period of 10 to 21 days occurs between the streptococcal infection and the onset of clinical manifestations. Disease secondary to streptococcal pharyngitis is more common in the winter or spring, but when APSGN is associated with pyoderma (principally **impetigo**), it may be more prevalent in late summer or early fall, especially in warmer climates. Second episodes of APSGN are rare.

Pathophysiology

The pathophysiology of APSGN is still uncertain. Immune complexes are deposited in the glomerular basement membrane. The glomeruli become edematous and infiltrated with polymorphonuclear leukocytes, which occlude the capillary lumen. The resulting decrease in plasma filtration results in an excessive accumulation of water and retention of sodium that expands plasma and interstitial fluid volumes, leading to circulatory congestion and edema. The cause of the hypertension associated with AGN cannot be completely explained by fluid retention. Excess renin may also be produced.

Diagnostic Evaluation

Typically, affected children are in good health until they experience a streptococcal infection. In some instances, they have a history of only a mild cold or no previous infection at all. The onset of nephritis appears after an average latency period of about 1 to 3 weeks (Box 26.3). Because the child appears to be well during the latency period, parents may not recognize the association. The edema is usually relatively moderate and may not be appreciated by someone unfamiliar with the child's normal appearance.

BOX 26.3 Clinical Manifestations of Acute Poststreptococcal Glomerulonephritis

Edema:
- Especially periorbital
- Facial edema more prominent in the morning
- Spreads during the day to involve extremities, genitalia, and abdomen

Anorexia

Urine:
- Cloudy, smoky brown (resembles tea or cola)
- Severely reduced volume

Pallor

Irritability

Lethargy

Child appearing ill

Child seldom expresses specific complaints

Older children complaining of:
- Headaches
- Abdominal discomfort
- Dysuria

Vomiting possible

Mild to severely elevated blood pressure

Urinalysis during the acute phase characteristically shows hematuria and proteinuria. Proteinuria generally parallels the hematuria and may be 3+ or 4+ in the presence of gross hematuria. Gross discoloration of the urine reflects RBC and hemoglobin content. Microscopic examination of the sediment shows many RBCs, leukocytes, epithelial cells, and granular and RBC casts. Bacteria are not seen.

Azotemia that results from impaired glomerular filtration is reflected in elevated blood urea nitrogen (BUN) and creatinine levels in at least 50% of cases. Occasionally, proteinuria is excessive, and the patient may have nephrotic syndrome (i.e., hypoproteinemia and hyperlipidemia).

Cultures of the pharynx are rarely positive for streptococci because the renal disease occurs weeks after the infection.

Some serologic tests are necessary to make the diagnosis of APSGN. Circulating serum antibodies to streptococci indicate the presence of a previous infection. The antistreptolysin O (ASO) titer is the most familiar and readily available test for streptococcal infection. Other antibodies that may aid in diagnosis are elevated antihyaluronidase (AHase), anti-deoxyribonuclease B (ADNase-B), and streptozyme. All patients with APSGN have reduced serum complement 3 (C3) activity in the early stages of the disease. Rising C3 levels are used as a guide to indicate improvement of the disease and should be normal in almost all patients 8 weeks after the disease onset.

Studies that may be useful include chest x-ray examination, which generally shows cardiac enlargement, pulmonary congestion, or pleural effusion during the edematous phase of acute disease. Renal biopsy for diagnostic purposes is seldom required but may be useful in the diagnosis of atypical cases.

Therapeutic Management

Management consists of general supportive measures and early recognition and treatment of complications. Children who have normal blood pressure and a satisfactory urinary output can generally be treated at home. Those with substantial edema, hypertension, gross hematuria, or significant oliguria should be hospitalized because of the unpredictability of complications.

Dietary restrictions depend on the stage and severity of the disease, especially the extent of edema. Moderate sodium restriction and even fluid restriction may be instituted for children with hypertension and

edema. Foods with substantial amounts of potassium are generally restricted during the period of oliguria.

Regular measurement of vital signs, body weight, and intake and output is essential to monitor the progress of the disease and to detect complications that may appear at any time during the course of the disease. A record of daily weight is the most useful means for assessing fluid balance. Rarely, children with APSGN will develop AKI with oliguria that significantly alters the fluid and electrolyte balance (resulting in hyperkalemia, acidosis, hypocalcemia, or hyperphosphatemia). These children require careful management. Peritoneal dialysis or hemodialysis is seldom needed.

Acute, sometimes severe, hypertension must be anticipated and identified early. Blood pressure measurements are taken every 4 to 6 hours. A variety of antihypertensive medications and diuretics are used to control hypertension. Antibiotic therapy is indicated only for children with evidence of persistent streptococcal infections. It is used to prevent transmission of nephritogenic streptococci to other family members.

Prognosis

Almost all children correctly diagnosed as having APSGN recover completely, and specific immunity is conferred, so subsequent recurrences are uncommon. Less than 1% of children will go on to develop **end-stage renal disease (ESRD)**, although abnormal urinalysis and renal function may persist for decades (Nast, 2012).

Nursing Care Management

Nursing care of the child with glomerulonephritis involves careful assessment of the disease status, with regular monitoring of vital signs (including frequent measurement of blood pressure), fluid balance, and behavior.

Vital signs provide clues to the severity of the disease and early signs of complications. They are carefully measured, and any deviations are reported and recorded. The volume and character of urine are noted, and the child is weighed daily. Children with restricted fluid intake, especially those who are not severely edematous or those who have lost weight, are observed for signs of dehydration.

Assessment of the child for signs of cerebral complications is an important nursing function, because the severity of the acute phase is variable and unpredictable. The child with edema, hypertension, and gross hematuria may be subject to complications, and anticipatory preparations such as seizure precautions and IV equipment are included in the unfolding case study (see the Next-Generation NCLEX® Examination-Style Unfolding Case Study box later in the chapter).

For most children, a regular diet is allowed, but it should contain no added salt. Foods high in sodium and salted treats are eliminated, and parents and friends are advised not to bring snacks, such as potato chips or pretzels. Fluid restriction, if prescribed, is more difficult, and the amount permitted should be evenly divided throughout the waking hours. Meal preparation and service require special attention because the child is indifferent to meals during the acute phase. Again, collaboration with parents and the dietitian and special consideration for food preferences facilitate meal planning.

During the acute phase, children are generally content to lie in bed. As they begin to feel better and their symptoms subside, they will want to be up and about. Activities should be planned to allow for frequent rest periods and avoidance of fatigue. Children who have mild edema and no hypertension, as well as convalescent children who are being treated at home, need follow-up care. Parent education and support in preparation for discharge and home care include education in home management, dietary restrictions, infection prevention, and the need for follow-up care and health supervision. Health supervision is continued with weekly and then monthly visits for evaluation and urinalysis.

MISCELLANEOUS RENAL DISORDERS

HEMOLYTIC UREMIC SYNDROME

Hemolytic uremic syndrome (HUS) is an uncommon, acute renal disease that occurs primarily in infants and small children between 6 months and 5 years old. HUS is one of the most frequent causes of acquired AKI in children (Walsh & Johnson, 2018). The clinical features of the disease include acquired hemolytic anemia, thrombocytopenia, renal injury, and central nervous system (CNS) symptoms. The etiology of HUS is thought to be associated with bacterial toxins, chemicals, and viruses. The appearance of the disease has been associated with *Rickettsia* organisms, viruses (especially coxsackievirus, echovirus, and adenovirus), *E. coli,* pneumococci, shigellae, and salmonellae and may represent an unusual response to these infections. Multiple cases of HUS caused by enteric infection of the *E. coli* O157:H7 serotype have been traced to undercooked meat, especially ground beef. Other sources are unpasteurized milk or fruit juice, especially apple; alfalfa sprouts; lettuce; and salami. Drinking or swimming in sewage-contaminated water can also cause infection. The clinical presentation is usually a history of a prodromal illness (most often gastroenteritis or an upper respiratory tract infection) followed by the sudden onset of hemolysis and renal failure.

Pathophysiology

The primary site of injury appears to be the endothelial lining of the small glomerular arterioles, which become swollen and occluded with deposits of platelets and fibrin clots (intravascular coagulation). RBCs are damaged as they attempt to move through the partially occluded blood vessels. These damaged cells are removed by the spleen, causing acute hemolytic anemia. The platelet aggregation within the damaged blood vessels or the damage and removal of platelets produce the characteristic thrombocytopenia.

Diagnostic Evaluation

The triad of anemia, thrombocytopenia, and renal failure is sufficient for diagnosis (Box 26.4). Renal involvement is evidenced by proteinuria, hematuria, and urinary casts; BUN and serum creatinine levels are elevated. A low hemoglobin and hematocrit and a high reticulocyte count confirm the hemolytic nature of the anemia.

BOX 26.4 Clinical Manifestations of Hemolytic Uremic Syndrome

Vomiting
Irritability
Lethargy
Marked pallor
Hemorrhagic manifestations:
- Bruising
- Petechiae
- Jaundice
- Bloody diarrhea

Oliguria or anuria
Central nervous system (CNS) involvement:
- Seizures
- Stupor or coma

Signs of acute heart failure (sometimes).

Therapeutic Management

The goals of therapy are early diagnosis and aggressive, supportive care of the AKI and hemolytic anemia. Hemodialysis or peritoneal dialysis is instituted in any child who has been anuric for 24 hours or who demonstrates oliguria with uremia or hypertension and seizures. Other treatments include use of pharmacologic agents, fresh-frozen plasma, and plasmapheresis. Blood transfusions with fresh, washed packed cells are administered for severe anemia but are used with caution to prevent circulatory overload from added volume.

Prognosis

With prompt treatment, the recovery rate is about 95%, but residual renal impairment ranges from 10% to 50%. Long-term complications include chronic kidney disease (CKD), hypertension, and CNS disorders. Death is usually caused by residual renal impairment or CNS injury.

Nursing Care Management

Nursing care is the same as that provided in AKI and, for children with continued impairment, includes management of chronic disease. Because of the sudden and life-threatening nature of the disorder in a previously well child, parents are often ill prepared for the impact of hospitalization and treatment. Therefore support and understanding are especially important aspects of care.

RENAL FAILURE

Renal failure is the inability of the kidneys to excrete waste material, concentrate urine, and conserve electrolytes. It can occur suddenly (e.g., AKI) in response to inadequate perfusion, kidney disease, or urinary tract obstruction, or it can develop slowly (e.g., CKD) as a result of long-standing kidney disease or an anomaly.

Azotemia and *uremia* are terms often used in relation to renal failure. **Azotemia** is the accumulation of nitrogenous waste within the blood. **Uremia** is a more advanced condition in which retention of nitrogenous products produces toxic symptoms. Whereas azotemia is not life threatening, uremia is a serious condition that often involves other body systems.

ACUTE KIDNEY INJURY

AKI is said to exist when the kidneys suddenly are unable to regulate the volume and composition of urine appropriately in response to food and fluid intake and the needs of the organism. The principal feature of AKI is oliguria[a] associated with azotemia, metabolic acidosis, and diverse electrolyte disturbances. AKI is not common in childhood, and the outcome depends on the cause, associated findings, and prompt recognition and treatment.

The pathologic conditions that produce AKI caused by glomerulonephritis and HUS are discussed in relation to those disorders. AKI can also develop as a result of a large number of related or unrelated clinical conditions: poor renal perfusion; urinary tract obstruction; acute renal injury; cardiac surgery (Susantitaphong, Cruz, Cerda, et al., 2013); or the final expression of chronic, irreversible renal disease. The most common cause in children is transient renal failure resulting from severe dehydration or other causes of poor perfusion that may respond to restoration of fluid volume.

[a]The definition of oliguria varies extensively in the literature, from 1.8 to 4 dl/m^2 every 24 hours.

BOX 26.5 Clinical Manifestations of Acute Kidney Injury

Specific:
- Oliguria
- Anuria uncommon (except in obstructive disorders)

Nonspecific (may develop):
- Nausea
- Vomiting
- Drowsiness
- Edema
- Hypertension

Manifestations of underlying disorder or pathologic condition

Pathophysiology

AKI is usually reversible, but the deviations of physiologic function can be extreme, and mortality in the pediatric age-group remains high. There is severe reduction in the GFR, an elevated BUN level, and a significant reduction in renal blood flow.

The clinical course is variable and depends on the cause. In reversible AKI, there is a period of severe oliguria, or a low-output phase, followed by an abrupt onset of diuresis, or a high-output phase, and then a gradual return to (or toward) normal urine volumes.

In many instances of AKI, the infant or child is already critically ill with the precipitating disorder, and the explanation for development of oliguria may or may not be readily apparent (Box 26.5). When a previously well child develops AKI without an obvious cause, a careful history is taken to reveal symptoms that may be related to glomerulonephritis, obstructive uropathy, or exposure to chemicals (e.g., ingestion of heavy metals; inhalation of organic solvents; medications such as vancomycin, aminoglycosides, or nonsteroidal antiinflammatory drugs) known to be toxic to the kidneys (Goldstein, 2016). Significant laboratory measurements during renal failure that serve as a guide for therapy are BUN, serum creatinine, pH, sodium, potassium, and calcium.

Diminished urinary output and lethargy in a child who is dehydrated, is in shock, or has recently undergone surgery should be evaluated for possible AKI.

! NURSING ALERT

Any of the following signs of hyperkalemia constitute an emergency and are reported immediately:
- Serum potassium concentrations in excess of 7 mEq/L
- Presence of electrocardiographic abnormalities, such as prolonged QRS complex, depressed ST segment, high peaked T waves, bradycardia, or heart block

Therapeutic Management

Treatment of AKI is directed toward (1) treatment of the underlying cause, (2) management of the complications of renal failure, and (3) provision of supportive therapy within the constraints imposed by the renal failure.

Treatment of poor perfusion resulting from dehydration consists of volume restoration, as described in Chapter 22, in treatment of dehydration. If oliguria persists after restoration of fluid volume or if the renal failure is caused by intrinsic renal damage, the physiologic and biochemical abnormalities that have resulted from kidney dysfunction must be corrected or controlled. Initially, a Foley catheter is inserted to rule out urine retention, to collect available urine for analysis, and to monitor results of diuretic administration. The catheter may or may not be removed during the oliguric phase.

The amount of exogenous water provided should not exceed the amount needed to maintain zero water balance. It is calculated on the basis of estimated endogenous water formation and losses from sensible (primarily gastrointestinal) and insensible sources. No allotment is calculated for urine as long as oliguria persists.

When the output begins to increase, either spontaneously or in response to diuretic therapy, the intake of fluid, potassium, and sodium must be monitored and adequate replacement provided to prevent depletion and its consequences. Some patients pass enormous amounts of electrolyte-rich urine.

Complications

The child with AKI has a tendency to develop water intoxication and hyponatremia, which makes it difficult to provide calories in sufficient amounts to meet the child's needs and reduce tissue catabolism, metabolic acidosis, hyperkalemia, and uremia. If the child is able to tolerate oral foods, food sources high in concentrated carbohydrate and fat but low in protein, potassium, and sodium may be provided. However, many children have functional disturbances of the gastrointestinal tract, such as nausea and vomiting; therefore the IV route is generally preferred and usually consists of essential amino acids or a combination of essential and nonessential amino acids administered by the central venous route.

Control of water balance in these patients requires careful monitoring of feedback information, such as accurate intake and output, body weight, and electrolyte measurements. In general, during the oliguric phase, no sodium, chloride, or potassium is given unless there are other large, ongoing losses. Regular measurement of plasma electrolyte, pH, BUN, and creatinine levels is required to assess the adequacy of fluid therapy and to anticipate complications that require specific treatment.

Hyperkalemia is the most immediate threat to the life of the child with AKI. Hyperkalemia can be minimized and sometimes avoided by eliminating potassium from all food and fluid, reducing tissue catabolism, and correcting acidosis. Measures used for the reduction of serum potassium levels are oral or rectal administration of an ion-exchange resin, such as sodium polystyrene sulfonate (Kayexalate) and peritoneal dialysis or hemodialysis (see later in the chapter). The resin produces its effect by exchange of its sodium for the potassium, thus binding potassium for removal from the body. This increased sodium concentration may contribute to fluid overload, hypertension, and cardiac failure. Dialysis removes potassium and other waste products from the serum by diffusion through a semipermeable membrane.

Hypertension is a frequent and serious complication of AKI, and to detect it early, blood pressure measurements are made every 4 to 6 hours. The most common cause of hypertension in AKI is overexpansion of extracellular fluid and plasma volume together with activation of the renin-angiotensin system. Hypertension is controlled with antihypertensive drugs. Other measures that may be used include limiting fluids and salt.

Anemia is frequently associated with AKI, but transfusion is not recommended unless the hemoglobin drops below 6 g/dl. Transfusions, if used, consist of fresh, packed RBCs given slowly to reduce the likelihood of increasing blood volume, hypertension, and hyperkalemia.

Seizures may occur when renal failure progresses to uremia and are also related to hypertension, hyponatremia, and hypocalcemia. Treatment is directed to the specific cause when known. More obscure causes are managed with antiepileptic drugs.

Cardiac failure with pulmonary edema is almost always associated with hypervolemia. Treatment is directed toward reduction of fluid volume, with water and sodium restriction and administration of diuretics.

Prognosis

The prognosis of AKI depends largely on the nature and severity of the causative factor or precipitating event and the promptness and competence of management. The outcome is least favorable in children with rapidly progressive nephritis and cortical necrosis. Children in whom AKI is a result of HUS or AGN may recover completely, but residual renal impairment or hypertension is more often seen. Complete recovery is usually expected in children whose renal failure is a result of dehydration, nephrotoxins, or ischemia. AKI after cardiac surgery is less favorable. It is often impossible to assess the extent of recovery for several months.

QUALITY PATIENT OUTCOMES: Acute Kidney Injury

- Underlying cause of acute kidney injury (AKI) identified and treated
- Water balance maintained
- Hypertension controlled
- Electrolyte balance maintained
- Diet maintains calories while minimizing tissue catabolism, metabolic acidosis, hyperkalemia, and uremia

Nursing Care Management

Meticulous attention to fluid intake and output is mandatory and includes all of the physical measurements discussed previously in relation to problems of fluid balance. Monitoring fluid balance and vital signs is a continuous process, and observers are constantly on the alert for signs of complications so that appropriate interventions can be implemented. Because these children require intensive observation and often specialized treatment (such as dialysis), they are usually admitted to an intensive care unit in which needed equipment and trained personnel are available (see the Next-Generation NCLEX® Examination-Style Unfolding Case Study box later in the chapter).

Limiting fluid intake requires ingenuity on the part of caregivers to cope with the child who is thirsty. Rationing the daily intake in small amounts of fluid served in containers that give the impression of larger volumes is one strategy. Older children who understand the rationale of fluid limits can help determine how their daily ration should be distributed.

Meeting nutritional needs is sometimes a problem; the child may be nauseated, and encouraging concentrated foods without fluids may be difficult. When nourishment is provided by the IV route, careful monitoring is essential to prevent fluid overload. In addition, nursing measures such as maintaining an optimal thermal environment, reducing any elevation of body temperature, and reducing restlessness and anxiety are used to decrease the rate of tissue catabolism.

The nurse must be continually alert for changes in behavior that indicate the onset of complications. Infection from reduced resistance, anemia, and general morbidity is a constant threat. Fluid overload and electrolyte disturbances can precipitate cardiovascular complications, such as hypertension and cardiac failure. Fluid and electrolyte imbalances, acidosis, and accumulation of nitrogenous waste products can produce neurologic involvement manifested by coma, seizures, or alterations in sensorium.

Although children with AKI are usually quite ill and voluntarily diminish their activity, infants may become restless and irritable, and children are often anxious and frightened. Frequent, painful, and stress-producing treatments and tests must be performed. A supportive, empathetic nurse can provide comfort and stability in a threatening and unnatural environment.

Family Support

Providing support and reassurance to parents is among the major nursing responsibilities. The seriousness of AKI and its emergency nature are stressful to parents, and most feel some degree of guilt regarding the child's condition, especially when the illness is a result of ingestion of a toxic substance, dehydration, or a genetic disease. They

also need to be kept informed of the child's progress and provided explanations regarding the therapeutic regimen. The equipment and the child's behavior are sometimes frightening and anxiety provoking. Nurses can do much to help parents comprehend and deal with the stresses of the situation.

CHRONIC KIDNEY DISEASE

The kidneys are able to maintain the chemical composition of fluids within normal limits until more than 50% of functional renal capacity is destroyed by disease or injury. Chronic renal insufficiency or failure begins when the diseased kidneys can no longer maintain the normal chemical structure of body fluids under normal conditions. Progressive deterioration over months or years produces a variety of clinical and biochemical disturbances that eventually culminate in the clinical syndrome known as **uremia**.

A variety of diseases and disorders can result in CKD. The most frequent causes are congenital renal and urinary tract malformations, VUR associated with recurrent UTI, chronic pyelonephritis, hereditary disorders, chronic glomerulonephritis, and glomerulonephropathy associated with systemic diseases, such as anaphylactoid purpura and lupus erythematosus (see the Next-Generation NCLEX® Examination-Style Unfolding Case Study)

Pathophysiology

Early in the course of progressive renal failure, the child remains asymptomatic with only minimal biochemical abnormalities. Unless the presence of CKD is detected in the process of routine assessment, signs and symptoms that indicate advanced renal damage frequently emerge only late in the course of the disease. Midway in the disease process, as increasing numbers of nephrons are totally destroyed and most others are damaged to varying degrees, the few that remain intact

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

The Child With Chronic Kidney Disease

Day 1 9:00 am

1. A 9-year-old girl who has a history of chronic pyelonephritis has increased symptoms. Over the past several months, she has experienced increased fatigue and lack of appetite, is unable to participate in physical activities, and appears pale and listless. Her parents took her to the pediatrician, who on examination found signs and symptoms of weight loss, facial puffiness, bone and joint pain, and dryness of the skin. She told the pediatrician she was having headaches. With the child's history of chronic pyelonephritis, she was immediately referred to a pediatric nephrologist. The nurse in the pediatric nephrology clinic performs a complete history and physical examination and finds the following data. Select the history and physical assessment findings that require follow-up by the nurse. **Select all that apply.**
   - A. Nausea
   - B. Pallor
   - C. Headache
   - D. Facial edema
   - E. Increased fatigue
   - F. Pulse 90 beats/min
   - G. Muscle cramps
   - H. Height=128 cm (25% for height)
   - I. BP= 128/90 mmHg
   - J. Weight=55 lbs (24.9 kg)
   - K. Respirations= 20 breaths/min
   - L. Temperature 98.4F (36.9C)
   - M. Dryness and itchiness of the skin

Day 1, 10:00 am

2. Chronic kidney disease (CKD) occurs when the diseased kidneys can no longer maintain the normal chemical structure of blood fluids and chronic pyelonephritis can cause CKD. The pediatric nephrologist confirms that this young girl has CKD. What are the most appropriate nursing actions for a child with chronic kidney disease (CKD)? **Indicate which nursing action listed in the far-left column is appropriate to prevent the potential complication of chronic kidney disease listed in the middle column. Indicate the nursing action number in the far-right column.**
   Note that ONLY one nursing action can be used for each potential postoperative complication and that NOT all nursing actions will be used.

Nursing Action	Potential Complication	Nursing Action to Prevent Complication
1. Close monitoring of the patient's status. Follow clinical and laboratory findings. Blood studies included complete blood count (CBC), electrolytes, and kidney status.	waste products accumulate	
2. Observe for evidence of accumulated waste products.	increased excretory kidney demands	
3. Provide dietary instructions for foods that reduce excretory demands on kidneys and provide sufficient calories and protein for growth.	changes in kidney status go unrecognized	
4. Limit phosphorus, salt, and potassium as prescribed.	growth failure unrecognized	
5. Monitor growth closely since short stature is a significant side effect.	accumulation of minerals	
6. Monitor cardiovascular status, including blood pressure measurement.	renal bone disease	
7. Minimize renal bone disease by maintaining optimal calcium, phosphorus, and intact parathyroid hormone levels, and acid-base balance.		
8. Monitor for anemia. Child may require school accommodations and rest periods due to fatigue.		
9. Identify patient and family stressors that may accompany a diagnosis of CKD.		

Continued

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—cont'd

The Child With Chronic Kidney Disease

30. days later, 9:00 am

3. A 9-year-old girl diagnosed with CKD is now being followed by a nephrology specialty team and has returned to the clinic for her monthly evaluation. The nurse performing the assessment finds Susie's blood pressure elevated and notices the child's skin is pale and sallow in appearance. The child tells the nurse that she has been really tired lately and her headaches have returned. She also says her feet are more swollen than usual. Which **immediate** steps would be taken to further evaluate the kidney status? **Select all that apply.**
   - A. Check CBC.
   - B. Check electrolyte status.
   - C. Check kidney function.
   - D. Check liver function.
   - E. Perform lumbar puncture.
   - F. Document weight, height and blood pressure.
   - G. Compare vital signs and weight to previous visit.
   - H. Evaluate patient adherence to medication and dietary recommendations.
4. The laboratory tests are ordered, and results are found below. Which findings require immediate follow-up? **Select all that apply.**
   - A. hematocrit, 29%
   - B. hemoglobin, 9.8 gm/dl
   - C. platelets, 150,000/mm^3
   - D. potassium, 4.9 mmol/L
   - E. sodium, 139 mmol/L
   - F. phosphorus 5.4 mmol/L
   - G. serum creatinine, 1.9 mg/dL
   - H. white blood count (WBC), 8,500/mm^3
   - I. blood urea nitrogen (bun), 25 mg/dL
   - J. urinalysis, elevated protein and hematuria
   - K. glomerular function rate (GFR), 45 ml/min/1.73 m^2

30. Days later, 11:00 am

5. A 9-year-old girl diagnosed with CKD is now being followed by a nephrology specialty team. There is concern that the kidney status may be deteriorating based on the history and physical examination. Based on the abnormal history, physical and laboratory findings, what are the most appropriate dietary management strategies at this time? **Select all that apply.**
   - A. Restrict sodium intake.
   - B. Restrict foods high in sugar.
   - C. Reduce foods high in calories.
   - D. Limit protein to the reference daily intake for age.
   - E. Reduce milk intake to correct sodium-glucose imbalance.
   - F. Give oral medications to decrease creatinine gastrointestinal absorption.
   - G. Provide sufficient calories and protein for growth while limiting excretory demands on the kidneys.

30. Days later, 1:00 pm

6. The nurse is meeting with the child and family to discuss CKD and what to observe for at home. The mother confides she is extremely scared that she will miss something, and symptoms will worsen without her recognizing them. She states, "I did not even realize her blood pressure was up and her kidneys were worse. How will I know when they are abnormal at home?" The nurse spends time reviewing the most important concerns to look for at home. The mother and child also meet with the dietician to review important things to remember about the diet. Which statements by the mother indicate that the health teaching was effective? **Select all that apply.**
   - A. "My child will need to restrict her total calories each day to under 1,500 a day."
   - B. "Her kidneys do not work to extract wastes from my child's body and we have to be careful about her diet."
   - C. "Her protein intake will be limited to the reference daily intake for her age and outlined by the dietician."
   - D. "I will need to call the health care team if I notice more swelling in her arms and feet and if she develops frequent headaches at home."
   - E. "Frequent rest periods can help my child have more energy since she is anemic."
   - F. "Since her blood pressure is elevated, I will follow the guidelines for medication administration and sodium restriction discussed with me by the dietician."

are hypertrophied but functional. These few normal nephrons are able to make sufficient adjustments to stresses to maintain reasonable degrees of fluid and electrolyte balance. Definitive biochemical examination at this time will reveal restricted tolerance to excesses or restrictions. As the disease progresses to the end stage, because of a severe reduction in the number of functioning nephrons, the kidneys are no longer able to maintain fluid and electrolyte balance, and the features of uremic syndrome appear.

The accumulation of various biochemical substances in the blood resulting from diminished renal function produces complications such as the following:

Retention of waste products, especially BUN and creatinine

Water and sodium retention, which contributes to edema and vascular congestion

Hyperkalemia of dangerous levels

Metabolic acidosis of a sustained nature because of continual hydrogen ion retention and bicarbonate loss

Calcium and phosphorus disturbances, resulting in altered bone metabolism, which in turn causes growth arrest or retardation, bone pain, and deformities known as **renal osteodystrophy**

Anemia caused by hematologic dysfunction, including a shortened life span of RBCs, impaired RBC production related to decreased production of erythropoietin, prolonged bleeding time, and nutritional anemia

Growth disturbance, probably caused by such factors as renal osteodystrophy, poor nutrition associated with dietary restrictions and loss of appetite, and biochemical abnormalities

Children with CKD seem to be more susceptible to infection, especially pneumonia, UTI, and septicemia, although the reason for this is unclear. These children become extraordinarily sensitive to changes in vascular volume that may cause pulmonary overload, CNS symptoms, hypertension, and cardiac failure.

Diagnostic Evaluation

The diagnosis of CKD is usually suspected on the basis of any number of clinical manifestations, a history of prior renal disease, or biochemical findings. The onset is usually gradual, and the initial signs and symptoms are vague and nonspecific (Box 26.6).

Laboratory and other diagnostic tools and tests are of value in assessing the extent of renal damage, biochemical disturbances, and related physical dysfunction (see Tables 26.1 to 26.3). Often they can help establish the nature of the underlying disease and differentiate among other disease processes and the pathologic consequences of renal dysfunction.

Therapeutic Management

In irreversible renal failure, the goals of medical management are to (1) promote maximum renal function, (2) maintain body fluid and electrolyte balance within safe biochemical limits, (3) treat systemic

BOX 26.6 Clinical Manifestations of Chronic Renal Failure

Early signs:
- Loss of normal energy
- Increased fatigue on exertion
- Pallor, subtle (may not be noticed)
- Elevated blood pressure (sometimes)

As the disease progresses:
- Decreased appetite (especially at breakfast)
- Less interest in normal activities
- Increased or decreased urinary output with compensatory intake of fluid
- Pallor more evident
- Sallow, muddy appearance of skin

Child may complain of:
- Headache
- Muscle cramps
- Nausea

Other signs and symptoms:
- Weight loss
- Facial edema
- Malaise
- Bone or joint pain
- Growth retardation
- Dryness or itching of the skin
- Bruised skin
- Sensory or motor loss (sometimes)
- Amenorrhea (common in adolescent girls)

Uremic syndrome (untreated):
- Gastrointestinal symptoms
  - Anorexia
  - Nausea and vomiting
- Bleeding tendencies
  - Bruises
  - Bloody diarrheal stools
  - Bleeding from lips and mouth
- Stomatitis
- Intractable itching
- Uremic frost (deposits of urea crystals on skin)
- Unpleasant "uremic" breath odor
- Deep respirations
- Hypertension
- Congestive heart failure
- Pulmonary edema
- Neurologic involvement
  - Progressive confusion
  - Dulled sensorium
  - Coma (ultimately)
  - Tremors
  - Muscular twitching
  - Seizures

complications, and (4) promote as active and normal a life as possible for the child for as long as possible. The child is allowed unrestricted activity and is allowed to set his or her own limits regarding rest and extent of exertion. School attendance is encouraged as long as the child is able. When the effort is too great, home tutoring is arranged.

Diet regulation is the most effective means, short of dialysis, of reducing the quantity of materials that require renal excretion. The goals of diet management in renal failure are to provide sufficient calories and protein for growth while limiting the excretory demands made on the kidneys, to minimize metabolic bone disease (**osteodystrophy**), and to minimize fluid and electrolyte disturbances. Dietary protein intake is limited only to the reference daily intake (Recommended Dietary Allowance [RDA]) for the child's age. Restriction of protein intake below the RDA is believed to negatively affect growth and neurodevelopment. Malnutrition due to factors including anorexia, dietary restrictions, metabolic acidosis, and increased energy expenditure is common in these children (Carrero, Stenvinkel, Cuppari, et al., 2013).

Sodium and water are not usually limited unless there is evidence of edema or hypertension, and potassium is not usually restricted. However, restrictions of any or all three may be imposed in later stages or at any time that abnormal serum concentrations are evident.

Dietary phosphorus is controlled through reduction of protein and milk intake to prevent or correct the calcium-phosphorus imbalance. Phosphorus levels can be further reduced by oral administration of calcium carbonate preparations or other phosphate-binding agents that combine with the phosphorus to decrease gastrointestinal absorption and thus the serum levels of phosphate. Treatment with (inactive) 25-OH vitamin D and/or (active) 1,25-dihydroxy vitamin D is begun to increase calcium absorption and suppress elevated parathyroid hormone levels (Wesseling-Perry & Salusky, 2013).

Metabolic acidosis is alleviated through administration of alkalizing agents, such as sodium bicarbonate or a combination of sodium and potassium citrate.

Growth failure is one major consequence of CKD, especially in preadolescents. These children grow poorly both before and after the initiation of hemodialysis. The use of recombinant human growth hormone to accelerate growth in children with growth retardation secondary to CKD has been successful (Gupta & Lee, 2012). **Osseous deformities** that result from renal osteodystrophy, especially those related to ambulation, are troublesome and require correction if they occur. Dental defects are common in children with CKD, and the earlier the onset of the disease, the more severe are the dental manifestations (including hypoplasia, hypomineralization, tooth discoloration, alteration in size and shape of teeth, malocclusion, and ulcerative stomatitis). Therefore regular dental care is important in these children.

Anemia in children with CKD is related to decreased production of erythropoietin. Recombinant human erythropoietin (rHuEPO) is being offered to these children as thrice-weekly or weekly subcutaneous injections and is replacing the need for frequent blood transfusions. The drug corrects the anemia, which in turn increases appetite, activity, and general well-being in the children who receive it.

Hypertension may be managed initially by cautious use of a low-sodium diet, fluid restriction, and perhaps diuretics, such as hydrochlorothiazide or furosemide. Severe hypertension requires the use of other antihypertensive agents, singly or in combination.

Intercurrent infections are treated with appropriate antimicrobials at the first sign of infection; however, any drug eliminated through the kidneys is administered with caution. Other complications are treated symptomatically (e.g., central-acting antiemetics for nausea, antiepileptics for seizures, and diphenhydramine [Benadryl] for pruritus).

When the child reaches end-stage renal failure, death will eventually occur unless waste products and toxins are removed from body fluids by dialysis or kidney transplantation. These techniques have been adapted for infants and small children and are implemented in most cases of renal failure after conservative management is no longer effective (see Technologic Management of Renal Failure later in the chapter).

Prognosis

Dialysis and transplantation are the only treatments currently available for children with ESRD. Although children may survive on dialysis, it is not an ideal long-term modality. Complications include infection of access sites, growth failure, and disruption of normal socialization. Many pediatric centers encourage families of children with ESRD to consider kidney transplantation. The North American Pediatric Renal Trials and Collaborative Studies' annual transplant report documents graft survival of 96% at 1 year and 84% at 5 years for living donor kidneys and of 95% at 1 year and 78% at 5 years for deceased donor kidneys (Smith, Martz, & Blydt-Hansen, 2013).

Posttransplant complications include infection, hypertension, steroid toxicity, hyperlipidemia, aseptic necrosis, malignancy, and growth retardation (Verghese, 2017). Long-term graft survival is not guaranteed, and many children require a second or third transplant. Successful kidney transplantation does improve rehabilitation of children with CKD, both educationally and psychologically. Increasing use of primary or preemptive kidney transplants is becoming the optimal form of renal replacement therapy, leading to substantial improvement in quality of life (Goldstein, Rosburg, Warady, et al., 2009).

QUALITY PATIENT OUTCOMES: Chronic Kidney Disease

- Sufficient calories and protein for growth maintained
- Excretory demands made on the kidney are limited
- Metabolic bone disease (osteodystrophy) minimal
- Fluid and electrolyte disturbances managed
- Hypertension managed
- Growth retardation treated

Nursing Care Management

The multiple complications of ESRD are managed according to medical protocols, such as the National Kidney Foundation Kidney Disease Outcomes Quality Initiative's evidence-based clinical practice guidelines (https://www.kidney.org/professionals/guidelines). However, progressive disease places a number of stresses on the child and family, including those of a potentially fatal illness (see Chapter 17). There is a continuing need for repeated examinations that often entail painful procedures, side effects, and frequent hospitalizations. Diet therapy becomes progressively more restricted and intense, and the child is required to take a variety of medications. Ever present in all aspects of the treatment regimen is the realization that without treatment, death is inevitable.

Some specific stresses related to ESRD and its treatment are predictable. When it first becomes apparent that ESRD is inevitable, both parents and child experience depression and anxiety. Acceptance is particularly difficult if renal failure progresses rapidly after diagnosis. Denial and disbelief are usually pronounced. After renal failure is established and symptoms become progressively more distressing, the initiation of dialysis is usually perceived as a positive experience, and after experiencing initial concerns regarding the treatment, the child begins to feel better, and parental anxiety is relieved for a time.

For children, however, initiating a dialysis regimen is a traumatic and anxiety-provoking experience, because it involves surgery for implantation of a graft, fistula, or peritoneal catheter. The initial experience with the dialysis procedure is frightening to most children. They need reassurance about the nature of the preparations for dialysis and the conduct of the treatment.

Adolescents, with their increased need for independence and their urge for rebellion, usually adapt less well than younger children. They resent the control and enforced dependence imposed by the rigorous and unrelenting therapy program. They resent being dependent on hemodialysis technology, their parents, and the professional staff. Depression or hostility is common in adolescents undergoing hemodialysis.

Both the graft and the fistula require needle insertions at each dialysis. The goal is to perform pain-free venipuncture. Using buffered lidocaine with a small-gauge needle (30-gauge) to anesthetize the area before venipuncture of the graft or fistula is one method. Using an anesthetizing topical preparation, such as eutectic mixture of local anesthetics (EMLA; lidocaine and prilocaine) 1 hour before venipuncture is another approach (see Chapter 5, Pain Management). External dual-lumen venous access devices eliminate the need for needles but are more prone to infection and other central line complications.

The availability of home peritoneal dialysis has offered a greater degree of freedom for persons undergoing long-term dialysis. The nurse is responsible for teaching the family about (1) the disease, its implications, and the therapeutic plan; (2) the possible psychologic effects of the disease and the treatment; and (3) the technical aspects of the procedure. The family learns to manage the various aspects of the dialysis procedure, how to maintain accurate records, and how to observe for signs of complications that need to be reported to the proper persons.

Body changes related to the disease process (such as pale or ashen skin color, growth retardation, and lack of sexual maturation) are stress provoking. Dietary restrictions are particularly burdensome for both children and parents. Children feel deprived when they are unable to eat foods previously enjoyed and that are unrestricted for other family members. Consequently, they may fail to cooperate. Diet restrictions may be interpreted as punishment. Some children, unable to understand fully the purpose of restrictions, will sneak forbidden food items at every opportunity. Allowing children, especially adolescents, maximum participation in and responsibility for their own treatment program is helpful.

After months or years of dialysis, the parents and child feel anxiety associated with the prognosis and continued pressures of the treatment. The continuous need for treatment interferes with family plans. The time spent in transportation to and from the dialysis unit and the time spent undergoing dialysis treatments cut into time for outside activities, including school. Graft and fistula problems, as well as peritoneal catheter exit site infections, may develop and present a common source of aggravation.

The possibility of kidney transplantation often provides hope for relief from the rigors of hemodialysis and peritoneal dialysis. Most children and families respond well to a kidney transplant, and most children can be successfully rehabilitated.

The National Kidney Foundation[b] and other agencies provide a number of services and information for families of children with renal disease.

TECHNOLOGIC MANAGEMENT OF RENAL FAILURE

DIALYSIS

Dialysis is the process of separating colloids and crystalline substances in solution by the difference in their rate of diffusion through a semipermeable membrane. Methods of dialysis currently available for

[b]30 E. 33rd St., New York, NY 10016; 212-889-2210, 800-622-9010; http://www.kidney.org. In Canada: Kidney Foundation of Canada, 310–5160 Decarie Blvd., Montreal, QC H3X 2H9; 514-369-4806, 800-361-7494; http://www.kidney.ca.

clinical management of renal failure are **peritoneal dialysis**, wherein the abdominal cavity acts as a semipermeable membrane through which water and solutes of small molecular size move by osmosis and diffusion according to their respective concentrations on either side of the membrane, and **hemodialysis**, in which blood is circulated outside the body through artificial membranes that permit a similar passage of water and solutes. A third type of dialysis is **hemofiltration**, in which blood filtrate is circulated outside the body by hydrostatic pressure exerted across a semipermeable membrane with simultaneous infusion of a replacement solution. Types of hemofiltration include continuous venovenous hemofiltration and continuous venovenous hemodialysis. These continuous renal replacement therapies are used in AKI, severe fluid overload, and inborn errors of metabolism or after bone marrow transplant.

Peritoneal dialysis is the preferred form of dialysis for infants, children, and parents who wish to remain independent, families who live a long distance from the medical center, and children who prefer fewer dietary restrictions and a gentler form of dialysis. Chronic peritoneal dialysis is most often performed at home. The two types of peritoneal dialysis are **continuous ambulatory peritoneal dialysis** and **continuous cycling peritoneal dialysis**. In both methods, commercially available sterile dialysis solution is instilled into the peritoneal cavity through a surgically implanted indwelling catheter tunneled subcutaneously and sutured into place. The warmed solution is allowed to enter the peritoneal cavity by gravity and remains for a variable length of time according to the rate of solute removal and glucose absorption in individual patients. The care and management of the procedure are the responsibility of the parents of young children. Some centers have initiated use of home health nurses to give parents respite from care. Older children and adolescents can carry out the procedure themselves, which provides them with some control and less dependency. This is especially important for adolescents.

Hemodialysis requires the creation of a vascular access and the use of special dialysis equipment—the hemodialyzer, or so-called artificial kidney. Vascular access may be one of three types: fistulas, grafts, or external vascular access devices. An **arteriovenous fistula** is an access in which a vein and artery are connected surgically. The preferred site is the radial artery and a forearm vein that produces dilation and thickening of the superficial vessels of the forearm to provide easy access for repeated venipuncture. An alternative is the creation of a subcutaneous (internal) **arteriovenous graft** by anastomosing artery and vein, with a synthetic prosthetic graft for circulatory access. The most commonly used material is expanded polytetrafluoroethylene (ePTFE). Both the graft and the fistula require needle insertions with each dialysis treatment.

For external vascular access devices, percutaneous catheters are inserted in the femoral, subclavian, or internal jugular veins, even in very small children. A more permanent form of external access is available via a central catheter inserted surgically into the internal jugular vein. This catheter has a dual lumen, which allows a larger volume of blood flow with minimum recirculation. Catheters eliminate the need for skin punctures but require some home care.

Hemodialysis is best suited to children who do not have someone in the family who is able to perform home peritoneal dialysis and to those who live close to a dialysis center. The procedure is usually performed three times per week for 4 to 6 hours, depending on the child's size. Studies suggest that intensified hemodialysis (shorter sessions done 5 to 7 days weekly or longer sessions done overnight three to seven times weekly) may improve outcomes (Thumfart, Pommer, Querfeld, et al., 2014). Hemodialysis achieves rapid correction of fluid and electrolyte abnormalities but can cause problems in association with this rapid change, such as muscle cramping and hypotension. Disadvantages include school absence during dialysis and strict fluid and dietary restrictions between dialysis sessions. Boredom for the child and family is often a problem during dialysis, and planned activities should be introduced (Fig. 26.7).

NURSING ALERT

Observe for changes in the color of the dialysate draining from the child. The spent solution should be clear. If the color is cloudy, notify the practitioner immediately.

Fig. 26.7 Diversional activities help lessen the boredom children can experience during hemodialysis.

Most children show rapid clinical improvement with the implementation of dialysis, although this is directly related to the duration of uremia before dialysis and good nutrition. Growth rate and skeletal maturation improve, but recovery of normal growth is infrequent. In many cases, sexual development, although delayed, progresses to completion.

TRANSPLANTATION

Kidney transplantation is an acceptable and effective means of therapy in the pediatric age-group. Although peritoneal dialysis and hemodialysis are life preserving, both require major alterations in lifestyle. Transplantation offers the opportunity for a relatively normal life and is the preferred form of treatment for children with ESRD.

Kidneys for transplant are available from two sources: a **living related donor**, usually a parent or a sibling, or a **cadaver donor**, wherein the family of a dead or brain-dead patient consents to donation of a healthy kidney. Retransplantation may be required if rejection occurs.

The primary goal in transplantation is the long-term survival of grafted tissue by securing tissue that is antigenically similar to that of the recipient and by suppressing the recipient's immune mechanism. The immunosuppressant therapy of choice has been corticosteroids (prednisone) in conjunction with cyclosporine or tacrolimus and mycophenolate mofetil. Other therapies include antilymphoblast globulin or monoclonal antibodies. New immunosuppressant medications and early withdrawal of steroids or steroid-free protocols are rapidly coming into clinical trials and use in large transplant centers (Kim, Webster, & Craig, 2013). It is important for the nurse to learn about the medications used in the antirejection protocols and their side effects.

Because the immunosuppressant medications are taken indefinitely, transplant patients experience many side effects of the drugs, including hypertension, growth retardation, cataracts, risk of infection, obesity, characteristics of Cushing syndrome, and hirsutism.

Rejection of the transplanted kidney is the most common cause of transplant failure. Rejection is treated aggressively with immunosuppressant medications and can often be reversed. Some patients do not respond to treatment of acute rejection or develop chronic rejection and must eventually return to dialysis or undergo another kidney transplant.

! NURSING ALERT

The child with a kidney transplant who exhibits any of the following should be evaluated immediately for possible rejection:

- Fever
- Swelling and tenderness over graft area
- Diminished urinary output
- Elevated blood pressure
- Elevated serum creatinine

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. The nurse is caring for a 4-year-old girl with a history of frequent urinary tract infections (UTIs). The child presents with strong-smelling urine, frequency and pain on urination. A urinalysis is needed for diagnostic evaluation and the nurse is preparing the child and mother for a clean voided urine specimen for evaluation. What does the nurse need to be aware of before obtaining the urine sample? **Select all that apply.**
   - **A.** Children who are toilet trained can provide a clean voided urine sample for culture.
   - **B.** The nurse should obtain the urine specimen through suprapubic aspiration.
   - **C.** Because children who have a UTI will have painful urination, have the child drink a large amount of fluid before obtaining the sample.
   - **D.** The specimen should be sent to the laboratory less than 8 hours after voiding with storage at room temperature or less than 8 hours after voiding with refrigeration.
   - **E.** The child should be told to urinate in the toilet and that midway through urination a small amount of urine should be collected in a sterile container.
   - **F.** Because the child is febrile, the nurse should immediately start an antimicrobial and then obtain a urine culture.

2. A 7-year-old girl with periorbital edema, hypertension, decreased urine output, pallor, and fatigue is admitted to the pediatric unit. She had a cold and sore throat 2 weeks ago that resolved. Her brother and younger sister also had these symptoms. She is active in school and plays soccer. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**

   Children who present with ____1____ glomerulonephritis may have a history of a ____2____ infection. ____3____ tests during the acute phase shows hematuria and proteinuria.

Options for 1	Options for 2	Options for 3
post staphylococcal	Group A beta-hemolytic streptococci	Blood
post meningitis	Group B beta-hemolytic streptococci	Urine
post streptococcal	Group A beta-hemolytic staphylococcus	Radiographic
post pneumococcal	Group B beta-hemolytic staphylococcus	Ultrasound

3. A three-year-old girl has a urinary tract infection (UTI) and is seen for follow-up in the pediatric office. The nurse after completing a history and physical examination is meeting with the mother to discuss important ways to prevent another urinary tract infection. Which of the topics listed below would be included in the health teaching for the parent before leaving the clinic? **Select all that apply.**
   - **A.** Give prophylactic antibiotics.
   - **B.** Encourage adequate fluid intake.
   - **C.** Make sure the child is not constipated.
   - **D.** How to cleanse the genital areas from front to back.
   - **E.** Encourage the child to hold urine as long as possible.
   - **F.** Make sure mother is aware of the signs and symptoms of UTI.
   - **G.** Make sure the child empties the bladder completely and frequently.

4. A 4-month-old child has had surgical correction for hypospadias. The nurse is meeting with the mother to give discharge instructions for home care. The mother is young and recently divorced. This is her first child. The infant will have a stent in place to drain urine for the next 5-10 days. The nurse recognizes a **need for additional teaching** when the mother says which of the following? **Select all that apply.**
   - **A.** "I know that the catheter will drain into the diaper for 5-10 days."
   - **B.** "I will give pain medication around the clock for 14 days after surgery."
   - **C.** "My child can take a tub bath when we arrive home because it will soothe the area."
   - **D.** "My child will be on an antibiotic to prevent infection until the catheter is removed."
   - **E.** "I realize that bladder spasms may occur and my child may arch his back and bring his knees up to his chest during the spasm."

The Child With Cerebral Dysfunction

Marilyn J. Hockenberry

CONCEPTS

- Intracranial Regulation
- Sensory Perception
- Infection
- Safety

THE BRAIN AND INCREASED INTRACRANIAL PRESSURE

The brain, tightly enclosed in the solid bony cranium, is well protected but highly vulnerable to pressure that may accumulate within the enclosure (Fig. 27.1). Its total volume—brain (80%), cerebrospinal fluid (CSF; 10%), and blood (10%)—must remain approximately the same at all times. A change in the proportional volume of one of these components (e.g., increase or decrease in intracranial blood) must be accompanied by a compensatory change in another (e.g., decrease or increase in CSF). In this way the volume and pressure normally remain constant. Examples of compensatory changes are reduction in blood volume, decrease in production of CSF, increase in CSF absorption, or shrinkage of brain mass by displacement of intracellular and extracellular fluid.

Children with open fontanels compensate for increased volume by skull expansion and widened sutures. However, at any age the capacity for spatial compensation is limited. An increase in intracranial pressure (ICP) may be caused by tumors or other space-occupying lesions, accumulation of fluid within the ventricular system, bleeding, or edema of cerebral tissues. Once compensation is exhausted, any further increase in volume results in a rapid rise in ICP.

The early signs and symptoms of increased ICP, such as headache, vomiting, personality changes, irritability, and fatigue, are often subtle (Box 27.1). In older children, subjective symptoms are headache, especially when arising after lying flat (e.g., on awakening in the morning) or when coughing, sneezing, or bending over, and nausea and vomiting. The child may complain of double vision or blurred vision with movement of the head. Seizures may occur. In children whose cranial sutures have not closed, there is an increase in head circumference and tense or bulging fontanels. Cranial sutures may widen. Head circumference can enlarge until the child is 5 years of age if the condition progresses slowly. As pressure increases, the pupils become progressively sluggish in reaction and eventually become fixed and dilated. The level of consciousness progressively deteriorates from drowsiness to eventual coma. Problems related to increased ICP are discussed later in the chapter in relation to head injury and hydrocephalus (see Chapter 25, Brain Tumors).

Physiologic and biochemical changes within the cerebral vasculature serve to complicate the primary causes of increased ICP. Especially in cases of trauma, blood flow often initially increases as a result of venous congestion or vasomotor paralysis. If cerebral hypoxia is associated with the cerebral dysfunction, the compensatory vasodilation caused by oxygen deficiency will tend to increase the cerebral flow. However, blood flow is reduced as ICP progressively increases, with diminished blood supply to the brain tissues. The classic responses observed in adults (widening pulse pressure, increased blood pressure) rarely occur in children or are very late signs. Periodic or irregular breathing is an ominous sign of brainstem (especially medullary) dysfunction that often precedes apnea.

EVALUATION OF NEUROLOGIC STATUS

Earlier chapters discuss methods to evaluate neurologic function in relation to numerous aspects of child care. The neurologic examination is an integral part of the health assessment (see Chapter 4) and newborn assessment (see Chapter 7). Chapter 30 discusses some of the tests used to differentiate neuromuscular disorders. The assessment tools and examinations in this chapter are primarily those used to assess intracranial integrity.

ASSESSMENT: GENERAL ASPECTS

Children younger than 2 years of age require special evaluation because they are unable to respond to directions designed to elicit specific neurologic responses. Early neurologic responses in infants are primarily reflexive; these responses are gradually replaced by meaningful movement in the characteristic cephalocaudal direction of development. This evidence of progressive maturation reflects more extensive myelinization and changes in neurochemical and electrophysiologic properties.

Most information about infants and small children comes from observation of spontaneous and elicited reflex responses. As they develop increasingly complex gross and fine motor skills and communication skills, more sophisticated techniques are used to assess acquisition of developmental milestones. Delay or deviation from expected milestones helps identify high-risk children. Persistence or reappearance of primitive reflexes indicates a pathologic condition. In evaluating the infant or young child, it is important to obtain the history of the pregnancy, delivery, respiratory status at birth, and neonatal health, including any need for intensive care hospitalization to determine the possible impact of intrauterine and extrauterine environmental influences known to affect the orderly maturation of the central nervous system (CNS). These influences include maternal infections, chemical exposure, trauma, medication, illicit drug use, and metabolic insults.

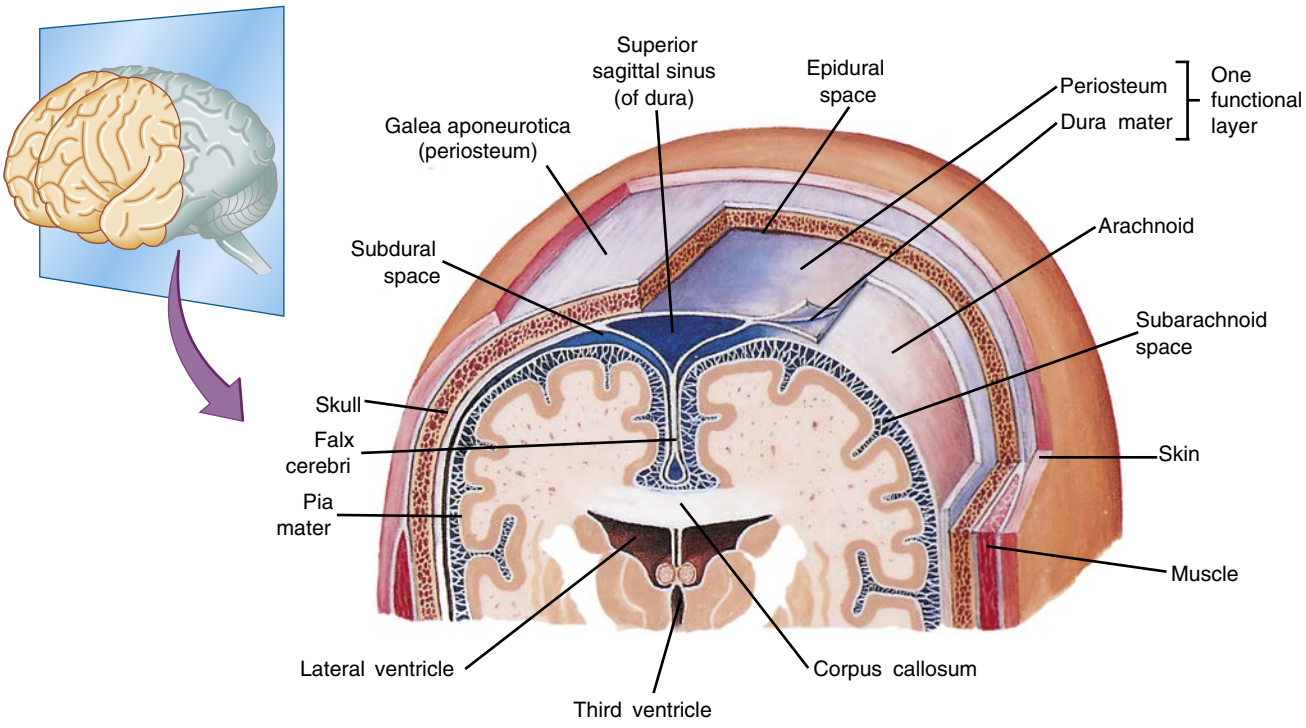

Fig. 27.1 Coronal section of top of head showing meningeal layers. (From Patton, K. T., & Thibodeau, G. A. [2010]. *Anatomy and physiology* [7th ed.]. St. Louis, MO: Mosby.)

BOX 27.1 Clinical Manifestations of Increased Intracranial Pressure in Infants and Children

Infants
Tense, bulging fontanel
Separated cranial sutures
Macewen (cracked-pot) sign
Irritability and restlessness
Drowsiness
Increased sleeping
High-pitched cry
Increased frontooccipital circumference
Distended scalp veins
Poor feeding
Crying when disturbed
Setting-sun sign

Children
Headache
Nausea
Forceful vomiting
Diplopia, blurred vision
Seizures
Indifference, drowsiness
Decline in school performance
Diminished physical activity and motor performance
Increased sleeping
Inability to follow simple commands
Lethargy

Late Signs in Infants and Children
Bradycardia
Decreased motor response to command
Decreased sensory response to painful stimuli
Alterations in pupil size and reactivity
Extension or flexion posturing
Cheyne-Stokes respirations
Papilledema
Decreased consciousness
Coma

History

A family history can sometimes offer clues regarding possible genetic disorders with neurologic manifestations. A review of family members often identifies conditions that might otherwise be overlooked, especially increased number of miscarriages or siblings or relatives who died at an early age. The nurse asks questions regarding specific neurologic problems, such as intellectual and developmental disabilities, deafness, epilepsy, blindness, unusual movements, weakness, ataxia, stroke, and progressive mental deterioration. History of consanguinity is also important.

A health history provides valuable clues regarding the cause of neurologic dysfunction. A history is assessed for injury with loss of consciousness, febrile illness, an encounter with an animal or insect, ingestion of neurotoxic substances, inhalation of chemicals, past illness, and known diabetes mellitus or sickle cell disease. Sudden or progressive alterations in movement or mental abilities may provide clues for investigation. It is also important to ascertain the chronologic course of the illness.

Physical Examination

Physical examination includes observation of the size and shape of the head (particularly in the infant and young child), spontaneous activity and postural reflex activity, and sensory responses. Note whether the patient is lethargic, drowsy, stuporous, alert, active, or irritable. The nurse also observes the overall tone, noting whether there is a normal flexed posture or one of extreme extension, opisthotonos, or hypotonia. Symmetry of movement is also assessed.

Facial features may suggest a specific syndrome. A high-pitched, piercing cry in an infant is often associated with CNS disorders. An abnormal respiratory cycle, such as prolonged apnea, ataxic breathing, paradoxic chest movement, and hyperventilation, may be the result of a neurologic problem.

Older children can be evaluated by the usual methods used in a neurologic examination. In addition, an estimation of the level of development provides essential information about neurologic function. This assessment is discussed throughout the book in relation to evaluation for specific disorders such as intellectual and developmental disabilities, failure to thrive, attention-deficit/hyperactivity disorder, cerebral palsy, cerebral tumors, and other physical or behavioral problems. Developmental screening tests can assess developmental progress in the young child.

Muscular activity and coordination, including ocular movements and gait, are valuable sources of information. Ocular movements,

pupillary response, facial movements, and mouth functions provide clues regarding CNS involvement or impingement (see Chapter 4 for CNS and reflex testing). Testing reflexes, strength, and coordination and for the presence and location of tremors, twitching, tics, or other unusual movements are also aspects of the neurologic assessment.

ALTERED STATES OF CONSCIOUSNESS

Consciousness implies awareness—the ability to respond to sensory stimuli and have subjective experiences. Consciousness has two aspects: alertness, an arousal-waking state that includes the ability to respond to stimuli, and cognition, which includes the ability to process stimuli and produce verbal and motor responses.

An ***altered state of consciousness*** usually refers to varying states of unconsciousness that may be momentary or may last for hours, days, or indefinitely. Unconsciousness is depressed cerebral function—the inability to respond to sensory stimuli and have subjective experiences. Coma is defined as a state of unconsciousness from which the patient cannot be aroused, even with powerful stimuli.

! NURSING ALERT

Lack of response to painful stimuli is abnormal and must be reported immediately.

Etiology

An altered state of consciousness may be the outcome of several processes that affect the CNS. Impaired neurologic function can result from a direct or indirect cause. Some altered states, such as the diffuse changes observed in encephalitis, are directly related to cerebral insult. Others are the result of dysfunction in other organs or processes. For example, biochemical changes can impair neurologic function without morphologic findings, as in hypoglycemia.

Level of Consciousness

Assessment of level of consciousness (LOC) remains the earliest indicator of improvement or deterioration in neurologic status. LOC is determined by observations of the child's responses to the environment. Other diagnostic tests, such as motor activity, reflexes, and vital signs, are more variable and do not necessarily directly parallel the depth of the comatose state. The most consistently used terms are described in Box 27.2.

BOX 27.2 Levels of Consciousness

Full consciousness—Awake and alert, orientated to time, place, and person; behavior appropriate for age.
Confusion—Impaired decision making.
Disorientation—Confusion regarding time, place, and/or person; decreased level of consciousness.
Lethargy—Limited spontaneous movement, sluggish speech, drowsiness.
Obtundation—Arousable with stimulation.
Stupor—Remaining in a deep sleep, responsive only to vigorous and repeated stimulation.
Coma—No motor or verbal response to noxious (painful) stimuli.
Persistent vegetative state (PVS)—Permanently lost function of the cerebral cortex. Eyes follow objects only by reflex or when attracted to the direction of loud sounds; all four limbs are spastic but can withdraw from painful stimuli; hands show reflexive grasping and groping; the face can grimace, some food may be swallowed, and the child may groan or cry but utter no words.

Modified from Ball, J. W., Dains, J. E., Flynn, J. A., et al. (Eds.). (2019). *Seidel's guide to physical examination* (9th ed.). St. Louis, MO: Elsevier.

Coma Assessment

Diminished alertness as a result of pathologic conditions occurs on a continuum and is designated as the comatose state, which extends from somnolence at one end to deep coma at the other. To produce coma, one of the following must occur: (1) extensive, diffuse, bilateral cerebral hemispheric destruction (the brainstem may be intact); (2) a lesion in the diencephalon; or (3) destruction of the brainstem down to the level of the lower pons.

Several scales have been devised in an attempt to standardize the description and interpretation of the degree of depressed consciousness. The most popular of these is the ***Glasgow Coma Scale (GCS)***, which consists of a three-part assessment: eye opening, verbal response, and motor response. The GCS was created to meet a clinical need to identify criteria for the consciousness level. For clinical purposes, the primary role of observation of the LOC is to detect a life-threatening complication such as cerebral edema. The GCS requires observational skills and is readily reproducible between observers.

A pediatric version of the GCS recognizes that expected verbal and motor responses must be related to the child's age (Fig. 27.2).

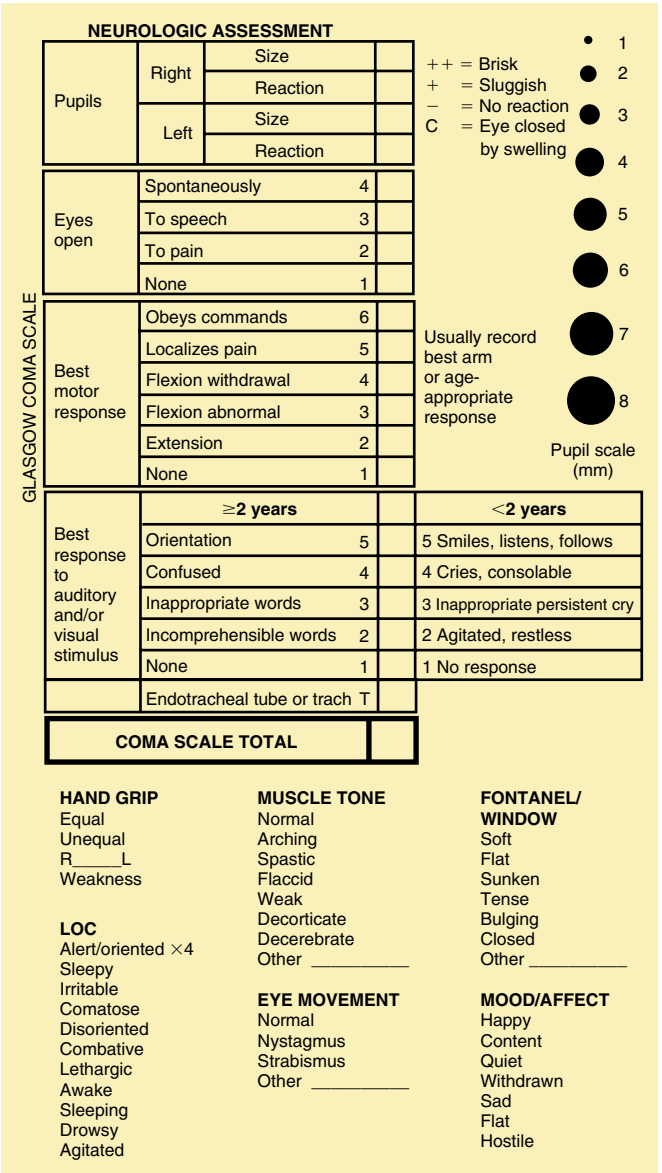

Fig. 27.2 Pediatric coma scale.

The pediatric coma scale does not assess verbal responses as such but records smiling, crying, and interaction. It uses a 6-point motor scale that is inappropriate for children younger than 6 months of age. In children younger than 5 years of age, speech is understood to be any sound at all, even crying. Young children demonstrate orientation by identifying their parents correctly or giving their own names. When assessing LOC in young children, the nurse may find it helpful to have a parent present to help elicit a desired response. An infant or child may not respond in an unfamiliar environment or to unfamiliar voices.

Numeric values are assigned to the levels of response in each category. The sum of these numeric values provides an objective measurement of the patient's LOC. The lower the score, the deeper the coma. A person with an unaltered LOC would score the highest, 15; a score of 8 or below is generally accepted as a definition of coma; the lowest score, 3, indicates deep coma or death.

The GCS in itself is not sufficient to determine depressed consciousness in all children. For example, because a child with quadriplegia cannot respond to commands physically, the child's GCS can be very low but the child may be cognitively intact. Nevertheless, the GCS provides a more objective method for evaluating the state of consciousness in most cases. Severely injured children (GCS ≤8) may have a consistent grading of motor response, verbal response, and eye opening.

The GCS score performed during preadmission (i.e., assessment in the field), in the emergency department, and throughout the inpatient admission is universally accepted as one criterion to determine the patient's prognosis (Braine & Cook, 2017). GCS scores of 5 or less are associated with poor outcome (Murphy, Thomas, Gertz, et al., 2017).

Clinical Death

There is no precise diagnosis for clinical death. Different tissues undergo permanent damage after varying periods of exposure to an ongoing insult; the brain (especially the cerebrum) has become the tissue of most importance in determining the time of death. The current concept of dying is a process that takes place over a finite interval of time rather than an event that occurs spontaneously. ***Brain death*** is a clinical diagnosis based on the total cessation of brainstem and cortical brain function that causes irreversible widespread brain injury and coma. In children the most common causes are trauma, anoxic encephalopathy, infections, and cerebral neoplasms. The pronouncement of brain death requires two conditions: (1) complete cessation of clinical evidence of brain function and (2) irreversibility of the condition. It is essential to establish the absence of a reversible condition, especially a toxic and metabolic disorder, sedative-hypnotic drugs, paralytic agents, hypothermia, hypotension, and surgically remediable conditions (Nakagawa, Ashwal, Mathur, et al., 2012).

Organ transplantation has created a need to separate the process of death from the retrieval of viable tissues at a time when the brain is already dead. The clinical criteria for brain death must be met so that there is no error. Although the legal status of the concept of death varies among individual states and communities in the United States, the Task Force for the Determination of Brain Death in Children has established guidelines for the determination of brain death in children (see Nursing Care Guidelines box and Chapter 17, Organ or Tissue Donation and Autopsy). At least two different attending physicians should participate in diagnosing brain death in children (Nakagawa et al., 2012).

NURSING CARE GUIDELINES

Establishing Brain Death in Children

Coma and apnea must coexist. Child must exhibit complete loss of consciousness, vocalization, and volitional activity.

Brainstem function must be absent, as defined by the following:

- Midposition or fully dilated pupils in both eyes that do not respond to light.
- Absence of spontaneous eye movements and those induced by oculocephalic and caloric (oculovestibular) testing.
- Absence of movement of bulbar musculature, including facial and oropharyngeal muscles.
- Absence of the corneal, gag, cough, sucking, and rooting reflexes.
- Absence of respiratory movements when child is removed from respirator. Apnea testing using standardized methods can be performed but is done after other criteria are met.

Child must not be significantly hypothermic or hypotensive for age.

Flaccid tone and absence of spontaneous or induced movements, including spinal cord events such as reflex withdrawal or spinal myoclonus, should exist.

Examination should remain consistent with brain death throughout the observation and testing period.

Observation periods according to age:

- Term newborn 37 weeks of gestational age and up to 30 days of age—Two separate examinations separated by at least 24 hours
- 31 days to 18 years old—Two separate examinations separated by at least 12 hours

Ancillary testing with electroencephalogram or cerebral blood flow testing should be considered if there is concern about the validity of the examination.

Data from Nakagawa, T. A., Ashwal, S., Mathur, M., et al. (2012). Guidelines for the determination of brain death in infants and children: An update of the 1987 task force recommendations—Executive summary. *Annals of Neurology, 71*(4), 573–585.

NEUROLOGIC EXAMINATION

The purpose of the neurologic examination is to establish an accurate, objective baseline of neurologic function. Therefore it is essential that the neurologic examination be documented in a descriptive and detailed fashion, thereby enhancing the ability to detect subtle changes in neurologic status over time. Descriptions of behaviors should be simple, objective, and easily interpreted—for example, "Drowsy but awake and conversationally rational/oriented" or "Sleepy but arousable with vigorous physical stimuli; pressure to nail base of right hand results in upper extremity flexion/lower extremity extension."

Vital Signs

Pulse, respiration, and blood pressure provide information on the adequacy of circulation and the possible underlying cause of altered consciousness. Autonomic activity is most intensively disturbed in deep coma and in brainstem lesions. Body temperature is often elevated; sometimes the elevation is extreme. High temperature is most often a sign of an acute infectious process or heatstroke, but it may be caused by ingestion of some drugs (especially salicylates, alcohol, and barbiturates) or by intracranial bleeding, especially subarachnoid hemorrhage. Hypothalamic involvement may cause elevated or decreased temperature. Serious infection may produce hypothermia.

The pulse is variable and may be rapid, slow and bounding, or feeble. Blood pressure may be normal, elevated, or very low. The Cushing reflex, or pressor response that causes a slowing of the pulse and an increase in blood pressure, is uncommon in children; when it does occur, it is a very late sign of increased ICP. Medications can also affect vital signs. For assessment purposes, actual changes in pulse and blood pressure are more important than the direction of the change.

Respirations are more often slow, deep, and irregular. Slow and deep breathing often occurs in the heavy sleep caused by sedatives, after seizures, or in cerebral infections. Slow, shallow breathing may result from sedatives or opioids. Hyperventilation (deep and rapid respirations) is usually the result of metabolic acidosis or abnormal stimulation of the respiratory center in the medulla caused by salicylate poisoning, hepatic coma, or Reye syndrome. A pattern of alternating hyperventilation and breath holding during wakefulness is common in Rett syndrome.

Breathing patterns have been described with a number of terms (e.g., *apneustic, cluster, ataxic, Cheyne-Stokes*). However, it is better to describe what is being observed rather than placing a label on it because the terms are often used and interpreted incorrectly. Periodic or irregular breathing is a sign of brainstem (especially medullary) dysfunction. This is an ominous sign that often precedes complete apnea. The odor of the breath may provide additional clues (e.g., the fruity and acetone odor of ketosis, the foul odor of uremia, the fetid odor of hepatic failure, or the odor of alcohol).

Skin

The skin may offer clues to the cause of unconsciousness. The body surface should be examined for injury, needle marks, petechiae, bites, and ticks. Evidence of toxic substances may be found on the hands, face, mouth, and clothing—especially in small children.

Eyes

Assess pupil size and reactivity (Fig. 27.3). Pupils either do or do not react to light. Pinpoint pupils are commonly observed in poisoning (e.g., opiate or barbiturate poisoning) or in brainstem dysfunction. Widely dilated and reactive pupils are often seen after seizures and may involve only one side. Widely dilated and fixed pupils suggest paralysis of CN III (oculomotor nerve) secondary to pressure from herniation of the brain through the tentorium. A unilateral fixed pupil usually suggests a lesion on the same side. Bilateral fixed pupils, if present for more than 5 minutes, usually imply brainstem damage. Dilated and nonreactive pupils also occur in hypothermia, anoxia, ischemia, poisoning with atropine-like substances, or prior instillation of mydriatic drugs. Some of the therapies used (e.g., barbiturates) can alter pupil size and reaction.

The description of eye movements should indicate whether one or both eyes are involved and how the reaction was elicited. Ask the parents if the child has strabismus, which may cause the eyes to appear misaligned.

! NURSING ALERT

The sudden appearance of a fixed and dilated pupil is a neurosurgical emergency.

Blinking observed at rest or in response to a sudden loud noise or bright light implies that the pontine reticular formation is intact. The corneal reflex, blinking of the eyelids when the cornea is touched with a wisp of cotton, can test the integrity of the ophthalmic division of CN V (trigeminal nerve). Posttraumatic strabismus indicates CN VI (abducens nerve) damage.

Eye movements are assessed by the doll's head maneuver, in which the child's head is rotated quickly to one side and then to the other. When the brainstem centers for eye movement are intact, there is conjugate (paired or working together) movement of the eyes in the direction opposite the head rotation. Absence of this response suggests dysfunction of the brainstem or CN III. Downward or lateral deviation is often observed in association with pupillary dilation in dysfunction of CN III.

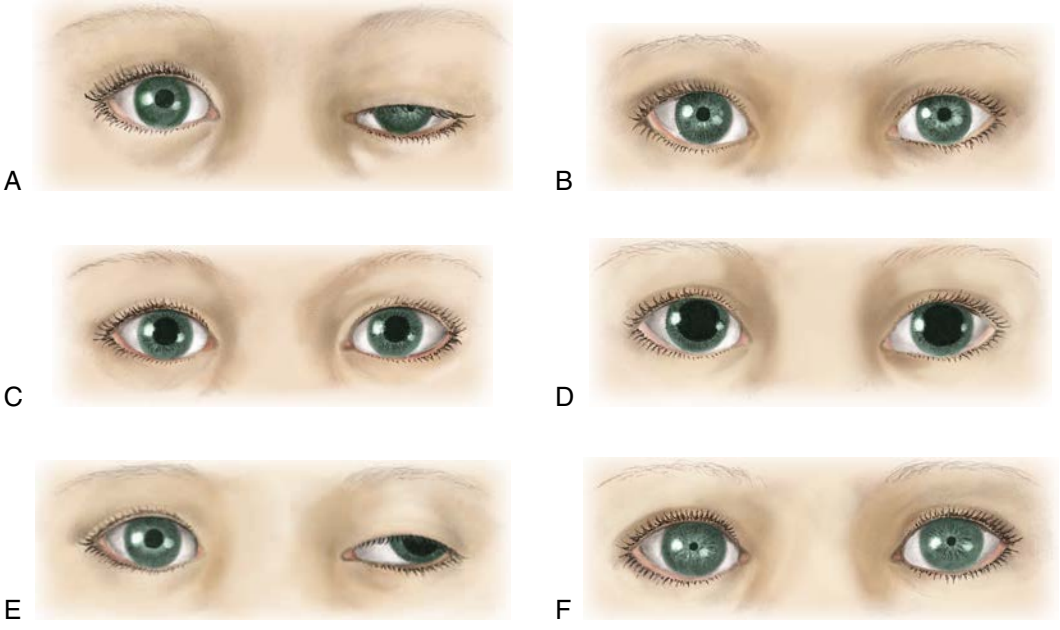

Fig. 27.3 Variations in pupil size with altered states of consciousness. **A,** Ipsilateral pupillary constriction with slight ptosis. **B,** Bilateral small pupils. **C,** Midposition, light fixed to all stimuli. **D,** Bilateral dilated and fixed pupils. **E,** Dilated pupils, left eye abducted with ptosis. **F,** Pinpoint pupils.

NURSING ALERT

Any tests that require head movement are not attempted until after cervical spine injury has been ruled out.

The caloric test, or oculovestibular response, is elicited by irrigating the external auditory canal with 10 ml of ice water over a period of approximately 20 seconds (with the head of bed elevated at a 30-degree angle). This test normally causes movement of the eyes toward the side of stimulation. This response is lost when the pontine centers are impaired and thus provides important information in assessment of the comatose patient.

NURSING ALERT

The ice water caloric test is painful and is never performed if the child is awake or the tympanic membranes are ruptured.

Funduscopic examination reveals additional clues. Because it takes 24 to 48 hours to develop, papilledema (e.g., optic disc swelling, indistinct margins, hemorrhages, tortuosity of vessels, absence of venous pulsations), if it develops at all, will not be evident early in the course of unconsciousness. The presence of retinal hemorrhages in children is usually the result of accidental or inflicted trauma with intracranial bleeding (usually subarachnoid or subdural hemorrhage) but is sometimes caused by infection (Minns, Jones, Tandon, et al., 2017).

Motor Function

Observation of spontaneous activity, posture, and response to painful stimuli provides clues to the location and extent of cerebral dysfunction. Asymmetric movements of the limbs or the absence of movement suggests paralysis. In hemiplegia the affected limb lies in external rotation and falls uncontrollably when lifted and allowed to drop. Observations should be described rather than labeled.

In the deeper comatose states, the child has little or no spontaneous movement, and the musculature tends to be flaccid. There is considerable variability in motor behavior in lesser degrees of coma. For example, the child may be relatively immobile or restless and hyperkinetic; muscle tone may be increased or decreased. Tremors, twitching, and spasms of muscles are common observations. The patient may display purposeless plucking or tossing movements. Combative or negativistic behavior is not uncommon. Hyperactivity is more common in acute febrile and toxic states than in cases of increased ICP. Seizures are common in children and may be present in coma as a result of any cause. Any repetitive movements and movements during seizures are described.

Posturing

Primitive postural reflexes emerge as cortical control over motor function is lost in brain dysfunction. These reflexes are evident in posturing and motor movements directly related to the area of the brain involved. Posturing reflects a balance between the lower exciting and the higher inhibiting influences. Strong muscles overcome weaker ones. Flexion posturing (Fig. 27.4A) occurs with severe dysfunction of the cerebral cortex or with lesions to corticospinal tracts above the brainstem. Typical flexion posturing includes rigid flexion, with arms held tightly to the body; flexed elbows, wrists, and fingers; plantar flexed feet; legs extended and internally rotated; and possibly fine tremors or intense stiffness. Extension posturing (see Fig. 27.4B) is a sign of dysfunction at the level of the midbrain or lesions to the brainstem. It is characterized by rigid extension and pronation of the arms and legs, flexed wrists and fingers, clenched jaw, extended neck, and possibly an arched back. Unilateral extension posturing is often caused by tentorial herniation.

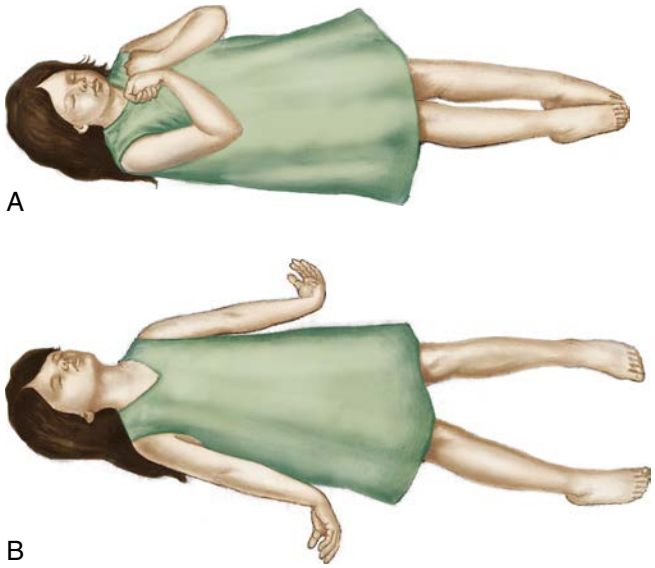

Fig. 27.4 A, Flexion posturing. B, Extension posturing.

Posturing may not be evident when the child is quiet but can usually be elicited by applying painful stimuli such as a blunt object pressed on the base of the nail. Nurses should avoid applying thumb pressure to the supraorbital region of the frontal bone (risk of orbital damage). Noxious stimuli (e.g., suctioning), turning, or touching will elicit a response. When the nurse is describing posturing, the stimulus needed to provoke the response is as important as the reaction.

Reflexes

Testing of certain reflexes, such as those present in an intact spinal cord, may be of limited value (see Chapter 4). In general, the corneal, pupillary, muscle-stretch, superficial, and plantar reflexes tend to be absent in deep coma. The state of reflexes is variable in lighter grades of unconsciousness and depends on the underlying pathologic process and the location of the lesion. The doll's eye reflex maneuver, described previously, reflects paralysis of CN III. The absence of corneal reflexes (CN V) and the presence of a tonic neck reflex are associated with severe brain damage. The Babinski reflex, in which the lateral portion of the bottom of the foot is stroked and causes the big toe to go up, may be of value if it is found to be present consistently in children older than 1 year. A positive Babinski reflex is significant in the assessment of pyramidal tract lesions when it is unilateral and associated with other pyramidal signs. A fluctuating Babinski reflex is often observed after seizures (see Fig. 7.8B).

NURSING TIP: Three key reflexes that demonstrate neurologic health in young infants are the Moro, tonic neck, and withdrawal reflexes.

SPECIAL DIAGNOSTIC PROCEDURES

Numerous diagnostic procedures are used for assessment of cerebral function. Laboratory tests that may help determine the cause of unconsciousness include blood glucose, urea nitrogen, and electrolyte (pH, sodium, potassium, chloride, calcium, and bicarbonate) tests; clotting studies, hematocrit, and a complete blood count; liver function tests; blood cultures if there is fever; and sometimes studies to detect lead or other toxic substances, such as drugs.

An electroencephalogram (EEG) may provide important information. For example, generalized random, slow activity suggests suppressed cortical function, and localized slow activity suggests a space-occupying lesion. A flat tracing is one of the criteria used as evidence of brain death. Examination of spinal fluid is carried out when toxic encephalopathy or infection is suspected. Lumbar puncture is delayed if intracranial hemorrhage is suspected and is contraindicated in the presence of increased ICP because of the potential for brainstem herniation.

Auditory and visual evoked potentials are sometimes used in neurologic evaluation of very young children. Brainstem auditory evoked potentials are useful for evaluating the continuity of brainstem auditory tracts and are particularly useful for detecting demyelinating disease and neoplasms of the brainstem and for distinguishing between brainstem and cortical lesions. For example, a normal evoked potential in a comatose patient suggests involvement of the cerebral hemispheres.

Highly sophisticated tests are carried out with specialized equipment. Two imaging techniques, computed tomography (CT) and magnetic resonance imaging (MRI), assist in diagnosis by scanning both soft tissues and solid matter. Most of these tests are listed in Table 27.1. Because these tests can be threatening to children, the nurse needs to prepare patients and their parents or guardians for the tests and provide support and reassurance during the tests. Consultation with a child life specialist can also be helpful (see Chapter 20, Preparation for Diagnostic and Therapeutic Procedures).

TABLE 27.1 Neurologic Diagnostic Procedures

Test	Description	Purpose	Comments
Lumbar puncture (LP)	Spinal needle is inserted between L3 and L4 or L4 and L5 vertebral spaces into subarachnoid space; cerebrospinal fluid (CSF) pressure is measured, and sample is collected for examination.	Measures spinal fluid pressure Obtains CSF for laboratory analysis Injection of medication	Contraindicated in patients with increased intracranial pressure (ICP) or infected skin over puncture site.
Subdural tap	Needle is inserted into anterior fontanel or coronal suture (midline to pupil).	Helps rule out subdural effusions Removes CSF to relieve pressure	Place infant in semierect position after subdural tap to minimize leakage from site; prevent child from crying if possible. Check site frequently for evidence of leakage.
Ventricular puncture	Needle is inserted into lateral ventricle via coronal suture (midline to pupil).	Removes CSF to relieve pressure	Risk of intracerebral or ventricular hemorrhage.
Electroencephalography (EEG)	EEG records changes in electrical potential of brain. Electrodes are placed at various points to assess electrical function in a particular area. Impulses are recorded by electromagnetic pen or digitally.	Detects spikes, or bursts of electrical activity, that indicate the potential for seizures Used to determine brain death	Patient should remain quiet during procedure; may require sedation. Minimize external stimuli during procedure.
Nuclear brain scan	Radioisotope is injected intravenously, then counted and recorded after fixed time intervals. Radioisotope accumulates in areas where blood-brain barrier is defective.	Identifies focal brain lesions (e.g., tumors, abscesses) Positive uptake of material with encephalitis and subdural hematoma Visualizes CSF pathways	Requires intravenous (IV) access; patient may require sedation. In normal children or noncommunicating hydrocephalus, no retrograde filling of ventricles occurs. Areas of concentrated uptake of material are termed *hot spots.*
Endocephalography	Pulses of ultrasonic waves are beamed through head; echoes from reflecting surfaces are recorded graphically.	Identifies shifts in midline structures from their normal positions as a result of intracranial lesions May show ventricular dilation	Simple, safe, rapid procedure.
Real-time ultrasonography (RTUS)	RTUS is similar to CT but uses ultrasound instead of ionizing radiation.	Allows high-resolution anatomic visualization in variety of imaging planes	Produces images similar to CT scan. Especially useful in neonatal central nervous system problems.

TABLE 27.1 Neurologic Diagnostic Procedures—cont'd

Test	Description	Purpose	Comments
Radiography	Skull films are taken from different views—lateral, posterolateral, axial (submentoventricular), half-axial.	Shows fractures, dislocations, spreading suture lines, craniostenosis Shows degenerative changes, bone erosion, calcifications	Simple, noninvasive procedure.
Computed tomography (CT) scan	Pinpoint x-ray beam is directed on horizontal or vertical plane to provide series of images that are fed into computer and assembled in image displayed on video screen. CT uses ionizing radiation.	Visualizes horizontal and vertical cross-section of brain in three planes (axial, coronal, sagittal) Distinguishes density of various intracranial tissues and structures—congenital abnormalities, hemorrhage, tumors, demyelinating and inflammatory processes, calcification	Requires IV access if contrast agent is used. Patient may require sedation.
Magnetic resonance imaging (MRI)	MRI produces radiofrequency emissions from elements (e.g., hydrogen, phosphorus), which are converted to visual images by computer.	Permits visualization of morphologic feature of target structures Permits tissue discrimination unavailable with many techniques	MRI is noninvasive procedure except when IV contrast agent is used. No exposure to radiation occurs. Patient may require sedation. Parent or attendant can remain in room with child. MRI does not visualize bone detail or calcifications. No metal can be present in scanner.
Positron emission tomography (PET)	PET involves IV injection of positron-emitting radionucleotide; local concentrations are detected and transformed into visual display by computer.	Detects and measures blood volume and flow in brain, metabolic activity, biochemical changes within tissue	Requires lengthy period of immobility. Minimum exposure to radiation occurs. Patient may require sedation.
Digital subtraction angiography (DSA)	Contrast dye is injected intravenously; computer "subtracts" all tissues without contrast medium, leaving clear image of contrast medium in vessels studied.	Visualizes vasculature of target tissue Visualizes finite vascular abnormalities	Safe alternative to angiography. Patient must remain still during procedure; may require sedation.
Single-photon emission computed tomography (SPECT)	SPECT involves IV injection of photon-emitting radionuclide; radionuclides are absorbed by healthy tissue at different rate than diseased or necrotic tissue; data are transferred to computer that converts image to film.	Provides information regarding blood flow to tissues; analyzing blood flow to organ may help determine how well it is functioning	Requires lengthy period of immobility. Minimum exposure to radiation occurs. Patient may require sedation.

Children who are old enough to understand require careful explanation of the procedure, why it is being done, what they will experience, and how they can help. School-age children usually appreciate a more detailed description of why contrast material is injected. Because children are often frightened of needles, they and their families need to be informed of any medication or contrast medium that will be administered intravenously. Special anxiety reduction strategies may be necessary for children who have blood-injury-injection (needle) phobia (McMurtry, Taddio, Noel, et al., 2016). This phobia is the most inheritable of all phobias. The nurse should talk with parents to find out if they also have this phobia and will need help with anxiety management.

The importance of lying still for tests needs to be stressed. Children unfamiliar with the machines can be shown a picture beforehand. Although radiographic examinations are not painful, the machinery often appears so frightening that the child protests because of anxiety. This is especially true of CT and MRI, both of which require that the child's head be placed within a special immobilizing device. Chin and cheek pads are sometimes used to prevent the slightest head movement, and straps are applied to the body to prevent a slight change in body position. The nurse can explain these events to a frightened child by comparing them to an astronaut's preparation for a space flight. It is important to emphasize to the child that at no time is the procedure painful.

It is helpful for nurses to become acquainted with the equipment and the general environment in which the test will take place so that they can better explain the procedure to children and their families at their level of understanding. Written material describing the procedure should be available for parents and may be appropriate to share with children. Equipment is often strange and ominous to children. They need constant reassurance from a trusted companion. The nurse should not expect cooperation from a young child. Sedation may be required. Many different agents are currently used for sedation of children undergoing neurologic diagnostic procedures (see Chapter 5, Pain Management).

Physical preparation for the diagnostic test may involve administration of a sedative. If so, children should be helped through the preparation and administration and assured that someone will remain with them (if this is possible). Children need continual support and reinforcement during procedures in which they remain conscious. Vital signs and physiologic responses to the procedure are monitored throughout. Many diagnostic procedures performed on an outpatient

basis require sedation, and children need recovery time and observation. The nurse should review written instructions with parents if the child is discharged after a procedure. Children who have undergone a procedure with a general anesthetic require postanesthesia care, including positioning to prevent aspiration of secretions and frequent assessment of vital signs, oxygen saturation, and LOC. In addition, other neurologic functions such as pupillary responses, motor strength, and movement are tested at regular intervals. Any surgical wound resulting from the test is checked for bleeding, CSF leakage, and other complications. Children who undergo repeated subdural taps should have their hematocrit monitored to detect excessive blood loss from the procedure.

THE CHILD WITH CEREBRAL COMPROMISE

NURSING CARE OF THE UNCONSCIOUS CHILD

The unconscious child requires nursing attendance with observation, recording, and evaluation of changes in objective signs. These observations provide valuable information regarding the patient's progress and often serve as a guide to diagnosis and treatment. Careful and detailed observations are essential for the child's welfare. In addition, vital functions must be maintained and complications prevented through conscientious and meticulous nursing care. The outcome of unconsciousness is variable and ranges from early and complete recovery to death within a few hours or days, or persistent and permanent unconsciousness, or recovery with varying degrees of residual mental or physical disability. The outcome and recovery of the unconscious child may depend on the level of nursing care and observational skills.

Direct emergency measures toward ensuring circulation, airway, and breathing (CAB); stabilizing the spine when indicated; treating shock; and reducing ICP (if present). Delayed treatment often leads to increased damage. Therapies for specific causes of unconsciousness begin as soon as emergency measures have been implemented; in many cases they occur concurrently. Because nursing care is closely related to the medical management, both are considered here.

Continual observation of the LOC, pupillary reaction, and vital signs is essential to management of CNS disorders. Regular assessment of neurologic status and vital signs is an integral part of the nursing care of unconscious children. The frequency depends on the cause of unconsciousness, the LOC, and the progression of cerebral involvement. Intervals between observations may be as short as every 15 minutes or as long as every 2 hours. Significant alterations are reported immediately.

The temperature is measured every 2 to 4 hours, depending on the child's condition. An elevated temperature may occur in children with CNS dysfunction; therefore a light covering may be sufficient. Vigorous efforts, such as tepid sponge baths or application of a hypothermia blanket, are needed to prevent brain damage if the rectal temperature exceeds 104°F (40°C).

The LOC is assessed periodically, including pupillary size, equality, and reaction to light. Signs of meningeal irritation, such as nuchal rigidity, need to be assessed. Assessment of LOC also includes response to vocal commands, spontaneous behavior, resistance to care, and response to painful stimuli. Note any abnormal movements, changes in muscle tone or strength, and body position. If a seizure occurs, describe the seizure, including the body areas involved from the beginning to the end of the seizure, and the duration of seizure (see Box 27.8 and Critical Thinking Case Study later in the chapter).

Pain management for the unconscious child requires astute nursing observation and management. Signs of pain include changes in behavior (e.g., increased agitation and rigidity) and alterations in vital signs and perfusion (usually an increased heart rate, respiratory rate, and blood pressure and decreased oxygen saturation). Because these findings are not specific for pain, the nurse should be alert for their appearance during times of induced or suspected pain and for their disappearance after the inciting procedure or the administration of analgesia. A pain assessment record is used to document indications of pain and the effectiveness of interventions (see Chapter 5, Pain Assessment). The use of opioids, such as morphine, to relieve pain is controversial because these drugs can mask signs of altered consciousness or depress respirations. However, unrelieved pain activates the stress response, which can elevate ICP. To block the stress response, some authorities advocate the use of analgesics, sedatives, and, in some cases such as head injury, paralyzing agents via continuous intravenous (IV) infusion. A commonly used combination is fentanyl, midazolam, and vecuronium (Norcuron). If there are concerns about assessing the LOC or respiratory depression, naloxone can be used to reverse the opioid effects. Regardless of the drugs used, adequate dosage and regular administration are essential to provide optimum pain relief.

! NURSING ALERT

When opioids are used, bowel elimination must be closely monitored because of the potential constipating effect. A stool softener should be given regularly with laxatives as needed to prevent constipation.

Other measures to relieve discomfort include providing a quiet, dimly lit environment; limiting visitors; preventing any sudden, jarring movement, such as banging into the bed; and preventing an increase in ICP. The latter is most effectively achieved by proper positioning and prevention of straining, such as during coughing, vomiting, or defecating (see Chapter 5, Pain Management). Antiepileptic drugs, such as fosphenytoin (Cerebyx) or phenobarbital, may be ordered for control of seizure activity.

Respiratory Management

Respiratory effectiveness is the primary concern in the care of the unconscious child, and establishment of an adequate airway is always the first priority. Carbon dioxide has a potent vasodilating effect and will increase cerebral blood flow (CBF) and ICP. Cerebral hypoxia at normal body temperature that lasts longer than 4 minutes often causes irreversible brain damage.

! NURSING ALERT

Respiratory obstruction and subsequent compromise lead to cardiac arrest. Always maintain an adequate, patent airway.

Children in lighter stages of coma may be able to cough and swallow, but those in deeper states of coma are unable to manage secretions, which tend to pool in the throat and pharynx. Dysfunction of CNs IX and X (glossopharyngeal and vagus nerves) places the child at risk of aspiration and cardiac arrest. Therefore position the child with the head and body to the side to prevent aspiration of secretions and empty the stomach to reduce the likelihood of vomiting. In infants, the blockage of air passages from secretions can happen in seconds. In addition, upper airway obstruction from laryngospasm is a common complication in comatose children.

An oral airway can be used for the child who is suffering a temporary loss of consciousness, such as after a contusion, seizure, or anesthesia. For children who remain unconscious for a longer time, a

nasotracheal or orotracheal tube is inserted to maintain the open airway and facilitate removal of secretions. A tracheostomy is performed in cases where laryngoscopy for introduction of an endotracheal tube would be difficult or dangerous or for a child who needs long-term ventilatory support. Suctioning is used only as needed to clear the airway, exerting care to prevent increasing ICP. Respiratory status is observed and evaluated regularly. Signs of respiratory distress may indicate a need for ventilator assistance.

Mechanical ventilation is usually indicated when the respiratory center is involved. Blood gas analysis is performed regularly, and oxygen is administered when indicated. Moderately severe hypoxia and respiratory acidosis are often present, but they are not always evident from clinical manifestations. Hypoventilation often accompanies unconsciousness and may lead to respiratory alkalosis, or it may represent the body's attempt to compensate for metabolic acidosis. Blood gas and pH determinations are essential guides for electrolyte therapy. Chest physiotherapy is carried out on a regular basis, and the child's position is changed at least every 2 hours to prevent pulmonary complications. Regular oral hygiene is recommended to reduce the risk of ventilator-associated pneumonia (VAP) (Hua, Xie, Worthington, et al., 2016).

Intracranial Pressure Monitoring

The role of ICP monitoring after traumatic brain injury (TBI) is controversial. Placement of the ICP monitor often occurs in the emergency department and where older in age (Kannan, Quistberg, Wang, et al., 2017). Early placement of ICP monitors may guide assessment management of patients with intracranial hypertension or those at higher risk for developing intracranial hypertension. ICP monitoring also may assist with decision making regarding transfer to the operating room or pediatric intensive care unit (PICU). However, in a large study using two national databases of 3084 children with severe TBI, no evidence was found of a benefit from ICP monitoring on functional survival of children with severe TBI (Bennett, DeWitt, Greene, et al., 2017). Development of noninvasive ICP sensors has the potential of decreasing the need for invasive interventions in pediatric patients in the future (Harary, Dolmans, & Gormley, 2018).

Direct ventricular pressure measurement remains the gold standard of ICP monitoring. The catheter method involves introduction of a catheter into the lateral ventricle on the nondominant side, if known, or placement in the subdural space. The catheter has the advantage of providing a means of extraventricular (or continuous) drainage of CSF to reduce pressure. A drainage bag attached to the system is kept at the level of the ventricles and can be lowered to decrease ICP. This device requires full penetration of the brain, requires skill and experience with placement, and carries the risk of infection. Infection risks can be lowered by always using aseptic technique when handling the external ventricular drainage (EVD) system, manipulating the EVD as little as possible, and sterile dressing changes only weekly or when the dressing is compromised, whichever occurs first (Hepburn-Smith, Dynkevich, Spektor, et al., 2016).

! NURSING ALERT

If the external ventricular drain is unclamped for cerebrospinal fluid (CSF) drainage, carefully monitor the level of the collection container. If the container is positioned too low, improper CSF decompression could lower intracranial pressure (ICP) too rapidly, causing bleeding and pain.

With the bolt method, the end of the bolt is placed into the subarachnoid space. The bolt cannot be adequately secured in a small child's pliant skull, although special modifications have been developed for children younger than 6 years of age. The placement of the bolt is not adjusted by anyone except the neurosurgeon who placed the device. The neurosurgeon is notified if a satisfactory waveform is not observed.

! NURSING ALERT

With the bolt method, the bolt is stabilized with dressings, but these are not changed or disturbed—not even to check the site.

An epidural sensor can be placed between the dura and the skull through a burr hole and connected to a stopcock assembly and a transducer, which provides a readout of the pressure. Although less invasive, the epidural sensor may have inconsistent correlation of pressure readings. In infants, a fontanel transducer can be used to detect impulses from a pressure sensor and convert them to electrical energy. The electrical energy is then converted to visible waves or numeric readings on an oscilloscope. ICP measurement from the anterior fontanel is noninvasive but may prove to be inaccurate if the equipment is poorly placed or inconsistently recalibrated. Intraparenchymal pressure monitoring devices (e.g., Camino) use fiberoptic technology and perform reliably.

ICP can be increased by direct instillation of solutions; antibiotics are administered systemically if a positive CSF culture is obtained. However, ICP monitoring rarely causes infection. CSF is a body fluid; implement Standard Precautions according to hospital policy (see Chapter 20, Infection Control).

Nurses caring for patients with intracranial monitoring devices must be acquainted with the system, assist with insertion, interpret the monitor readings, and be able to distinguish between danger signals and mechanical dysfunction. Because systemic blood pressure, ICP, and therefore cerebral perfusion pressure (CPP) are normally lower in children, the child's age must be taken into account when deciding what constitutes abnormally high ICP or abnormally low CPP.

Several medical measures are available to treat increased ICP resulting from cerebral edema. These include sedation, CSF drainage, and osmotic diuretics. Osmotic diuretics may provide rapid relief of ICP in emergency situations. Although their effect is transient, lasting only about 6 hours, they can be life-saving in emergencies. These substances are rapidly excreted by the kidneys and carry with them large quantities of sodium and water. Mannitol (or sometimes urea) administered intravenously is the drug most commonly used for rapid reduction of ICP. The infusion is generally given slowly but may be pushed rapidly if there is herniation or impending herniation. Because of the profound diuretic effect of the drug, an indwelling catheter is inserted to ensure bladder emptying. Arterial carbon dioxide ($PaCO_2$) should be maintained at approximately 30 mm Hg to produce vasoconstriction, which reduces CBF, thereby decreasing ICP. Recording and analyzing the child's volume state, plasma sodium concentration, and serum osmolarity can avert potential fluid and electrolyte problems. Administration of adrenocorticosteroids is not recommended for cerebral edema secondary to head trauma.

Nursing Activities

In cases of high levels of increased ICP, nursing procedures tend to trigger reactive pressure waves in many children. For example, increased intrathoracic or abdominal pressure will be transmitted to the cranium. The goals of monitoring a child who is neurologically compromised include maintaining CPP; controlling ICP, cerebral edema, and factors that increase cerebral metabolism (e.g., fever, seizures); and maintaining hemodynamic stability. Take particular care in positioning these patients to avoid neck vein compression that may further increase ICP by interfering with venous return.

NURSING ALERT

Elevate the head of the bed 15 to 30 degrees and position the child so that the head is maintained in midline to facilitate venous drainage and avoid jugular compression. Turning side to side is contraindicated because of the risk of jugular compression.

Sandbags or other support devices can help maintain correct head position. The child can be propped to one side or the other, and the use of a pressure-relieving or pressure-decreasing mattress decreases the chance of prolonged pressure to vulnerable skin areas. Frequent clinical assessment of the child cannot be replaced by an ICP monitoring device.

It is important to avoid activities that may increase ICP by causing pain or emotional stress. Clustering nursing activities together and minimizing environmental stimuli by decreasing noxious procedures help control ICP. Range-of-motion exercises can be carried out gently but should not be performed vigorously. Any necessary disturbing procedures should be scheduled to take advantage of therapies that reduce ICP, such as osmotherapy and sedation. Make efforts to minimize or eliminate environmental noise, including managing the number of visitors. Assessment and intervention to relieve pain are important nursing functions to decrease ICP.

Suctioning and percussion are poorly tolerated; these procedures are contraindicated unless the child has concurrent respiratory problems. Hypoxia and the Valsalva maneuver associated with cough acutely elevate ICP. Vibration, which does not increase ICP, accomplishes excellent results and should be tried first if treatment is needed. If suctioning is necessary, it should be used judiciously and preceded by hyperventilation with 100% oxygen, which can be monitored during suctioning with a pulse oxygen sensor reading to determine oxygen saturation.

Nutrition and Hydration

In the unconscious child, fluids and calories are supplied initially by the IV route. The type of fluid administered depends on the patient's general condition. Children on the ketogenic diet and with certain metabolic disorders, such as pyruvate dehydrogenase deficiency, should receive normal saline rather than fluids containing dextrose, which can cause seizures and worsen their condition. Fluid therapy requires careful monitoring and adjustment based on neurologic signs and electrolyte determinations. Often unconscious children cannot tolerate the same amounts of fluid as when they are healthy. Overhydration must be avoided to prevent fatal cerebral edema. When cerebral edema is a threat, fluids may be restricted to reduce the chance of fluid overload. Examine skin and mucous membranes for signs of dehydration. Adjustments to fluid administration are based on urinary output, serum electrolytes and osmolarity, blood pressure, and arterial filling pressure. Observation for signs of altered fluid balance related to abnormal pituitary secretions is a part of nursing care.

Provide long-term nutrition in a balanced formula given by nasogastric or gastrostomy tube. The nasogastric tube is usually taped in place, with care taken to prevent pressure on the nares. Most children have continuous feedings. When bolus feedings are used, the tube is rinsed with water after each feeding. Tubes are replaced according to institutional policy. Irritation of the nasal mucosa is prevented by alternating nares each time the nasogastric tube is replaced.

Avoid overfeeding to prevent vomiting and the associated risk of aspiration. Stomach contents are aspirated with a syringe and measured before feeding to ascertain the amount remaining in the stomach. The removed contents may be refed. If the residual volume is excessive (depending on the child's size), consult the dietitian and physician regarding the composition and amount to determine whether changes are required to provide calories and nutrients in a smaller volume.

Altered Pituitary Secretion

An altered ability to handle fluid loads is attributed in part to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and diabetes insipidus (DI) resulting from hypothalamic dysfunction (see Chapter 28). SIADH often accompanies CNS conditions such as head injury, meningitis, encephalitis, brain abscess, brain tumor, and subarachnoid hemorrhage. In the child with SIADH, scant quantities of urine are excreted, electrolyte analysis reveals hyponatremia and hypoosmolality, and manifestations of overhydration are evident. It is important to evaluate all parameters because the reduced urinary output might be erroneously interpreted as a sign of dehydration. The treatment of SIADH consists of fluid restriction until serum electrolytes and osmolality return to normal levels. If fluid restriction is not completely ineffective, medications such as sodium chloride and diuretics may be used.

DI may occur after intracranial trauma. In DI there is increased urinary volume and the accompanying danger of dehydration. Adequate replacement of fluids is essential, and observation of electrolyte balance is necessary to detect signs of hypernatremia and hyperosmolality. Exogenous vasopressin may be administered.

Medications

The cause of unconsciousness determines specific drug therapies. Children with infectious processes are given antibiotics appropriate to the disease and the infecting organism. Corticosteroids are prescribed for inflammatory conditions and edema. Cerebral edema is an indication for osmotic diuretics. Antiepileptic medications are prescribed for seizure activity. Sedation in the combative child provides amnesic and anxiolytic properties in conjunction with a paralytic agent. This combination decreases ICP and allows treatment of cerebral edema. Usual drugs include morphine and midazolam. Midazolam is attractive because of its short half-life.

Deep coma induced by the administration of barbiturates is controversial in the management of ICP. Barbiturates are currently reserved for the reduction of increased ICP when all else has failed. Barbiturates decrease the cerebral metabolic rate for oxygen and protect the brain during times of reduced CPP. Barbiturate coma requires extensive monitoring. EEG monitoring can assess depth of coma, record EEG background abnormalities that can help predict outcome, and evaluate any seizure activity. Cardiovascular and respiratory support and ICP monitoring are needed to assess response to therapy. Paralyzing agents such as vecronium may be needed to aid in performing diagnostic tests, improving effectiveness of therapy, and reducing the risks of secondary complications. Elevation of ICP or heart rate in patients who are being given paralyzing agents or are under sedation may indicate the need for another dose of either or both medications or the need for pain medication.

Thermoregulation

Hyperthermia often accompanies cerebral dysfunction; if it is present, the nurse implements measures to reduce the temperature to prevent brain damage from hyperthermia and to reduce metabolic demands generated by the increased body temperature. Antipyretics are the method of choice for fever reduction; cooling devices are used for hyperthermia (see Chapter 20, Controlling Elevated Temperatures). Laboratory tests and other methods help determine the cause, if any, of the hyperthermia. Treatment with hypothermia and barbiturates increases the risk of iatrogenic complications.

Elimination

A urinary catheter is usually inserted in the acute phase, but diapers may be used and weighed to record urinary output. The child who previously had bowel and bladder control is generally incontinent. If the child remains comatose for a long period, the indwelling catheter may be removed and periodic bladder emptying accomplished by intermittent catheterization. Stool softeners are usually sufficient to maintain bowel function, but suppositories or enemas may be needed occasionally for adequate elimination and to prevent fecal impaction. The passage of liquid stool after a period of no bowel activity is usually a sign of impaction. To avoid this preventable problem, daily recording of bowel activity is essential.

Hygienic Care

Routine measures for cleansing and maintaining skin integrity are an integral part of nursing care of the unconscious child. Skinfolds require special attention to prevent excoriation. The child who is unable to move is prone to develop tissue breakdown and necrosis; the child is placed on a resilient appliance (e.g., alternating-pressure or water-filled mattress) to prevent pressure on prominent areas of the body. The goal is prevention by regular change of position and inspection of vulnerable areas (e.g., the ankle, heels, trochanter, sacrum, and shoulder). Unconscious children undergo numerous invasive procedures, and the skin sites used for these procedures require special assessment and intervention to promote healing and prevent infection. Keep bed linens and any clothing dry and free of wrinkles. Rubbing the back and extremities with lotion stimulates circulation and helps prevent drying of the skin. However, to prevent further tissue damage, do not massage reddened and nonblanching skin (see Chapter 20, Maintaining Healthy Skin). If the child requires surgery or radiography, the nurse checks all dressings, bony sites, catheters, and IV access lines before and after the procedure.

Oral care is performed at least twice daily because the mouth tends to become dry or coated with mucus. The teeth are carefully brushed with a soft toothbrush or cleaned with gauze saturated with saline. Commercially prepared cleansing devices, such as Toothettes, are convenient for cleansing the mouth and teeth. Lips are coated with ointment to protect them from drying, cracking, or blistering.

The unconscious child is also prone to eye irritation. The corneal reflexes are absent; therefore the eyes are easily irritated or damaged by linens, dust, or other substances that may come in contact with them. Excessive dryness results from incomplete closure of the lids and/or decreased secretions, especially if the child is undergoing osmotherapy to reduce or prevent brain edema.

! NURSING ALERT

The eyes are examined regularly and carefully for early signs of irritation or inflammation. Artificial tears (methylcellulose) are placed in the eyes every 1 to 2 hours. Eye patches may be required to protect the eyes from possible damage.

Keep the child's hair combed and secure to prevent tangling. Keep the scalp clean with dry or wet shampoos as needed. The child's head may need to be shaved for tests or surgical procedures. The family may want the hair saved.

Positioning and Exercise

The unconscious child is positioned to minimize ICP and to prevent aspiration of saliva, nasogastric secretions, and vomitus. The head of the bed is elevated, and the child is placed in a side-lying or semiprone position. A small, firm pillow is placed under the head, and the uppermost limbs are flexed and supported with pillows. The weight of the body should not rest on the dependent arm. In the semiprone position the child lies with the dependent arm at the side behind the body; the opposite side is supported on pillows, and the uppermost arm and leg are flexed and resting on the pillows. This position prevents undue pressure on the dependent extremities. The dependent position of the face encourages drainage of secretions and prevents the flaccid tongue from obstructing the airway.

Normal range-of-motion exercises help maintain function and prevent contractures of joints. Perform exercises gently to minimize increasing ICP and with full range of motion. Place a small rolled pad in the palms to help maintain proper positioning of fingers. Splinting may be needed to prevent severe contractures of the wrists, knees, or ankles.

Stimulation

Sensory stimulation is as important in the care of the unconscious child as it is in the care of the alert child. For the temporarily unconscious or semiconscious child, sensory stimulation helps arouse the child to the conscious state and orient the child in terms of time and place. Auditory and tactile stimulation are especially valuable. Tactile stimulation is not appropriate for a child in whom it may elicit an undesirable response. However, for other children tactile contact often has a relaxing and calming effect. When the child's condition permits, holding or rocking the child is soothing and provides the body contact needed by young children.

Hearing is often intact in a state of coma. Hearing is the last sense to be lost and the first one to be regained; speak to the child as any other child. Conversation around the child should not include thoughtless or derogatory remarks. Soft music is often used to provide auditory stimulation. Singing the child's favorite songs or reading a favorite story is a strategy used to maintain the child's contact with a familiar world. Playing songs or favorite stories recorded in the parents' voices can provide a continuous source of familiar stimulation.

Family Support

Helping the parents of an unconscious child cope with the situation is especially difficult. They may demonstrate all of the guilt, fear, hostility, and anxiety of any parent of a seriously ill child (see Chapter 19). In addition, these parents face the uncertain outcome of the cerebral dysfunction. The fear of death, cognitive impairment, or permanent physical disability is present. Nursing intervention with parents depends on the nature of the pathologic condition, the parents' coping skills, and the parent-child relationship before injury or illness.

Awakening from a coma is a gradual process; however, some children regain consciousness within a short time. If there is little or no residual effect, the child is discharged home fairly soon. The parents need the most intensive nursing intervention during the period of crisis and uncertainty. During the recovery phase the nurse gives them information, clarifies it as needed, and encourages them to become involved in the child's care. Often the child's hospitalization is brief; however, some children require extended hospitalization for intensive therapy and rehabilitation. The parents of children who die require support and guidance to cope with the reality of the death and to resolve their grief (see Chapter 17).

Probably the most difficult situations are those that involve children who never regain consciousness. Unlike losing a child through death, these children lack finality, which often leaves the parents in a state of suspended grief. Like parents of dying children, parents of comatose children search for any signs of hope. Well-meaning friends

and relatives relate instances of miraculous recoveries. The parents seek confirmation and support for such possibilities and assign erroneous meanings to any sign in the child that might be interpreted as evidence of recovery (e.g., reflexive muscle contractions).

At these times nurses need to respond with compassion and honesty. They can acknowledge that miraculous recoveries do occur but are rare. The important message is to maintain open communication with the family.

Like parents who lose a child through death, the parents of a child who is unconscious attempt to construct a representation of the child. They bring items that belong to the child, such as favorite toys or music. This may be interpreted as an attempt to provide stimulation for the child in the hope of eliciting a response, to let the hospital staff know the child as the unique individual he or she was, and to reconstitute an image of the child "lost" to them and for whom they mourn. The nurses' recognition and understanding of these behaviors and coping mechanisms is important to support the parents in their grief process.

In addition to the process of grieving for the "lost" child, the parents may face difficult decisions. When the child's brain is so severely damaged that vital functions must be maintained by artificial means, the parents must make the final decision whether to remove the life support systems and allow a natural death. After parents are provided with information about what allowing a natural death and removal from life support mean, the parents may turn to both the provider and the nurses with their questions and concerns. Nurses play a critical role in assisting families in participating in their child's care to the greatest extent possible and in planning the child's death when that is the inevitable outcome of the neurologic disorder (Bloomer, Endacott, Copnell, et al., 2016).

HEAD INJURY

Head injury is a pathologic process involving the scalp, skull, meninges, or brain as a result of mechanical force. Unintentional injuries are the number-one health risk for children and the leading cause of death in children older than 1 year of age (Chen, Shi, Stanley, et al., 2017). However, children younger than 1 year of age have a significantly higher rate of severe head injury (Chen et al., 2017). In 2013 approximately 660,000 children 0 to 14 years old experienced a TBI and 17,900 of those children were hospitalized; 1484 children died as a result of their brain injury (Taylor, Bell, Breiding, et al., 2017).

Etiology

The most common causes of head injury in children are falls, being struck by or striking an object with one's head, and motor vehicle accidents, in that order (Centers for Disease Control and Prevention, 2017a). Assaults are the leading cause of death from TBI in children 4 years of age or younger (Taylor et al., 2017). Neurologic injury accounts for the highest mortality rate, with boys usually affected twice as often as girls. There are a number of head trauma strategies, including safety gates on stairs, restricting sleeping in the top bunk to children older than 6 years of age, seat belts and car seat use, and helmets during recreational activities such as biking and skiing. Furthermore, preventing child abuse is necessary and possible.

Pathophysiology

The pathology of brain injury is directly related to the force of impact. Intracranial contents (brain, blood, CSF) are damaged because the force is too great to be absorbed by the skull and musculoligamentous support of the head. Although nervous tissue is delicate, it usually requires a severe blow to cause significant damage.

A child's response to head injury is different from that of adults. The larger head size in proportion to body size and insufficient musculoskeletal support render the very young child particularly vulnerable to acceleration-deceleration injuries.

Primary head injuries are those that occur at the time of trauma and include skull fractures, contusions, intracranial hematomas, and diffuse injuries. Subsequent complications include hypoxic brain injury, increased ICP, and cerebral edema. The predominant feature of a child's brain injury is the diffuse amount of swelling that occurs. Hypoxia and hypercapnia threaten the energy requirements of the brain and increase CBF. The added volume across the blood-brain barrier along with the loss of autoregulation exacerbates cerebral edema. Pressure inside the skull that is greater than arterial pressure results in inadequate perfusion. Because the cranium of very young children has the ability to expand and the thin skull is more compliant, they may tolerate increases in ICP better than older children and adults.

Physical forces act on the head through acceleration, deceleration, or deformation. Acceleration or deceleration is more descriptive of the circumstances responsible for most head injuries. When the stationary head receives a blow, the sudden acceleration causes deformation of the skull and mass movement of the brain. Continued movement of the intracranial contents allows the brain to strike parts of the skull (e.g., the sharp edges of the sphenoid or the irregular surface of the anterior fossa) or the edges of the tentorium.

Although the brain volume remains unchanged, significant distortion and cavitation occur as the brain changes shape in response to the force transmitted from the impact to the skull. This deformation can cause bruising at the point of impact (coup) or at a distance as the brain collides with the unyielding surfaces opposite or far removed from the point of impact (contrecoup) (Fig. 27.5). Thus a blow to the occipital region can cause severe injury to the frontal and temporal areas of the brain.

When a moving head strikes a stationary surface, such as during a fall, sudden deceleration occurs and causes the greatest cerebral injury

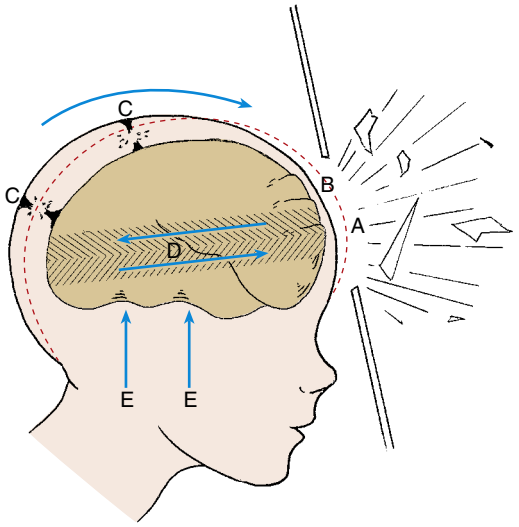

Fig. 27.5 Mechanical distortion of cranium during closed head injury. *A,* Preinjury contour of skull. *B,* Immediate postinjury contour of skull. *C,* Torn subdural vessels. *D,* Shearing forces. *E,* Trauma from contact with floor of cranium. (Redrawn from Grubb, R. L., & Coxe, W. S. [1974]. Central nervous system trauma: Cranial. In S. G. Eliasson, A. L. Presky, & W. B. Hardin [Eds.], *Neurological pathophysiology.* New York, NY: Oxford University Press.)

at the point of impact. Deceleration is responsible for most severe brainstem injuries.

Children with an acceleration-deceleration injury demonstrate diffuse generalized cerebral swelling produced by increased blood volume or by a redistribution of cerebral blood volume (cerebral hyperemia) rather than by the increased water content (edema).

Another effect of brain movement is shearing forces, which are caused by unequal movement or different rates of acceleration at various levels of the brain. A shearing force may tear small arteries that travel from the cerebral surfaces through the meninges to the dural sinuses and cause subdural hemorrhages. Shearing or stretching effects can also be transmitted to nerve fibers. Maximum stress from the shearing force occurs at the interface between structures of different density so that the gray matter (cell body) rapidly accelerates, whereas the white matter (axons) tends to lag behind. Although maximum shearing forces are at the cerebral surface and extend toward the center of rotation within the brain, the most serious effects are often in the area of the brainstem. Severe compression of the skull can cause the brain to be forced through the tentorial opening and produce irreparable damage to the brainstem.

A GCS value of 8 or less in pediatric patients indicates severe injury and requires aggressive therapeutic management (Hartman & Cheifetz, 2020). Three out of four children with a score of 3 or 4 will be severely disabled, be in a persistent vegetative state, or die within a year of their injury (Fulkerson, White, Rees, et al., 2015). A number of studies indicate that the Simplified Motor Scale (SMS) is equivalent to the GCS in predictive power but that the GCS is better for prognosticating death (Singh, Murad, Prokop, et al., 2013).

Concussion

The most common and mildest TBI is ***concussion***, an alteration in mental status with or without loss of consciousness that occurs immediately after a head injury (McCrea, Nelson, & Guskiewicz, 2017). Direct head trauma and "whiplash" seen with rapid acceleration and deceleration of the head are the most frequent causes in children. Sports-related activities are responsible for the majority of concussions (Mullally, 2017).

The hallmarks of a concussion are confusion and amnesia. These are often not preceded by loss of consciousness and may occur immediately after the injury or several minutes later. The belief that loss of consciousness is the hallmark of concussion is a common misconception. A study of 182 adolescent athletes who sustained a concussion found that only 22% lost consciousness, whereas 34% experienced amnesia (Meehan, Mannix, Stracciolini, et al., 2013).

The pathogenesis of concussion is still unclear, but it may be a result of shearing forces that cause stretching, compression, and tearing of nerve fibers, particularly in the area of the central brainstem, the seat of the reticular activating system. It has also been suggested that the anatomic alterations of nerve fibers cause the release of large quantities of acetylcholine into the CSF and a reduction in oxygen consumption with increased lactate production.

Contusion and Laceration

The terms *contusion* and *laceration* are used to describe visible bruising and tearing of cerebral tissue. Contusions represent petechial hemorrhages or localized bruising along the superficial aspects of the brain at the site of impact (coup injury) or a lesion remote from the site of direct trauma (contrecoup injury). In serious accidents there may be multiple sites of injury.

The major areas of the brain susceptible to contusion or laceration are the occipital, frontal, and temporal lobes. In addition, the irregular surfaces of the anterior and middle fossae at the base of the skull are capable of producing bruises or lacerations on forceful impact. Contusions may cause focal disturbances in strength, sensation, or visual awareness. The degree of brain damage in the contused areas varies according to the extent of vascular injury. Signs vary from mild, transient weakness of a limb to prolonged unconsciousness and paralysis. However, the signs and symptoms may be clinically indistinguishable from those of concussion.

Infants who are roughly shaken, referred to as shaken baby syndrome or abusive head trauma, can sustain profound neurologic impairment, seizures, retinal hemorrhages (usually bilateral), and intracranial subarachnoid or subdural hemorrhages (Joyce & Huecker, 2019).

Cerebral lacerations are generally associated with penetrating or depressed skull fractures. However, they may occur without fracture in small children. When brain tissue is actually torn, with bleeding into and around the tear, more severe and prolonged unconsciousness and paralysis usually occur, leaving permanent scarring and some degree of disability.

Fractures

Skull fractures result from a direct blow or injury to the skull and are often associated with intracranial injury. Many of the falls that resulted in a skull fracture in children younger than 2 years of age involved short distances of less than 3 feet, such as falls from a caregiver's arms (Burrows, Trefan, Houston, et al., 2015).

The types of skull fractures that occur are linear, comminuted, depressed, open, basilar, and growing fractures. As a rule, the faster the blow, the greater the likelihood of a depressed fracture; a low-velocity impact tends to produce a linear fracture.

Linear skull fractures are a single fracture line that starts at the point of maximum impact and spreads; however, they do not cross suture lines. Linear skull fractures constitute the majority of childhood skull fractures and typically occur in the parietal bone. Most linear skull fractures are associated with an overlying scalp hematoma, particularly in infants younger than 2 years of age and in the parietal or temporal region (Burns, Grool, Klassen, et al., 2016). Scalp hematomas, in turn, are associated with the presence of intracranial injury whether there is a linear fracture or not (Burns et al., 2016).

Comminuted fractures consist of multiple associated linear fractures. They usually result from intense impact, often from repeated blows against an object or ejection from a car at a high rate of speed. They may suggest child abuse.

Depressed fractures are those in which the bone is locally broken, usually into several irregular fragments that are pushed inward. The greater the depression, the higher the risk of a tear in the dura or cortical laceration. Depressed skull fractures may be associated with direct underlying parenchymal damage and should be suspected when a child's head appears misshapen. Surgery may be needed to elevate the depressed bone fragment if there is an associated intracranial hematoma and if the depression is greater than 1 cm (0.4 inch).

Basilar fractures involve the bones at the base of the skull in either the posterior or the anterior region. The bones involved are the ethmoid, sphenoid, temporal, or occipital bones. These fractures usually result in a dural tear. Because of the proximity of the fracture line to structures surrounding the brainstem, a basal skull fracture is a serious head injury. Basilar fractures often involve frontal bone fractures. This can result in clinical features such as leakage of CSF from the nose (CSF rhinorrhea) or ear (CSF otorrhea), blood behind the tympanic membrane (hemotympanum), subcutaneous bleeding over the mastoid process that is located posterior to the ear, and subcutaneous bleeding around the orbit (Bonfield, Naran, Adetayo,

et al., 2014). Meningitis, although rare, is always a potential risk with CSF leakage.

NURSING ALERT

Suspect posttraumatic meningitis in children with increasing drowsiness and fever who also have basilar skull fractures.

Open fractures result in a communication between the skull and the scalp or the mucosa of the upper respiratory tract. The risk of CNS infection is increased with open fractures. Compound fractures consist of a skin laceration overlying the bone fracture. Open fractures that involve the paranasal sinuses or middle ear may lead to leakage of CSF (rhinorrhea or otorrhea). Prophylactic antibiotics are recommended to prevent osteomyelitis.

Growing skull fracture is an unusual complication of head trauma. The fracture is accompanied by an underlying tear in the dura or brain injury that fails to heal properly. A leptomeningeal cyst, dilated ventricles, or herniated brain may result and cause growth of the original fracture. Most growing skull fractures occur before 30 months of age and occur in the parietal bone (Vezina, Al-Halabi, Shash, et al., 2017). Physical examination usually shows a swelling scalp and skull defect. Clinical neurologic symptoms may be delayed for months to years after the initial skull fracture and include headache, seizures, hemiparesis, and learning and intellectual disabilities (Vezina et al., 2017).

Complications

The major complications of trauma to the head are hemorrhage, infection, edema, and herniation through the brainstem. Infection is always a hazard in open injuries. Edema is related to tissue trauma. Vascular rupture may occur even in minor head injuries, causing hemorrhage between the skull and cerebral surfaces. Compression of the underlying brain produces effects that can be rapidly fatal or insidiously progressive.

Epidural Hematoma

Epidural (extradural) hematoma is a hemorrhage into the space between the dura and the skull. As the hematoma enlarges, the dura is stripped from the skull; this accumulation of blood results in a mass effect on the brain, forcing the underlying brain contents downward as it expands (Fig. 27.6A). Because bleeding is generally arterial, brain compression occurs rapidly. The lower incidence of epidural hematoma in childhood is attributed to the fact that the middle meningeal artery is not embedded in the skull's bone surface until approximately 2 years old. Therefore a temporal bone fracture is less likely to lacerate the artery. Neuroimaging studies in 210 infants and young children with isolated mild TBI showed skull fractures with extra-axial hemorrhage/no midline shift (30%), nondisplaced skull fractures (28%), and intracranial hemorrhage without fractures/midline shift (19%) (Noje, Jackson, Nasr, et al., 2019).

Child abuse accounts for a significant number of cases of epidural hematomas in infants and children, whereas motor vehicle accidents account for most epidural hematomas in adolescents.

Because bleeding is generally arterial, brain compression occurs rapidly. Most often the expanding hematoma is located in the parietal and temporal regions (Teichert, Rosales, Lopes, et al., 2012), which forces the medial portion of the temporal lobe under the edge of the tentorium, where it places pressure on nerves and blood vessels. Pressure on the arterial supply and venous return to the reticular formation causes loss of consciousness; pressure on CN III produces dilation and (later) fixation of the ipsilateral pupil. Pressure on the fibers of the pyramidal tract is evidenced by contralateral weakness or paralysis and increased deep tendon reflexes. Extreme pressure may cause brain herniation and death. Expanding epidural hemorrhages may be better tolerated in young children with open sutures that allow for expansion of the skull. In addition, young children have larger subarachnoid and extracellular spaces, which provide space for the expanding hematoma without compression on the brain parenchyma.

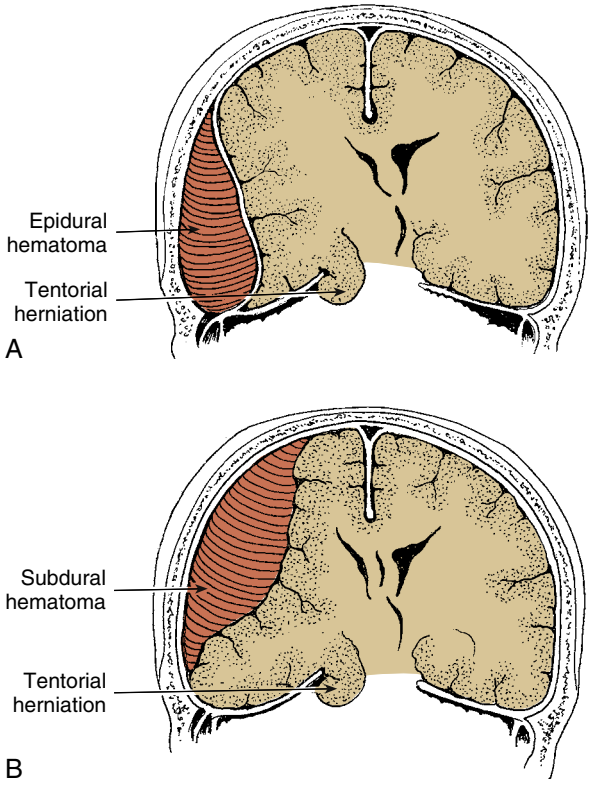

Fig. 27.6 A, Epidural (extradural) hematoma and compression of temporal lobe through tentorial herniation. B, Subdural hematoma.

The classic clinical picture of an epidural hemorrhage is a lucid interval of minutes to hours followed by rapidly altered mental status, then loss of consciousness or coma due to blood accumulation in the epidural space and compression of the brain. The child may be seen with varying degrees of impaired consciousness, depending on the severity of the traumatic injury. Common symptoms in a child with no neurologic deficit are irritability, headache, and vomiting. In infants younger than 24 months of age, common symptoms are scalp swelling, irritability, and lethargy. They may also have seizures, reduced oral intake, and increasing head circumference (Sellin, Moreno, Ryan, et al., 2017).

An epidural hematoma can be detected by an initial CT scan. If the severity of the child's symptoms is not recognized, herniation and death will result. ***Cushing triad*** (systemic hypertension, bradycardia, and respiratory depression) is a late sign of impending brainstem herniation.

NURSING ALERT

Children with a subdural hematoma and retinal hemorrhages should be evaluated for the possibility of child abuse, especially shaken baby syndrome.

Subdural Hematoma

A subdural hematoma is a hemorrhage between the dura and the arachnoid membrane that overlies the brain and the subarachnoid space. The hemorrhage may be from two sources: (1) tearing of the veins that bridge the subdural space and (2) hemorrhage from the cortex of the brain caused by direct brain trauma (see Fig. 27.6B). Subdural hematomas are much more common than epidural hematomas in infants and children.

Unlike epidural hemorrhage, which develops inwardly against the less resistant brain tissue, subdural hemorrhage tends to develop more slowly and spreads thinly and widely, crossing cranial sutures, until it is limited by the dural barriers: the falx and the tentorium. The small subdural space and the dura, which is firmly attached to the skull in this area, are highly vulnerable to increased ICP.

Subdural hematoma is fairly common in infants. Most often it is the result of assaults or violent shaking. The caregiver's response to infant crying, often perceived as inconsolable, is an important risk factor (Barr, 2014). In neonates, subdural hematoma can be a consequence of labor and delivery. Subdural hemorrhage can cause either acute or chronic subdural hematoma. Acute subdural hematoma may be associated with contusions or lacerations and develops within minutes or hours of injury. Chronic subdural hematoma is more common. The clinical course and manifestations vary depending on the damage sustained by the brain and the child's age.

Presenting signs of acute hematoma include irritability, vomiting, increased head circumference, bulging anterior fontanel (in the infant), lethargy, coma, or seizures. In infants with open fontanels, large amounts of intracranial blood may accumulate, causing hemorrhagic shock or fever before there are any changes in the neurologic examination. Retinal hemorrhages and skull and skeletal fractures are suggestive of physical abuse. An infant who has an altered LOC and in whom the CT scan shows subarachnoid hemorrhage or subdural hematoma may have been physically abused. A child with a GCS of 12 or less or a decrease in GCS score by 2 or more points requires emergency consultation with the neurosurgeon (Huang, Bi, Abd-El-Barr, et al., 2016).

Closely observe older children for signs of neurologic deterioration, including altered mental status, vomiting, lethargy, and signs of increased ICP. Hemiparesis, hemiplegia, and anisocoria (unequal pupils) are signs of brainstem compression and require emergency treatment targeted at decreasing ICP. The surgical management of subdural hematomas depends on the physical examination, size of the hematoma, and presence of other abnormalities on the CT scan. Not all children require surgery or are candidates for surgery. Various surgical options to treat subdural hematomas include transfontanel percutaneous aspiration, subdural drains, placement of burr hole, or craniotomy (Huang et al., 2016).

Other Hemorrhagic Lesions

A subarachnoid hemorrhage is bleeding within the subarachnoid space, which is normally filled with CSF. Nontraumatic intracranial hemorrhages are rare in children. The most common causes of spontaneous intracranial hemorrhage in children are arteriovenous malformations and fistulas and brain tumors (Ding, Starke, Kano, et al., 2017). Sudden onset of a severe headache, headaches occurring out of sleep, first-time seizure, and abnormal neurologic examination are symptoms that require evaluation including neuroimaging (Blume, 2017).

Cerebral Edema

Some degree of brain edema is expected after craniocerebral trauma and often accompanies any of the previously mentioned disorders. Cerebral edema peaks at 24 to 72 hours after injury and may account for changes in a child's neurologic status. Cerebral edema associated with traumatic brain injury may be a result of two different mechanisms: cytotoxic edema or vasogenic edema. Cytotoxic edema is a result of direct cell injury and is caused by intracellular swelling. In many cases the brain cells are irreversibly damaged. Vasogenic edema is due to increased permeability of capillary endothelial cells, resulting in increased intracellular fluid. In vasogenic edema the nerve cells are not primarily injured. Either mechanism can result in increased ICP as a result of increased intracranial volume and changes in CBF as a result of loss of autoregulation and/or hypercapnia or hypoxia. Children at risk for deterioration can be identified by abnormalities seen on noncontrast CT scans.

Sequelae of Traumatic Brain Injury

Postconcussion syndrome is a sequela to brain injury with or without loss of consciousness. Concussions usually resolve in 1 to 3 weeks without complications. Up to a third of children may have ongoing somatic, behavioral, cognitive, and psychologic symptoms, including headaches, visual and balance problems, difficulty concentrating, irritability, and changes in their sleep patterns (Morgan, Zuckerman, Lee, et al., 2015). The pathophysiology of these symptoms is unclear. When these symptoms continue for more than 4 weeks after the concussion, the term *postconcussion syndrome* (PCS) is used (Zemek, Barrowman, Freedman, et al., 2016). Risk factors for PCS in youth athletes include a personal or family history of mood disorders and other psychiatric illnesses and migraines (Morgan et al., 2015). Previously, concussion treatment guidelines recommended cognitive and physical rest as a path to recovery. Recent studies, though, have found that early participation in physical activity is significantly likely to prevent the development of PCS (Grool, Aglipay, Momoli, et al., 2016).

Posttraumatic headaches, one of the most common symptoms after mild TBI, may occur within 1 week to 3 months after a mild TBI. They occur in 25% to 75% of individuals and are most commonly classified as migraines (Kuczynski, Crawford, Bodell, et al., 2013). Posttraumatic headaches are treated based on the primary headache type: migraine or tension/chronic headache (Kacperski & Arthur, 2016).

Posttraumatic seizures occur in a number of children who survive a head injury, often within 24 hours, but they also can occur sometime after the injury (Rumalla, Smith, Letchuman, et al., 2018). Risk factors for seizures include preexisting comorbidities, shaken infant syndrome, subdural hematoma, closed-type injury, and changes in LOC (Rumalla et al., 2018).

Hydrocephalus may develop after subarachnoid hemorrhage or infection. Normal pressure hydrocephalus can be a complication of TBI. In infants, signs and symptoms include rapidly increasing head circumference, irritability, refusal to feed, and sleepiness. The clinical signs and symptoms in children include changes in personality, developmental regression, ataxia, and incontinence. These signs are also seen during posttraumatic amnesia, making early recognition of this syndrome difficult. Focal deficits, including optic atrophy, cranaial nerve (CN) palsies, motor deficits, DI, or aphasia, may be seen. The type of residual effect depends on the location and nature of the trauma.

Diagnostic Evaluation

A detailed health history, both past and present, is essential in evaluating the child with head trauma. Certain disorders such as drug allergies, hemophilia, diabetes mellitus, or epilepsy may produce similar symptoms. Even a minor traumatic injury can aggravate a preexisting

BOX 27.3 Clinical Manifestations of Acute Head Injury

Minor Injury
May or may not lose consciousness
Transient period of confusion
Somnolence
Listlessness
Irritability
Pallor
Vomiting (one or more episodes)

Signs of Progression
Altered mental status (e.g., difficulty arousing child)
Mounting agitation
Development of focal lateral neurologic signs
Marked changes in vital signs

Severe Injury
Signs of increased intracranial pressure (see Box 27.1)
Bulging fontanel (infant)
Retinal hemorrhages
Extraocular palsies (especially cranial nerve III)
Hemiparesis
Quadriplegia
Elevated temperature
Unsteady gait (older child)
Papilledema (older child)
Retinal hemorrhages

Associated Signs
Scalp trauma
Other injuries (e.g., to extremities)

disease process, thereby producing neurologic signs out of proportion to the injury.

After a minor injury, initial unconsciousness (if present) is brief. The child ordinarily exhibits a transient period of confusion, somnolence, and listlessness; this period is most often accompanied by irritability, pallor, and one episode of vomiting. A severe head injury requires immediate evaluation and treatment. Because head injuries are often accompanied by injuries in other areas (e.g., spine, viscera, extremities), the examination is performed with care to avoid further damage. Box 27.3 lists manifestations of head injury.

! NURSING ALERT

Stabilize the spine after head injury until spinal cord injury is ruled out.

Initial Assessment

Priorities in the initial phase in the care of a child with a head injury include assessment of the CAB (circulation, airway, breathing); neurologic examination focusing on mental status, papillary responses, and motor responses; and assessment for spinal cord injury. The assessment is carried out quickly in relation to vital signs (see Emergency Treatment box).

EMERGENCY TREATMENT

Head Injury

1. Assess child:
   - C—Circulation
   - A—Airway
   - B—Breathing
   - Neurologic and thermoregulatory status
2. Stabilize neck and spine immediately. Use jaw thrust, not chin lift, to open airway.
3. Clean any abrasions with soap and water.
   - Apply clean dressing.
   - If child is bleeding, apply ice to relieve pain and swelling.
4. Keep child NPO (nothing by mouth) until instructed otherwise.
5. Assess pain but give no analgesics or sedatives.
6. Check level of consciousness and pupillary reaction every 4 hours (including twice during night) for 48 hours.
7. Seek medical attention for any of the following:
   - Injury sustained at high speed (e.g., automobile)
   - Fall from a significant distance (height greater than that of the child)
   - Injury sustained from great force (e.g., baseball bat)
   - Injury sustained under suspicious circumstances
   - Loss of consciousness
   - Amnesia
   - Discomfort (crying) more than 10 minutes after injury
   - Headache that is severe, worsens, interferes with sleep, or lasts more than 24 hours
   - Vomiting three or more times or vomiting that begins or continues 4 to 6 hours after injury
   - Swelling in front of or above earlobe or swelling that increases in size
   - Fluid leak from ears or nose; blackened eyes
   - Confusion or abnormal behavior
   - Difficulty arousing child from sleep
   - Difficulty speaking
   - Blurring of vision or diplopia
   - Unsteady gait
   - Difficulty using extremities; weakness or incoordination
   - Neck pain or stiffness
   - Pupils dilated, fixed, or unequal
   - Infant with bulging fontanel
   - Seizures

! NURSING ALERT

Deep, rapid, periodic, or intermittent and gasping respirations; wide fluctuations or noticeable slowing of the pulse; and widening pulse pressure or extreme fluctuations in blood pressure are signs of brainstem involvement. Marked hypotension may represent internal injuries.

Ocular signs such as fixed, dilated, and unequal pupils; fixed and constricted pupils; and pupils that are poorly reactive or unreactive to light and accommodation indicate increased ICP or brainstem involvement. It is important to remain with the patient who demonstrates fixed and dilated pupils because these are ominous signs often associated with impending respiratory arrest. Dilated, nonpulsating blood vessels indicate increased ICP before the appearance of papilledema. Retinal hemorrhages often occur with acute head injuries, specifically with shaken baby syndrome.

NURSING ALERT

Observation of asymmetric pupils or one dilated, unreactive pupil in a comatose child is a neurologic emergency.

Funduscopic examination should be performed routinely to detect retinal hemorrhages in a child with CNS trauma. Vestibulo-ocular symptoms such as diplopia, dizziness, motion sensitivity, eye-tracking and eye-focusing problems, photosensitivity, and visual inattention may develop (Ellis, Cordingley, Vis, et al., 2015). Transient vision loss may occur after mild head trauma but may not be obvious in children unless this diagnosis is evaluated. Theories of possible causes are vasospasm or localized cerebral edema.

Less urgent but important assessments include examination of the scalp for lacerations, widely separated sutures, and the size and tension of fontanels, which indicate intracranial hemorrhage or rapidly developing cerebral edema. Scalp lacerations may require surgical intervention. A significant amount of blood loss can occur from scalp lacerations. CT scan may be necessary to evaluate possible skull fractures and acute intracranial hemorrhage (Ryan, Jaju, Ciolino, et al., 2016).

NURSING ALERT

Bleeding from the nose or ears needs further evaluation, and a watery discharge from the nose (rhinorrhea) that is positive for glucose (as tested with reagent strips [e.g., Dextrostix]) suggests leaking of cerebrospinal fluid (CSF) from a skull fracture.

A documented accurate assessment of clinical signs provides baseline information. Serial evaluations, preferably by a single observer, help detect changes in neurologic status. Alterations in mental status, evidenced by increased difficulty in rousing the child, mounting agitation, development of focal neurologic signs, or marked changes in vital signs, usually indicate extension or progression of the basic pathologic process.

Evaluation of reflexes provides information about cerebral and pyramidal involvement, although transient abnormalities of the primitive reflexes and Babinski sign may be present in children with mild head trauma. Conscious, cooperative children are examined for cerebellar signs such as ataxia and dysmetria. Children may display unsteadiness, clumsiness, or tremor with intentional movement after head injury. Temperature may be moderately elevated for 1 or 2 days after an initial mild hypothermia after injury. A persistent fever may indicate subarachnoid hemorrhage or infection.

Special Tests

After a thorough clinical examination, a variety of diagnostic tests are helpful in providing a more definitive diagnosis of the type and extent of the trauma. A hematocrit and urinalysis are typically done. Serum electrolytes and glucose may also be measured in children with severe head injuries; hyperglycemia and disseminated intravascular coagulation are associated with a poor prognosis. The severity of a head injury may not be apparent on clinical examination of the child but detectable on a CT scan. Whenever the child has a history consistent with a serious head injury (as with an unrestrained occupant in a severe motor vehicle accident or a fall from higher than their own height), it is important to perform a scan even if the child initially appears alert and oriented. All children with head injuries who have any alteration of consciousness, headache, vomiting, skull fracture, seizure, or predisposing medical condition should undergo a diagnostic evaluation that includes CT scanning.

MRI may be done to further assess cerebral edema or other structural brain abnormalities. A neurodevelopmental assessment after early head injury may be useful in documenting cognitive impairment. Skull radiographs are of little benefit in diagnosing skull fractures. Other radiographic tests may be indicated, depending on the severity or cause of the trauma. Electroencephalography is not helpful for diagnosis of a head injury but is useful for defining seizures and looking for subclinical seizures, which can impair consciousness (Gainza-Lein, Sanchez-Fernandez, & Loddenkemper, 2017). Lumbar puncture is rarely used for craniocerebral trauma and is contraindicated in the presence of increased ICP because of the possibility of herniation.

Therapeutic Management

Most children with mild TBI who have not lost consciousness can be cared for and observed at home after careful examination reveals no serious intracranial injury. The nurse should give parents both verbal and written instructions of signs and symptoms that warrant concern and the need for reevaluation. These include persistent or worsening headaches, vomiting, change in mental status or behavior, unsteady gait, or seizure. The child should have a physical examination 1 or 2 days after the injury. The manifestations of epidural hematoma in children do not generally appear until 24 hours or more after injury.

Maintaining contact with parents for continued observation and reevaluation of the child, when indicated, facilitates early diagnosis and treatment of possible complications from head injury, such as hematoma, cerebral edema, and posttraumatic seizures. Children are generally hospitalized for 24 to 48 hours of observation if their family lives far from medical facilities or lacks transportation or a telephone, which would provide access to immediate help. Other circumstances, such as language or other communication barriers or even emotional trauma, may hinder learning and make it difficult for families to feel confident caring for their child at home.

NURSING ALERT

If a child loses consciousness or develops a severe headache after a head injury, medical attention should be sought.

Children with severe injuries, those who have lost consciousness for more than a few minutes, and those with prolonged and continued seizures or other focal or diffuse neurologic signs must be hospitalized until their condition is stable and their neurologic signs have diminished. The child is maintained on nothing-by-mouth (NPO) status or restricted to clear liquids (if able to take fluids by mouth) until it is determined that vomiting will not occur. IV fluids are indicated in the child who is comatose, displays dulled sensorium, or is persistently vomiting.

The volume of IV fluid is carefully monitored to minimize the possibility of overhydration in case of SIADH and cerebral edema. However, damage to the hypothalamus or pituitary gland may produce DI, with its accompanying hypertonicity and dehydration. Fluid balance is closely monitored by daily weight, strict intake and output measurement, and serum osmolality (to detect early signs of water retention).

Sedating drugs are usually withheld in the acute phase. Headache is usually controlled with acetaminophen, although opioids may be needed. Antiepileptics are used for seizure control. Antibiotics are administered if there are lacerations or penetrating injuries. Prophylactic tetanus toxoid is given as appropriate (see Chapter 6). Cerebral edema is

managed as described for the unconscious child. Hyperthermia is controlled with tepid sponges or a hypothermia blanket.

Surgical Therapy

Approximately 10% to 30% of pediatric head traumas will result in skull fractures. Because of the greater capacity of a child's skull fracture to heal, conservative nonsurgical management is often adequate. Children hit in the head or who have TBI as a result of a motor vehicle accident are more likely to require surgical intervention, especially if the frontal bones have been fractured (Bonfield et al., 2014).

Scalp lacerations are sutured after careful examination of underlying bone. The use of topical lidocaine, adrenaline, and tetracaine (LAT) or lidocaine, epinephrine, and tetracaine (LET) provides noninvasive, effective anesthesia for suturing, particularly when combined with consultation from and the bedside presence of a child life specialist (Martin, 2017).

Depressed fractures require surgical reduction and removal of bone fragments. Torn dura is also sutured. A skull fracture depressed more than the thickness of the skull or an intracranial hematoma that causes more than a 5-mm (0.2-inch) midline shift is an indication for surgery. Direct pressure should never be applied to a depressed skull fracture. Parents should be advised that painful hardware and wound infections may need further surgical intervention. Parents and other caregivers must be taught the importance of meticulous hand washing after surgical repair of a skull fracture.

Prognosis

The outcome of craniocerebral trauma depends on the extent of injury and complications. Neurologic, cognitive, emotional, and behavioral symptoms can result in significant impairment. They may not present until the child is older and preparing to reach certain developmental milestones (Babikian, Merkley, Savage, et al., 2015). These symptoms can become chronic and include epilepsy, attention-deficit/hyperactivity disorder, and learning or psychiatric disorders. Children with learning and behavior problems before their head trauma are more likely to suffer these consequences (Beauchamp & Anderson, 2013). More than 90% of children with concussions or simple linear fractures recover without symptoms after the initial period.

Children may be more vulnerable than adults to long-term cognitive and behavioral dysfunction after diffuse brain injury. Contrary to what was previously thought about "brain plasticity," evidence now indicates that children's brains may be especially vulnerable to early injury due to their ongoing maturation processes, which can be disrupted by head trauma (Babikian et al., 2015). Parents of children who have suffered TBI should be advised to seek evaluation and treatment sooner rather than later if any of these symptoms present. TBI is recognized as a disability that may qualify a child for special education services under the Individuals with Disabilities Education Act (IDEA) of 1990.

True coma (i.e., not obeying commands, eyes closed, and not speaking) usually does not last for more than 2 weeks. A child's eventual outcome can range from brain death to a persistent vegetative state to complete recovery. However, even the best recovery may be associated with personality changes, including mood lability and loss of confidence, impaired short-term memory, headaches, and subtle cognitive impairments. In general, 90% of the long-term neurologic outcome has been achieved within 6 months to 1 year after the injury.

Nursing Care Management

The hospitalized child requires careful neurologic assessment and evaluation repeated as frequently as every 15 minutes to establish a correct diagnosis, identify signs and symptoms of increased ICP, determine clinical management, and prevent many complications. The goals of nursing management of the child with a head injury are to maintain adequate ventilation, oxygenation, and circulation; to monitor and treat increased ICP; to minimize cerebral oxygen requirements; and to support the child and family during recovery (see Quality Patient Outcomes box).

QUALITY PATIENT OUTCOMES: Acute Head Injury

- Early recognition of signs and symptoms of increased intracranial pressure
- Adequate ventilation, oxygenation, and circulation maintained
- Cerebral oxygen requirements minimized
- Sedation and analgesia provided while allowing for neurologic assessment

The child is placed on bed rest, usually with the head of the bed elevated slightly and the head in midline position. Appropriate safety measures, such as side rails kept up and seizure precautions, are implemented. If the child is extremely restless, hard surfaces may be padded and restraints used to prevent further injury. Individualize care according to the child's specific needs.

A key nursing role is to provide sedation and analgesia for the child. The conflict between the need to promote the child's comfort and relieve anxiety versus the need to assess for neurologic changes presents a dilemma. Both goals can be achieved with close observation of the child's LOC and response to analgesics (using a pain assessment record) and effective communication with the provider. Decreasing restlessness after administration of an analgesic most likely reflects pain control rather than a decreasing LOC (see Chapter 5, Pain Assessment and Pain Management).

Children may be restless and irritable, but more often their reaction is to fall asleep when left undisturbed. A quiet environment can help reduce restlessness and irritability. Bright lights are irritating. This often makes checking the ocular responses more difficult and aggravating to the child.

Frequent examinations of vital signs, neurologic signs, and LOC are extremely important nursing observations. When possible, they should be performed by a single observer to better detect subtle changes that may indicate worsening of neurologic status. Pupils are checked for size, symmetry, reaction to light, and accommodation. Unless there is brainstem involvement, vital signs generally return to normal after the initial changes seen after injury.

The most important nursing observation is assessment of the child's LOC. In the progression of an injury, alterations in consciousness appear earlier than alterations in vital signs or focal neurologic signs (see evaluation of responsiveness later in the chapter). Frequent examinations of alertness are fatiguing to the child; the child often desires to fall asleep, which may be confused with depressed consciousness. It is not uncommon to observe ocular divergence through the partially closed eyelids.

Observations of position and movement provide additional information. Note any abnormal posturing and whether it occurs continuously or intermittently. Questions nurses might ask include the following:

- Are the child's hand grips strong and equal in strength?
- Are there any signs of extension or flexion posturing?
- What is the child's response to auditory and physical stimulation?
- Is movement purposeful, random, or absent?
- Are movement and sensation equal on both sides or restricted to one side only?

The child may report a headache or other discomfort. The child who is too young to describe a headache may be fussy and resist being handled. The child who suffers from vertigo often vigorously resists

being moved from a position of comfort. Forcible movement causes the child to vomit and display spontaneous nystagmus. Seizures are relatively common in children at the time of head injury and may be of any type. Carefully observe any seizure activity and describe it in detail. Children in postictal states are more lethargic, with sluggish pupils.

Document drainage from any orifice. Bleeding from the ear suggests the possibility of a basal skull fracture. Clear nasal drainage is suggestive of an anterior basal skull fracture. Observe the amount and characteristics of the drainage.

! NURSING ALERT

Suctioning through the nares is contraindicated because there is a risk of the catheter entering the brain through a fracture in the skull.

Head trauma is often accompanied by other undetected injuries; therefore any bruises, lacerations, or evidence of internal injuries or fractures of the extremities are noted and reported. Associated injuries are evaluated and treated appropriately.

The child with a normal LOC is usually allowed clear liquids unless fluid is restricted. If the child has an IV infusion, it is maintained as prescribed. The diet is advanced to that appropriate for the child's age as soon as the condition permits. Intake and output are measured and recorded with attention to the development of constipation. Any incontinence of bowel or bladder is noted for the child who has been toilet trained.

Assessment for unusual behavior can be made only in relation to the child's typical behavior. For example, urinary incontinence during sleep would be of no consequence in a child who routinely wets the bed but would be highly significant for one who is always dry. Parents are invaluable resources in evaluating objective behaviors of their children. Information obtained from parents at or shortly after admission is essential in evaluating the child's behavior (e.g., the ease with which the child is roused normally, the usual sleeping position, how much the child sleeps during the day, the child's motor activities [rolling over, sitting up, climbing], hearing and visual acuity, appetite, and manner of eating [spoon, bottle, cup]). Documentation of the child's baseline developmental and behavioral level is crucial. There is less concern about a child who falls asleep several times during the day if this is consistent with the child's usual behavior.

When the child is discharged, advise the parents of probable posttraumatic symptoms they may observe, such as behavioral changes, sleep disturbances, phobias, and seizures. Parents should be taught seizure first aid. They should understand observations they need to make and when and how to contact the provider or health facility in case the child develops any unusual signs or symptoms. Emphasize the importance of follow-up evaluation.

Family Support

The emotional and educational support of the family presents a challenge. Witnessing the parents' grief and helplessness on seeing their child in an intensive care unit connected to monitoring equipment and in an altered state evokes empathy. The nurse can encourage the family to be involved in the child's care, to bring in familiar belongings, or to make a recording of familiar voices and sounds. Parents may need a demonstration on how to touch or cuddle their child and may want to talk about their grief. The nurse listens attentively, reinforces what is being done to assist the child, and directs parents toward signs and symptoms of recovery to instill hope without promises. Honesty and kindness, along with consistent and competent care, help families through this difficult time.

Rehabilitation

Rehabilitation and management of the child with permanent brain injury are essential aspects of care. Rehabilitation begins as soon as possible and usually involves the family and a rehabilitation team. The nurse makes a careful assessment of the child's capabilities and limitations and implements appropriate interventions to maximize the residual capacities. The Brain Injury Association of America[a] provides information and listings of rehabilitation services and support groups throughout the country.

The child with a disability resulting from head trauma requires functional assessment of his or her physical, cognitive, emotional, and social levels. The child has experienced separation, pain, sensory deprivation and overload, changes in circadian cycle, and fear of the unknown. Recovery and transition require new coping strategies at the same time that regressive and acting-out behaviors may start. Parents and children need honest communication for decision making.

Rehabilitation is recommended when the child is making progress and no longer requires acute care hospitalization but continues to require daily therapies to return to his or her premorbid functional level. Children are more likely to continue in outpatient rehabilitation if they have had an inpatient assessment of their rehabilitation needs (Jimenez, Symons, Wang, et al., 2016). The Rancho Los Amigos Scale provides a systematic assessment of the progress that a child with a severe head injury may achieve.

Pediatric rehabilitation focuses on the child's strengths and needs. The rehabilitation team should include physical medicine; rehabilitation nursing; nutritional counseling; physical, occupational, and speech therapy; special education; and psychologic, neuropsychologic, child life, and social services support. Before the child's transfer, the hospital team should provide a detailed care plan of the child's needs and abilities, especially communication skills, and a description of the child's usual schedule, nursing care interventions, and the family's concerns and needs. To augment the care plan, a video introducing the child and family and showing any unique aspects of their care can be sent to the rehabilitation center.

Prevention

Preventive strategies are underused in almost all cases of accidental childhood injury. Head injuries occur in the most serious accidents—especially motor vehicle accidents, sports, and falls.

Strides are being made in the prevention of secondary brain tissue damage after the initial head injury in children. This secondary injury is caused by altered cerebral blood flow that results in ischemia, hypoxia, and eventually the death of brain cells (Popernack, Gray, & Reuter-Rice, 2015). Studies are ongoing in both humans and animals using therapeutic hypothermia, glucagon, blood pressure medications, and antioxidants (Toth, Szarka, Farkas, et al., 2016). The roles of calcium, oxyradicals, and prostaglandins are being investigated.

However, the greatest benefit lies in prevention of head injuries. Nurses can exert a valuable influence on behalf of children through education. Accidents that are preventable occur because unnecessary risks go unchecked. Inadequate supervision combined with a child's natural sense of curiosity and exploration can lead to lethal results. Nurses are in the unique position of influencing caregivers in terms of growth and development. The use of car seats; seat belts in strollers and feeding chairs; and helmets for biking, skateboarding, and other sports

[a]1608 Spring Hill Road, Suite 110, Vienna, VA 22182; 703-761-0750; fax: 703-761-0755; http://www.biausa.org.

has been shown to reduce both the number and the severity of head injuries in children (Gaw, Chounthirath, & Smith, 2017).

Studies of ways to prevent abusive head trauma are ongoing. Promising interventions include teaching parents about infant crying and ways to cope with it (Lopes & Williams, 2016). Infants who have been hospitalized after birth have an increased risk of being abused after discharge. Neonatal nurses have an important role to play in teaching parents of these children about child abuse prevention.

Public education coupled with legislative support can aid in the prevention of childhood injuries. Research has shown that increased household income can prevent abusive head trauma (Klevens, Schmidt, Luo, et al., 2017). For extensive discussions of childhood injuries, see the information on injury prevention in Chapters 10, 12, 13, and 15.

SUBMERSION INJURY

Drowning is one of the major causes of unintentional injury-related death in children ages 1 to 19 years. In children ages 1 to 4 years it is the leading cause of unintentional injury-related death (Gilchrist & Parker, 2014). The term *near-drowning* is no longer used; instead, the term *submersion injury* should be used until the time of drowning-related death.

Most cases of submersion injury are accidental, usually involving children who are helpless in water, such as inadequately attended children in or near swimming pools or infants in bathtubs; small children who fall into ponds, streams, and flooded excavations, usually near home; occupants of pleasure boats who fail to wear life preservers; children who have diving accidents; and children who are able to swim but overestimate their endurance. Accidental submersion injury occurs predominantly in males, toddlers, and African Americans (Gilchrist & Parker, 2014).

Submersion injury can take place in any body of water. Children less than 1 year of age are most likely to have a submersion injury in a bathtub, whereas top-heavy toddlers fall headfirst into a pail of water and are unable to free themselves (Xu, 2014). Preschoolers are at risk for injury in swimming pools, and school-age children and adolescents are most commonly at risk in natural bodies of water such as lakes, ponds, and rivers (Xu, 2014). The suction created at the outlet of pools, hot tubs, or whirlpool spas is strong enough to trap even larger children underwater. Submersion injury as a form of fatal child abuse also occurs. Homicidal submersion injuries are not witnessed, usually occurring in the home, and the victims are either infants or toddlers.

Pathophysiology

Physiologically, most organ systems are affected, especially the pulmonary, cardiovascular, and neurologic systems. The major pulmonary changes that occur in submersion injury are directly related to the length of submersion (regardless of the type and amount of fluid aspirated), the victim's physiologic response, and the development and degree of immersion hypothermia. Cerebral hypoxia is a major component of morbidity and mortality in these individuals. Therefore early and aggressive resuscitation is imperative.

Physiologic factors in submersion injuries are hypothermia, aspiration, and hypoxia. The temperature of the liquid plays an important role. Cold water decreases metabolic demands and activates the diving reflex, which causes blood to be shunted away from the periphery to vital organs (i.e., the brain and heart). Hypothermia occurs rapidly in infants and children, partly because of their large surface area relative to size and partly as a result of the cold water itself. Profound hypothermia is usually evidence of lengthy submersion. Prolonged submersion in cold liquids can impair cognition, coordination, and muscle strength that ultimately results in loss of consciousness, decreased cardiac output, and cardiac arrest (Thomas & Caglar, 2020). Submersion in cold water had previously been thought to be somewhat neuroprotective, but it is not (Quan, Mack, & Schiff, 2014).

Submerged children struggle initially to stay above water, and often breath-holding leads to air hunger. Reflex inspiration eventually occurs, which leads to aspiration (Thomas & Caglar, 2020). Fluid is quickly absorbed in the pulmonary circulation, resulting in pulmonary edema, atelectasis, and airway spasm. Hypoxia is the primary problem because it results in global cell damage, with different cells tolerating variable lengths of anoxia. Neurons, especially cerebral cells, sustain irreversible damage after 4 to 6 minutes of submersion. The heart and lungs can survive up to 30 minutes. Regardless of the amount of water aspirated, the victim suffers arterial hypoxemia (resulting from atelectasis and shunting of blood through the nonventilated alveoli), combined respiratory acidosis (resulting from retained carbon dioxide), and metabolic acidosis (caused by buildup of acid metabolites because of anaerobic metabolism). Although electrolyte imbalances are contributing factors, they are not the major causes of morbidity and mortality. The pathologic events are directly related to the duration of submersion. Approximately 10% of submersion injury victims die without aspirating fluid but succumb from acute asphyxia as a result of prolonged reflex laryngospasm.

! NURSING ALERT

All children who have a submersion injury should be admitted to the hospital for observation. Although many patients do not appear to have suffered adverse effects from the event, complications (e.g., respiratory compromise, cerebral edema) may occur 24 hours after the incident.

Aspiration of fluid occurs in most submersion injuries. The aspirated fluid results in pulmonary edema, atelectasis, airway spasm, and pneumonitis, which aggravates hypoxia. Submersion in salt water is associated with better outcomes than submersion in fresh water, although duration of the submersion is the main factor that predicts outcome (Quan, Bierens, Lis, et al., 2016).

Clinical Manifestations

Clinical manifestations are directly related to the duration of loss of consciousness and neurologic status after rescue and resuscitation.

Therapeutic Management

With rapid treatment, some children can be saved. Resuscitative measures should begin at the scene, and the victim should be transported to the hospital with maximum ventilatory and circulatory support. In the hospital, intensive pulmonary care is implemented and continued according to the patient's needs.

In general, management of the victim with a submersion injury is based on the degree of cerebral insult. The first priority is to restore oxygen delivery to the cells and prevent further hypoxic damage. A spontaneously breathing child does well in an oxygen-enriched atmosphere; the more severely affected child requires endotracheal intubation and mechanical ventilation. Blood gases and pH are monitored at frequent intervals as a guide to oxygen, fluid, and electrolyte therapies. Rewarming the hypothermic patient is initiated. Seizures may occur due to hypoxia and cerebral edema. Seizures result in increased cerebral oxygen consumption. Therefore it is imperative to aggressively control seizure activity. In addition, blood glucose should be monitored; both hypoglycemia and hyperglycemia are harmful to the brain.

All children who have a submersion injury should be hospitalized for observation. Although some children do not appear to have sustained adverse effects from the event, respiratory compromise or cerebral edema may occur within 24 hours after the incident. In the acute recovery period, fever should be prevented, although prophylactic antibiotics are not recommended. Aspiration pneumonia is a common complication that occurs approximately 48 to 72 hours after the episode. Bronchospasm, alveolar-capillary membrane damage, atelectasis, abscess formation, and acute respiratory distress syndrome are other complications that occur after aspiration of fluid.

Prognosis

Children who have submersion injuries usually have a good outcome with no or mild neurologic sequelae, no severe neurologic disabilities, and rarely morbidity (Thomas & Caglar, 2020). The best predictors of a good outcome are length of submersion less than 5 minutes and the presence of sinus rhythm, reactive pupils, and neurologic responsiveness at the scene. The worst outcomes are for children submerged for more than 10 minutes and unresponsive to advanced life support within 25 minutes. All children without spontaneous, purposeful movement and normal brainstem function 24 hours after sustaining a submersion injury suffered severe neurologic deficits or death (Thomas & Caglar, 2020).

Nursing Care Management

Nursing care depends on the child's condition. A child who survives may need intensive respiratory nursing care with attention to vital signs, mechanical ventilation or tracheostomy, blood gas determination, chest physiotherapy, and IV infusion. Often the child has sustained a hypoxic insult and requires the same care as an unconscious child.

A difficult aspect in the care of the child who sustained a submersion injury is helping the parents cope with the grief, guilt, and anger reactions. Given the magnitude of the event, parents need repeated assurance that everything possible is being done to treat their child.

Nurses often have difficulty relating to the parents if obvious neglect has precipitated the accident and subsequent problems; it is important for those who care for these children and their families to assess their own feelings about the situation, in addition to assessing the family's coping abilities and resources. Caring for victims of a submersion injury and their families requires the nurse to be sensitive to the needs of the child and the family and to recognize his or her own reactions and emotions.

Prevention

Most submersion injuries are preventable. The most common cause of submersion injury in infants and young children is inadequate adult supervision, including a momentary lapse of supervision. Parents are often unaware that they must be within arm's reach and constantly supervising without being distracted (Thomas & Caglar, 2020). Children with known risk factors such as epilepsy and autism require eyes-on surveillance. In general, children are not developmentally ready for formal swimming lessons until their fourth birthday. All parents and swimming pool owners should be familiar with basic cardiopulmonary resuscitation (CPR) because rapid, basic CPR is one of the keys to improving outcomes (Tobin, Ramos, Pu, et al., 2017). Water safety and survival training should be required for all school-age children. Pool covers and fencing on all sides and the presence of lifeguards can prevent accidents.

Nurses can be active advocates in their communities. Nurses are also in a position to emphasize the importance of adequate adult supervision when children are around any body of water and should include the necessity of the adult not engaging in distracting activities.

INTRACRANIAL INFECTIONS

The nervous system is subject to infection by the same organisms that affect other organs of the body. However, the nervous system is limited in the ways in which it responds to injury. Laboratory studies are needed to identify the causative agent. The inflammatory process can affect the meninges (meningitis) or brain (encephalitis).

Meningitis can be caused by a variety of organisms, but the three main types are (1) bacterial, or pyogenic, caused by pus-forming bacteria, especially meningococci and pneumococci organisms; (2) viral, or aseptic, caused by a wide variety of viral agents; and (3) tuberculous, caused by the tuberculin bacillus. The majority of children with acute febrile encephalopathy have either bacterial meningitis or viral meningitis as the underlying cause.

BACTERIAL MENINGITIS

Bacterial meningitis is an acute inflammation of the meninges and CSF. The advent of antimicrobial therapy has had a marked effect on the course and prognosis. The introduction of conjugate vaccines against *Haemophilus influenzae* type b (Hib vaccine) in 1990 and *Streptococcus pneumoniae* (pneumococcus) in 2000 has led to dramatic changes in the epidemiology of bacterial meningitis (see Translating Evidence Into Practice box). Today, Hib infection has been virtually eradicated among young children in areas where the Hib vaccine is administered routinely. By 2013 there were fewer than 40 cases of Hib disease in children younger than 5 years old (Centers for Disease Control and Prevention, 2016). Before the vaccine, Hib was responsible for almost half of all cases of bacterial meningitis, but now it is the least likely pathogen to cause meningitis (Castelblanco, Lee, & Hasbun, 2014). Since the introduction of widespread vaccination for *S. pneumoniae,* the incidence of pneumococcal meningitis in children in the United States has decreased, but it remains the most common cause of meningitis in children ages 3 months to 11 years (Castelblancoet al., 2014). It is also the most likely to result in death (Heckenberg, Brouwer, & Van de Beek, 2014).

Etiology

A variety of bacterial agents can cause bacterial meningitis. Since the introduction of vaccinations against most common causes of community-acquired pathogens, the incidence of bacterial meningitis has declined precipitously. The leading causes of neonatal meningitis are group B streptococcus (GBS) and *Escherichia coli* (Ku, Boggess, & Cohen-Wolkowiez, 2015).

Meningococcal meningitis is the only type readily transmitted by droplet infection from nasopharyngeal secretions and so has the potential to occur in outbreaks (Vetter, Baxter, Denizer, et al., 2016). Before the development of a vaccine it occurred predominantly in school-age children and adolescents; now it is most common in children under 12 months old, with a secondary peak in incidence in 16- to 23-year-olds (Centers for Disease Control and Prevention, 2017b). Meningitis caused by pneumococcal and meningococcal infections can occur at any time but is more common in late winter and early spring.

Maternal factors, such as premature rupture of fetal membranes and maternal infection during the last week of pregnancy, are major causes of neonatal meningitis. It is a devastating disease with significant morbidity and mortality. Vaccination of pregnant women is being explored as a way to protect infants from meningitis (Jones, Munoz, Spiegel, et al., 2016). Children who survive neonatal meningitis are 10 times more likely to have moderate to severe disabilities than those who have not had meningitis (Ku et al., 2015). The incidence of early-onset GBS meningitis has been reduced by more than 70% with the adoption of antenatal screening and administration of intrapartum prophylactic antibiotics (Ku et al., 2015).

TRANSLATING EVIDENCE INTO PRACTICE

Children With Bacterial Meningitis and Preventive Vaccines

Ask the Question

In children and adolescents with bacterial meningitis, has the administration of *Haemophilus influenzae* type b (Hib), pneumococcal, and meningococcal preventive vaccines reduced the incidence and mortality rates associated with bacterial meningitis?

Search for the Evidence

Search Strategies

Search selection criteria included English-language publications within the past 10 years, research-based articles, children and adult populations.

Databases Used

PubMed and Cochrane Collaboration.

Critically Analyze the Evidence

GRADE criteria: Evidence quality high; recommendation strong (Balshem, Hefland, Schunemann, et al., 2011). A review of the literature revealed two literature reviews, one Cochrane review, and one population-based observational study.

- Watt and colleagues (2009) performed a literature review with studies evaluating Hib disease incidence, fatality ratios, and the effect of the Hib vaccine. In 2000 there were 173,000 cases of Hib meningitis and 78,300 deaths among children under the age of 5 years worldwide. Expanded use of the Hib vaccine can reduce the incidence and mortality rates of Hib-related disease.
- A Cochrane review determined the effect, duration of protection, and age-specific effects of polysaccharide serogroup A vaccine (SgAV) to prevent meningococcal meningitis in children. The vaccine had a 95% protective effect during the first year in children older than 5 years of age, but its efficacy after the first year could not be determined. Children ages 1 to 5 years in low-income countries also experienced protective effects from the SgAV, but the exact efficacy could not be determined (Patel & Lee, 2010).
- A literature review assessed the impact of the 7-valent pneumococcal conjugate vaccination on morbidity and mortality rates from invasive pneumococcal diseases. The six studies from North America consistently reported a decline in invasive pneumococcal disease mortality rate after the introduction of the pneumococcal vaccine, with reductions ranging from 57% to 62% among children and 37% to 76% among all age-groups (Myint, Madhava, Balmer, et al., 2013).
- A population-based observational study evaluated the incidence of bacterial meningitis from 1997 to 2010, after conjugate vaccination introduction. The incidence of *Streptococcus pneumoniae* decreased from 0.8 to 0.3 per 100,000 people; the incidence of *Neisseria* meningitis decreased from 0.721 to 0.123 per 100,000 people; and the mortality rate from pneumococcal meningitis decreased from 0.073 to 0.024 per 100,000 people (Castelblanco, Lee, & Hasbun, 2014).

Apply the Evidence: Nursing Implications

The evidence strongly suggests that all children should be immunized against the most common organisms responsible for bacterial meningitis (i.e., Hib, *S. pneumoniae,* and *Neisseria meningitidis*) as prevention to decrease the incidence of bacterial meningitis. Nurses should stress to the parents, children, adolescents, and young adults the importance of adhering to the immunization schedule to protect against serious childhood diseases.

Risk factors for children developing meningitis include lack of immunization to the specific pathogen; recent exposure to someone with invasive *Neisseria meningitidis* or Hib disease; penetrating head trauma; cochlear implant devices; and anatomic defects such as midline facial defects, inner ear fistulas, or recent placement of a ventricular shunt (Swanson, 2015).

Pathophysiology

The most common route of infection is vascular dissemination from a focus of infection elsewhere. For example, organisms from the nasopharynx invade the underlying blood vessels, cross the blood-brain barrier, and multiply in the CSF. Invasion by direct extension from infections in the paranasal and mastoid sinuses is less common. Organisms also gain entry by direct implantation after penetrating wounds, skull fractures that provide an opening into the skin or sinuses, lumbar puncture or surgical procedures, anatomic abnormalities such as spina bifida, or foreign bodies such as an internal ventricular shunt or an external ventricular device. Once implanted, the organisms spread into the CSF, by which the infection spreads throughout the subarachnoid space.

The infective process is like that seen in any bacterial infection: inflammation, exudation, white blood cell accumulation, and varying degrees of tissue damage. The brain becomes hyperemic and edematous, and the entire surface of the brain is covered by a layer of purulent exudate that varies with the type of organism. For example, meningococcal exudate is most marked over the parietal, occipital, and cerebellar regions; the thick, fibrinous exudate of pneumococcal infection is confined chiefly to the surface of the brain, particularly the anterior lobes; and the exudate of streptococcal infections is similar to that of pneumococcal infections but thinner. As infection extends to the ventricles, thick pus, fibrin, or adhesions may occlude the narrow passages and obstruct the flow of CSF.

Clinical Manifestations

The clinical manifestations of acute bacterial meningitis depend to a large extent on the child's age. The type of organism, the effectiveness of therapy for antecedent illness, and whether it occurs as an isolated entity or as a complication of another illness or injury also influence the clinical manifestation (Box 27.4).

Children and Adolescents

The onset of illness may be abrupt and rapid, or develop progressively over one or several days, and may be preceded by a febrile illness. Most children with meningitis are seen with fever, chills, headache, and vomiting that are associated with or quickly followed by alterations in sensorium; however, some may present only with lethargy and irritability (Weinberg & Thompson-Stone, 2018). The child is extremely irritable and agitated and may develop seizures, photophobia, confusion, hallucinations, aggressive behavior, drowsiness, stupor, or coma.

BOX 27.4 Clinical Manifestations of Bacterial Meningitis

Children and Adolescents

Usually abrupt onset
Fever
Chills
Headache
Vomiting
Alterations in sensorium
Seizures (often the initial sign)
Irritability
Agitation
May develop the following:
- Photophobia
- Delirium
- Hallucinations
- Aggressive behavior
- Drowsiness
- Stupor
- Coma

Nuchal rigidity; may progress to opisthotonos
Positive Kernig and Brudzinski signs
Hyperactivity but variable reflex responses
Signs and symptoms peculiar to individual organisms:
- Petechial or purpuric rashes (meningococcal infection), especially when associated with a shock-like state
- Joint involvement (meningococcal or *Haemophilus influenzae* infection)
- Chronically draining ear (pneumococcal meningitis)

Infants and Young Children

Classic picture (above) rarely seen in children between 3 months and 2 years of age
Fever
Poor feeding
Vomiting
Marked irritability
Frequent seizures (often accompanied by a high-pitched cry)
Bulging fontanel
Nuchal rigidity possible
Brudzinski and Kernig signs not helpful in diagnosis
Difficult to elicit and evaluate in this age-group
Subdural empyema (*H. influenzae* infection)

Neonates

Specific Signs

Child well at birth but within a few days begins to look and behave poorly
Refuses feedings
Poor sucking ability
Vomiting or diarrhea
Poor tone
Lack of movement
Weak cry
Full, tense, and bulging fontanel may appear late in course of illness
Neck usually supple

Nonspecific Signs That May Be Present

Hypothermia or fever (depending on the infant's maturity)
Jaundice
Irritability
Drowsiness
Seizures
Respiratory irregularities or apnea
Cyanosis
Weight loss

The child resists flexion of the neck (nuchal rigidity). Kernig and Brudzinski signs are positive. Reflex responses are variable, although they show hyperactivity (see Chapter 4, Reflexes). The skin may be cold and cyanotic with poor peripheral perfusion.

Other signs and symptoms that are specific to individual organisms may appear. Petechial or purpuric rashes occur in 50% of cases and indicate a meningococcal infection (meningococcemia), especially when the eruption is associated with a septic shock–like state. Joint involvement is seen in meningococcal and *H. influenzae* infection. A chronically draining ear commonly accompanies pneumococcal meningitis. *E. coli* infection may be associated with a congenital dermal sinus that communicates with the subarachnoid space.

Infants and Young Children

Between 3 months and 2 years of age, the illness is characterized by fever or hypothermia, poor feeding, vomiting, marked irritability, restlessness, seizures, and a bulging or tense fontanel, which are often accompanied by a high-pitched cry.

Neonates

Meningitis in newborn and premature infants is extremely difficult to diagnose. The vague and nonspecific manifestations, which are characteristic of all neonatal sepsis, bear little resemblance to the findings in older children. These infants are usually well at birth but within a few days begin to appear ill. They refuse feedings, have poor sucking ability, and may vomit or have diarrhea. They display poor muscle tone and lack of movement and have a poor cry. Other nonspecific signs that may be present include hypothermia or fever (depending on the infant's maturity), jaundice, irritability, drowsiness, seizures, respiratory irregularities or apnea, cyanosis, and weight loss. The full, tense, and bulging fontanel may or may not be present until late in the course of the illness, and the neck is usually supple. Untreated, the infant's condition will decline to cardiovascular collapse, seizures, and apnea. Even with improved antibiotics and more rapid diagnosis, the prognosis of neonatal meningitis has not improved in decades, likely due to the virulence of the infectious pathogen (Gordon, Srinivasan, & Harris, 2017).

Complications

The incidence of complications from acute bacterial meningitis has been significantly reduced with early diagnosis and vigorous antimicrobial therapy. If infection extends to the ventricles, thick pus, fibrin, or adhesions may occlude the narrow passages, thereby obstructing the flow of CSF and causing obstructive hydrocephalus. Subdural effusions often occur, and thrombosis may occur in meningeal veins or venous sinuses. Destructive changes may take place in the cerebral cortex, and brain abscesses may form by direct extension of the infection or by vascular dissemination. Extension of the infection to the areas of the cranial nerves or compression necrosis from increased pressure may cause deafness, blindness, or weakness or paralysis of facial or other muscles of the head and neck.

One of the most dramatic and serious complications usually associated with meningococcal infections is meningococcal sepsis, or meningococcemia. When the onset is severe, sudden, and rapid, it is

known as the Waterhouse-Friderichsen syndrome. The syndrome is characterized by overwhelming septic shock, disseminated intravascular coagulation, massive bilateral adrenal hemorrhage, and purpura. Meningococcemia requires immediate emergency treatment, hospitalization, and intensive care because of the serious sequelae that can quickly develop (Weinberg & Thompson-Stone, 2018).

! NURSING ALERT

Any child who is ill and develops a petechial or purpural rash may have meningococcemia and must receive immediate medical attention.

Other acute complications of meningitis include SIADH (see Chapter 28), subdural effusions, seizures, cerebral edema and herniation, and hydrocephalus. Obstruction to the flow of CSF occurs during the acute phase of illness by clumping of purulent material in the drainage channels and during the chronic phase of illness by adhesive arachnoiditis or fibrotic obstruction through any of the ventricular foramina. Postmeningitic complications in neonates include ventriculitis, which results in cystic, walled-off areas of the brain with fluid accumulation and pressure.

Extension of the inflammation to cranial nerves or compression and destruction of the nerves from ICP can produce permanent impairment of vision or hearing and other nerve palsies. CN VIII damage is usually followed by permanent deafness, the most common permanent neurologic sequela of bacterial meningitis (Weinberg & Thompson-Stone, 2018). Other long-term complications include cerebral palsy, cognitive impairments, learning disorders, attention-deficit/hyperactivity disorder, and seizures.

Hemiparesis and quadriparesis may result from damage caused by arteritis or thrombosis or other mechanisms. Behavioral changes occur in some children. Evidence indicates that psychometric and behavioral defects may be a significant concomitant sign of meningitis in childhood, although it is difficult to determine the degree to which meningitis affects the intelligence of young children. Meningitis in the neonatal period is more likely to cause lifelong impairments, including moderate to severe developmental delay, blindness, deafness, and epilepsy (Swanson, 2015).

Diagnostic Evaluation

A lumbar puncture is the definitive diagnostic test. The fluid pressure is measured, and samples are obtained for culture, Gram stain, blood cell count, and determination of glucose and protein levels. The findings are usually diagnostic. Culture and sensitivity are needed to identify the causative organism. Spinal fluid pressure is usually elevated, but interpretation is often difficult when the child is crying. Sedation with fentanyl and midazolam can alleviate the child's pain and fear associated with this procedure (see Atraumatic Care box). If there is evidence or suspicion of increased ICP, a CT scan of the head may be warranted before the procedure (Weinberg & Thompson-Stone, 2018).

ATRAUMATIC CARE

Lumbar Puncture

If time permits, LMX (4% lidocaine) or EMLA cream (a eutectic mixture of lidocaine and prilocaine), both topical anesthetics, should be applied to the skin overlying L3 to L5 to reduce pain before lumbar puncture. For maximum effect, apply EMLA cream at least 1 hour or LMX 30 minutes before the procedure.

The patient generally has an elevated white blood cell count, often predominantly polymorphonuclear leukocytes. The glucose level is reduced, generally in proportion to the duration and severity of the infection. The relationship between the CSF glucose and serum glucose levels is important in evaluating the glucose content of CSF; therefore a serum glucose sample is drawn approximately a half-hour before the lumbar puncture. Protein concentration is usually increased.

Blood culture is advisable for all children suspected of having meningitis if antibiotics are started before obtaining CSF. Blood culture will occasionally be positive when CSF culture is negative. Nose and throat cultures may provide helpful information in some cases.

Therapeutic Management

Acute bacterial meningitis is a medical emergency that requires early recognition and immediate therapy to prevent death and avoid residual disabilities. The initial therapeutic management includes the following:

- Isolation precautions
- Initiation of antimicrobial therapy
- Maintenance of hydration
- Maintenance of ventilation
- Reduction of increased ICP
- Management of systemic shock
- Control of seizures
- Control of temperature
- Treatment of complications

The child is usually moved to an intensive care unit for close observation. An IV infusion is started to facilitate administration of antimicrobial agents, fluids, antiepileptic drugs, and blood, if needed. The child is placed in respiratory isolation.

Drugs

Until the causative organism is identified, empiric therapy is administered. After identification of the organism, antimicrobial agents are adjusted accordingly. Signs of gastrointestinal hemorrhage or secondary infection may complicate steroid administration. Antibiotic treatment with cephalosporins demonstrates superiority for promptly sterilizing the CSF and reducing the incidence of severe hearing impairment. With increasing prevalence of antibiotic-resistant *S. pneumoniae,* vancomycin should be given until antibiotic susceptibility test results are available.

Nonspecific Measures

Maintaining hydration is a prime concern. The patient's condition determines whether IV fluids are needed and the type and amount of fluid. The optimum hydration involves correction of any fluid deficits and electrolyte abnormalities, followed by fluid restriction until normal serum sodium levels and no signs of increased ICP are present. If needed, measures to decrease ICP are implemented (see earlier in the chapter); however, long-term fluid restriction is not the standard of care because a lack of fluid volume can reduce blood pressure and CPP, causing CNS ischemia (Janowski & Hunstad, 2020c).

Complications, such as subdural effusion in infants and disseminated intravascular coagulation syndrome, are treated appropriately. Shock is managed by restoration of circulating blood volume and maintenance of electrolyte balance. Seizures can occur during the first few days of treatment. These are controlled with the appropriate antiepileptic drug.

Hearing loss is common. The patient should undergo auditory evaluation shortly after discharge so that audiology and speech and communication therapies can begin as soon as possible.

Lumbar puncture is carried out as needed to determine the effectiveness of therapy. The patient is evaluated neurologically during the convalescent period.

Prognosis

Less than 10% of cases of bacterial meningitis are fatal; the highest mortality rate is seen in pneumococcal meningitis and in infants under the age of 6 months (Janowski & Hunstad, 2020c). Prognosis is dependent in large part on the length of time between onset of illness and initiation of antibiotic therapy, rapidity of diagnosis after onset, type of organism, prolonged or complicated seizures, low CSF glucose concentration, and adequacy of therapy. Up to half of those who recover from meningitis will have some neurodevelopmental sequelae ranging from mild behavioral and learning problems to profound hearing impairment, intractable epilepsy, and significant intellectual disability (Janowski & Hunstad, 2020c).

DRUG ALERT

Antibiotic Use in Meningitis

A major priority of nursing care of a child suspected of having meningitis is to administer antibiotics as soon as they are ordered. The child is placed on respiratory isolation for at least 24 hours after initiation of antimicrobial therapy.

The sequelae of bacterial meningitis occur most often when the disease occurs in the first 2 months of life and least often in children with meningococcal meningitis. The residual deficits in infants are primarily a result of communicating hydrocephalus and the greater effects of cerebritis on the immature brain. In older children the residual effects are related to the inflammatory process itself or result from vasculitis associated with the disease. Bacterial meningitis continues to cause substantial morbidity in infants and children.

Prevention

Vaccination is the foundation of prevention of CNS infections. Vaccines are available for pneumococci; types A, C, Y, and W-135 meningococci; and Hib. Routine meningococcal conjugate vaccination of children is recommended at age 11 to 12 years, with a booster at 16 years, but can be given to children 2 months to 10 years of age if they are considered at high risk (e.g., asplenia, foreign travel to high-risk areas, or present during outbreaks). Routine vaccinations for Hib and pneumococcal conjugate vaccines are recommended for all children beginning at 2 months of age (see Chapter 6, Immunizations).

Nursing Care Management

Nurses should take the necessary precautions to protect themselves and others from possible infection. Teach parents proper hand washing technique and remind them as needed.

Keep the room as quiet as possible and environmental stimuli at a minimum, as most children with meningitis are sensitive to noise, bright lights, and other external stimuli. Help the family limit the number and frequency of visitors until the child is and feels better. Most children are more comfortable without a pillow under their head but with the head of the bed slightly elevated. Use pillows alongside a child in a side-lying position and between the child's knees for comfort in cases of nuchal rigidity. Avoid actions that cause pain or increase discomfort, such as lifting the child's head. Evaluating the child for pain and implementing appropriate relief measures are important ongoing interventions. Measures are used to ensure safety because the child is often restless, disoriented, and subject to seizures. Prevention of falls is essential.

The nursing care of the child with meningitis is determined by the child's symptoms and treatment (see Box 27.4). Observation of vital signs, neurologic signs, LOC, urinary output, and other pertinent data is carried out at frequent intervals. The child who is unconscious is managed as described previously, and all children are observed carefully for signs of the complications just described, especially increased ICP, shock, and respiratory distress. Frequent assessment of the open fontanels is needed in the infant because subdural effusions and obstructive hydrocephalus can develop as a complication of meningitis.

Administration of fluids and nourishment is determined by the child's status. The child who is not alert and oriented is given nothing by mouth. Other children are allowed clear liquids initially and, if tolerated, progress to a diet suitable for their age. Careful monitoring and recording of intake and output are needed to determine deviations that might indicate impending shock or increasing fluid accumulation, such as cerebral edema or subdural effusion.

One of the most challenging issues in the nursing care of children with meningitis is maintaining IV infusion for the length of time needed to provide adequate antimicrobial therapy (usually 10 days). Because continuous IV fluids are usually not necessary, an intermittent infusion device is used. In some cases children who are recovering uneventfully are sent home with the device, and the parents are taught IV drug administration (see Quality Patient Outcomes box).

QUALITY PATIENT OUTCOMES: Bacterial Meningitis

- Early recognition of signs and symptoms of meningitis
- Antibiotics administered as soon as diagnosis is established
- Cerebral edema prevented
- Exposure prevented by early isolation
- Side effects managed
- Neurologic sequelae prevented

Family Support

The sudden nature of the illness makes emotional support of the child and parents extremely important (see Family-Centered Care box). Parents are upset and concerned about their child's condition and often feel guilty for not having suspected the seriousness of the illness sooner. They need reassurance that the natural onset of meningitis is sudden and that they acted responsibly in seeking medical assistance when they did. The nurse encourages the parents to openly discuss their feelings to minimize blame and guilt. Some parents will benefit from referral to a hospital chaplain, social worker, psychologist, or psychiatrist. The nurse keeps parents informed of the child's progress and of all procedures, results, and treatments. In the event that the child's condition worsens, the parents need the same psychologic care as other parents facing the possible death of their child (see Chapter 17).

FAMILY-CENTERED CARE

Preventing Bacterial Meningitis

With immunization schedules calling for administration of *Haemophilus influenzae* type b vaccine and pneumococcal conjugate vaccine to infants at 2 months of age, encourage parents to bring their child to a health facility so that the full series of inoculations is completed. Given the 10% mortality rate associated with bacterial meningitis, early immunization can help families avoid the tragic death or permanent disability of a child. Nurses play a significant role in educating families on preventive measures, such as having children immunized on schedule.

NONBACTERIAL (ASEPTIC) MENINGITIS

The term *aseptic meningitis* refers to the onset of meningeal symptoms, fever, and pleocytosis without bacterial growth from CSF cultures. Aseptic meningitis is caused by many different viruses, including arbovirus, enterovirus, herpes simplex virus, cytomegalovirus, and human immunodeficiency virus. Enterovirus is the most common cause of aseptic meningitis (Janowski & Hunstad, 2020b).The onset may be abrupt or gradual, and many of the presenting signs and symptoms are the same as for bacterial meningitis, including headache, fever, photophobia, and nuchal rigidity.

Diagnosis is based on clinical features and CSF findings. Table 27.2 lists variations in CSF values in bacterial and viral meningitis. It is important to differentiate this usually self-limiting disorder from the more serious forms of meningitis.

Treatment is primarily symptomatic, such as acetaminophen for headache and muscle pain, maintenance of hydration, and positioning for comfort. Until a definitive diagnosis is made, antimicrobial agents may be administered and isolation enforced as a precaution against the possibility that the disease might be of bacterial origin. Nursing care is similar to the care of the child with bacterial meningitis. The course of aseptic meningitis is usually much shorter and typically without significant complications.

TUBERCULOUS MENINGITIS

Tuberculous meningitis must be considered in children who have traveled to or lived in developing countries or who live with or are immigrants from developing countries. In 2015 the incidence of tuberculous meningitis in the United States increased for the first time in more than 2 decades (Smith, Pratt, Trieu, et al., 2017). Tuberculous meningitis is more likely to be disseminated (including CNS involvement) in very young or immunosuppressed children.

Ischemic infarction can occur with tuberculous meningitis. The most common clinical findings are meningeal signs, fever, altered consciousness, CN involvement, seizures, and focal neurologic deficit.

Early diagnosis of tuberculous meningitis in the child can significantly reduce the disability caused by hydrocephalus, a common complication of this type of meningitis. Nursing care is similar to the care of the child with bacterial meningitis and involves administration of medications, support of the child, control of pain, and neurologic monitoring.

BRAIN ABSCESS

Intracerebral abscesses form when pyogenic organisms gain access to neural tissue by way of the bloodstream from foci of infection or from direct inoculation of organisms from infections, penetrating trauma, or surgical procedures. Chronic ear infection, mastoiditis, sinusitis, and congenital heart disease are the most common predisposing factors for children with brain abscesses. The majority (70%) of brain abscesses are caused by aerobic and anaerobic streptococci (Janowski & Hunstad, 2020a). In neonates, *Citrobacter* is most common, and fungi are more common in immunocompromised children (Janowski & Hunstad, 2020a).

The most common sites of intracerebral abscesses are the parietal, temporal, and frontal lobes. Early signs of the disease are vague; however, the most common symptom is a severe headache. As the inflammatory process proceeds, symptoms intensify and include vomiting, lethargy, fever, seizures, papilledema, focal neurologic signs (hemiparesis), and progression to coma (Janowski & Hunstad, 2020a). Because mortality rates from brain abscesses may exceed 20%, prompt diagnosis and treatment are critical (Janowski & Hunstad, 2020a). Successful management consists of surgical drainage and antibiotic therapy. Surgical drainage is necessary if the mass is greater than 2 cm in diameter or there are signs of increased ICP. Where possible, the source of the infection is eradicated. Children may experience epilepsy, hemiparesis, cranial nerve abnormalities, and behavior or learning problems as long-term complications (Janowski & Hunstad, 2020a).

ENCEPHALITIS

Encephalitis is an inflammatory process of the CNS that is caused by a variety of organisms, including bacteria, spirochetes, fungi, protozoa, helminths, and viruses. Most infections are associated with viruses, and this discussion is limited to those agents.

Etiology

Encephalitis can occur as a result of direct invasion of the CNS by a virus or postinfectious involvement of the CNS after a viral disease. Enteroviruses are the most common etiology (Janowski & Hunstad, 2020b); however, the specific type of encephalitis often may not be identified. The cause of more than half of the cases reported in the United States is unknown.

Autoimmune encephalitis syndromes are a recently recognized cause of new-onset neurologic deficits in children (Longoni, Levy, & Yeh, 2016). In some children, antibodies are identified, and there is a small group (<20%) whose etiology is a tumor, particularly ovarian teratoma, but the majority of children will not have either of these conditions (Dubey, Sawhney, Greenberg, et al., 2015). Diagnosis is usually based on clinical symptoms, which can be neurologic, psychiatric, or both (Scheer & John, 2016). Neurologic symptoms include seizures, encephalopathy, and movement disorders (Dale, Gorman, & Lim, 2017). Behavioral changes, hallucinations, anxiety, and aggression are some of the more commonly seen psychiatric manifestations (Scheer & John, 2016).

TABLE 27.2 Variation of Cerebrospinal Fluid Analysis in Bacterial and Viral Meningitis

Manifestations	Bacterial[a]	Viral
White blood cell count	Elevated; increased neutrophils	Slightly elevated; increased lymphocytes
Protein content	Elevated	Normal or slightly increased
Glucose content	Decreased	Normal
Gram stain; bacteria culture	Positive	Negative
Color	Turbid or cloudy	Clear or slightly cloudy
Opening pressure	Elevated	Normal

[a]Results may vary in the neonate.

Herpes simplex encephalitis is an uncommon disease, but 30% of cases involve children. The initial clinical findings are nonspecific (e.g., fever, altered mental status), but most cases evolve to demonstrate focal neurologic signs and symptoms. Children may experience focal seizures. The CSF is abnormal in most cases. Because of a rise in the number of children with herpes simplex encephalitis, suspected cases require prompt attention, especially because the diagnosis can be difficult. CSF polymerase chain reaction (PCR) testing can confirm the clinical diagnosis rapidly. The early use of IV acyclovir reduces mortality and morbidity rates. Empiric therapy with acyclovir is given before precise virologic diagnosis has been established.

The multiple causes of viral encephalitis make diagnosis difficult. Most are those involved with arthropod vectors (e.g., togaviruses, bunyaviruses) and those associated with hemorrhagic fevers (e.g., arenaviruses, filoviruses, hantaviruses). In the United States, the vector reservoir for most agents pathogenic for humans is the mosquito (St. Louis or West Nile encephalitis); therefore most cases of encephalitis appear during the hot summer months and subside during the autumn.

Clinical Manifestations

The clinical features of encephalitis are similar regardless of the agent involved. Manifestations can range from a mild benign form that resembles aseptic meningitis, lasts a few days, and is followed by rapid and complete recovery, to a rapidly progressing encephalitis with severe CNS involvement. The onset may be sudden or may be gradual with malaise, fever, headache, dizziness, apathy, nuchal rigidity, nausea and vomiting, ataxia, tremors, hyperactivity, and speech difficulties (Box 27.5). In severe cases the patient has high fever, stupor, seizures, disorientation, spasticity, and coma that may proceed to death. Ocular palsies and paralysis also may occur.

Diagnostic Evaluation

The diagnosis is made based on clinical findings and, where possible, identification of the specific virus. Early in the course of encephalitis, CT scan results may be normal. Later, hemorrhagic areas in the frontotemporal region may be seen. Arboviruses are rarely detected in the blood or spinal fluid, but viruses of herpes, mumps, measles, and enteroviruses may be found in the CSF. Serologic testing may be required. The first blood sample should be drawn as soon as possible after onset, with the second sample drawn 2 or 3 weeks later.

Therapeutic Management

Patients suspected of having encephalitis are hospitalized promptly for observation, including ICP monitoring. In autoimmune encephalitis rapid initiation of immunotherapy, including corticosteroids, plasmapheresis, and IV immunoglobulin, improves outcomes. Herpes simplex virus encephalitis is the only viral encephalitis that has specific treatment available. In other cases, treatment is primarily supportive and includes conscientious nursing care, control of cerebral manifestations, and adequate nutrition and hydration, with observations and management as for other cerebral disorders.

Prognosis

Viral encephalitis can cause devastating neurologic injury. The prognosis for the child with encephalitis depends on the child's age, the type of encephalitis, and residual neurologic damage. Very young children (younger than 2 years of age) with viral encephalitis have an increased risk of neurologic disability, including learning difficulties and epilepsy. About 80% of patients with autoimmune encephalitis make a full or nearly full recovery (Longoni et al., 2016).

Follow-up care with periodic reevaluation and rehabilitation is important for patients who develop residual effects of encephalitis.

BOX 27.5 Clinical Manifestations of Encephalitis

Onset: Sudden or Gradual

Malaise
Fever
Headache
Dizziness
Apathy
Lethargy
Nuchal rigidity
Ataxia
Tremors
Hyperactivity
Speech difficulties: mutism
Altered mental status

Severe Cases

High fever
Stupor
Seizures
Disorientation
Spasticity
Coma (may proceed to death)
Ocular palsies
Paralysis

Nursing Care Management

Nursing care of the child with encephalitis is the same as for any unconscious child and for the child with meningitis. Additional nursing interventions include observation for deterioration in consciousness. Isolation of the child is not necessary; however, always use good hand washing technique. A main focus of nursing management is the control of rapidly rising ICP. Neurologic monitoring, administration of medications, and support of the child and parents are the major aspects of care (see Quality Patient Outcomes box).

QUALITY PATIENT OUTCOMES: Encephalitis

- Early recognition of signs and symptoms
- Cerebral edema prevented
- Side effects managed
- Neurologic sequelae prevented

RABIES

Rabies is an acute infection of the nervous system caused by a virus that is almost invariably fatal if left untreated. It is transmitted to humans by the saliva of an infected mammal introduced through a bite or skin abrasion. After entry into a new host, the virus multiplies in muscle cells and is spread through neural pathways without stimulating a protective host immune response.

Through dog vaccination, rabies from dog bites has been eliminated in the United States (World Health Organization, 2017). Carnivorous wild animals (e.g., raccoons, skunks, bats, foxes) are the animals most often infected with rabies and the cause of most indigenous cases of human rabies in the United States (Singh, Singh, Cherian, et al., 2017).

The circumstances of a biting incident are important. An unprovoked attack is more likely than a provoked attack to indicate a rabid animal. Bites inflicted on a child attempting to feed or handle an

apparently healthy animal can generally be regarded as provoked. Any child bitten by a wild animal is assumed to be exposed to rabies.

NURSING ALERT

Unusual behavior in an animal is cause for suspicion; children should be warned to beware of wild animals that appear to be friendly.

Although rabies is common among wildlife species, human rabies is rarely acquired. The highest incidence of rabies occurs in children under age 15 years. The incubation period usually ranges from 1 to 3 months but may be as short as 5 days or longer than 6 months (Willoughby, 2020). Modern-day prophylaxis is nearly 100% successful. Only 10% to 15% of persons bitten develop the disease, but once symptoms are present, rabies progresses to a fatal outcome. In the United States, human fatalities associated with rabies occur in people who fail to seek medical attention, usually because they are unaware of their exposure.

The disease is characterized by a period of nonspecific flulike symptoms, including general malaise, anorexia, fever, and sore throat, followed by a phase of excitement that features hypersensitivity and increased reaction to external stimuli, seizures, hallucinations, hypersalivation, and choking. Attempts at swallowing may cause spasms of respiratory muscles so severe that they produce apnea, cyanosis, and anoxia—the characteristics from which the term *hydrophobia* was derived.

Diagnosis is made on the basis of history and clinical features. Hydrophobia is a cardinal sign of rabies. The diagnosis is confirmed by skin biopsy. Antibodies maybe detected 7 to 8 days after the onset of clinical symptoms (Crowcroft & Thampi, 2015).

Therapeutic Management

Treatment is of little avail once symptoms appear, but the long incubation period allows time for the induction of active and passive immunity before the onset of illness. Two types of immunizing products are available for use in humans: (1) the inactivated rabies vaccines, which induce an active immune response; and (2) the globulins, which contain preformed antibodies. The two types of products should be used concurrently for rabies postexposure treatment when prophylaxis is indicated.

The current therapy for a rabid animal bite consists of three steps: (1) thorough cleansing of the wound with soap and water (suturing should be avoided whenever possible); (2) administration of rabies vaccine; and (3) administration of rabies immunoglobulin. The rabies vaccine and immunoglobulin should be initiated as soon as possible after exposure. The rabies vaccine consists of four doses administered intramuscularly at days 0, 3, 7, and 14 but can be stopped if the animal remains healthy throughout the 10-day observation period or is proved to be negative for rabies by a reliable laboratory (Crowcroft & Thampi, 2015). Rabies immunoglobulin is administered locally at the wound and provides passive antibodies at the site of exposure. Rabies immunoglobulin is given once within 7 days after the first vaccine dose before the child develops an active immune response (Crowcroft & Thampi, 2015).

Nursing Care Management

Parents and children are frightened by the urgency and seriousness of the situation. They need anticipatory guidance for the therapy and support and reassurance regarding the efficacy of the preventive measures for this dreaded disease. The vaccine is well tolerated by children, although they need preparation for the series of injections. Mass immunization is unnecessary and unlikely to be implemented. In areas in which rabies is rare, the schedule given is sufficient. However, certain circumstances may warrant preexposure vaccination, such as when a child is being taken to an area of the world where rabies in stray dogs is still a problem.

REYE SYNDROME

Reye syndrome (RS) is a disorder defined as a metabolic encephalopathy associated with other characteristic organ involvement. It is characterized by fever, profoundly impaired consciousness, and disordered hepatic function.

The etiology of RS is not well understood, but most cases follow a common viral illness, typically influenza or varicella. RS is a condition characterized pathologically by cerebral edema and fatty changes of the liver. The onset of RS is notable for profuse effortless vomiting and lethargy that quickly progresses to neurologic impairment, including delirium, seizures, and coma, and can ultimately lead to increased ICP, herniation, and death (Ibrahim & Balistreri, 2016). The cause of RS is a mitochondrial insult induced by various viruses, drugs, exogenous toxins, and genetic factors. Elevated serum ammonia levels tend to correlate with the clinical manifestations and prognosis.

Definitive diagnosis is established by liver biopsy. The staging criteria for RS are based on liver dysfunction and on neurologic signs that range from lethargy to coma. As a result of improved diagnostic techniques, children who in the past would have been diagnosed with RS are now diagnosed with other illnesses such as viral or inborn metabolic errors affecting organic acid, ammonia, and carbohydrate metabolism. Cases of unrecognized, drug-induced encephalopathy by antiemetics given to children during viral illnesses have symptoms similar to those of RS.

The potential association between aspirin therapy for the treatment of fever in children with varicella or influenza and the development of RS precludes its use in these patients. However, by the time the Food and Drug Administration required aspirin product labeling in 1986, most of the decline in RS incidence had already occurred.

Nursing Care Management

The most important aspect of successful management of the child with RS is early diagnosis and aggressive therapy. Rapid progression to coma and high peak ammonia concentrations are associated with a more serious prognosis. Cerebral edema with increased ICP represents the most immediate threat to life.

Care and observations are implemented as for any child with an altered state of consciousness (see earlier in the chapter) and increasing ICP. Accurate and frequent monitoring of intake and output is essential for adjusting fluid volumes to prevent both dehydration and cerebral edema. Because of related liver dysfunction, monitor laboratory studies to determine impaired coagulation, such as prolonged bleeding time.

Keep the parents of children with RS informed of the child's progress and explain diagnostic procedures and therapeutic management. Recovery from RS is rapid and usually without sequelae if the diagnosis is determined early and therapy is initiated promptly. Patients who survive have full liver function recovery (Ibrahim & Balistreri, 2020).

DRUG ALERT

Salicylates

Families need to be aware that salicylates, the alleged offending ingredient in aspirin, are contained in other products (e.g., Pepto-Bismol). They should refrain from administering any product for influenza-like symptoms without first checking the label for "hidden" salicylates.

SEIZURES AND EPILEPSY

A seizure is a "transient occurrence of signs and/or symptoms due to abnormal excessive and synchronous neuronal activity in the brain" (Fisher, Acevedo, Arzimanoglou, et al., 2014). Seizures are the most common pediatric neurologic disorder. About 4% to 10% of children will have at least one seizure in the first 16 years of life (Mikati & Tchapyjnikov, 2020). The manifestation of seizures depends on the region of the brain in which they originate and may include unconsciousness or altered consciousness; involuntary movements; and changes in perception, behaviors, sensations, and/or posture. Seizures are a symptom of an underlying disease process. They are individual events. Potential causes include infections, intracranial lesions or hemorrhage, metabolic disorders, trauma, brain malformations, genetic disorders, or toxic ingestion (see Nursing Care Guidelines box).

NURSING CARE GUIDELINES

Terminology for Seizures

Many words are used synonymously with the terms *seizure, epilepsy,* and *seizure disorder.* Epilepsy used to belong to the medical discipline of psychiatry, and therefore words such as *attacks* and *fits* are sometimes used to describe seizure events. These words, however, still create images of medieval superstitions, evil spirits, and the horrors of mental institutions. Parents are often hesitant to inform caregivers and the school that their child has a seizure disorder or epilepsy for fear of prejudice and misunderstandings. When working with families, health professionals should consider the words they use to discuss epilepsy and seizures. Correct terminology can help lessen the stigma and fear often associated with epilepsy and seizures.

The words *convulsion, convulsive disorder,* and *anticonvulsive drugs* are often used to cover all seizure types and antiepileptic drugs. However, the word *convulsion* conjures up images of a raving, wild person who is out of control and possibly dangerous. Therefore referring to all seizures as convulsions is questionable because most seizures are not convulsive in nature. In this chapter the word *event, episode,* or *experience* is used to describe a seizure; likewise, medications are referred to as *antiepileptic drugs.*

Epilepsy is defined as two or more unprovoked seizures more than 24 hours apart and can be caused by a variety of pathologic processes in the brain. A single seizure is not classified as epilepsy and is generally not treated with long-term antiepileptic drugs. Some seizures may result from an acute medical or neurologic illness and cease after the illness is treated. In other cases, children may have one or more seizures without the cause ever being found.

When a child has had a seizure, it is important to classify the seizure according to the International Classification of Epileptic Seizures. Optimal treatment and prognosis require an accurate diagnosis and a determination of the cause whenever possible.

EPILEPSY

The clinical definition of epilepsy was recently updated by the International League Against Epilepsy (ILAE). "Epilepsy is a disease of the brain defined by the following conditions: (1) at least two unprovoked seizures occurring more than 24 hours apart OR (2) one unprovoked seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures occurring over the next 10 years" (Fisher et al., 2014). Seizures are a symptom of an underlying disease process. A single seizure event should be classified as epilepsy only if it meets criteria in number 2. Single seizures in children are generally not treated with long-term antiepileptic drugs. Some seizures may result from an acute medical or neurologic illness and cease once the illness is treated. In other cases, children may have a single seizure without the cause ever being known.

Etiology

Seizures in children have many different causes (Box 27.6). Seizures had been classified according to type and etiology. The ILAE 2017 classification of seizures focuses on location of onset rather than etiology: focal

BOX 27.6 Etiology of Seizures in Children

Nonrecurrent (Acute)

Febrile episodes
Intracranial infection
Intracranial hemorrhage
Space-occupying lesions (cyst, tumor)
Acute cerebral edema
Anoxia
Toxins
Drugs
Tetanus
Lead encephalopathy
Shigella and *Salmonella* organisms
Metabolic alterations:
- Hypocalcemia
- Hypoglycemia
- Hyponatremia or hypernatremia
- Hypomagnesemia
- Alkalosis
- Disorders of amino acid metabolism
- Deficiency states
- Hyperbilirubinemia

Recurrent (Chronic)

Idiopathic epilepsy
Epilepsy secondary to the following:
- Trauma
- Hemorrhage
- Anoxia
- Infections
- Toxins
- Degenerative phenomena
- Congenital defects
- Parasitic brain disease
- Hypoglycemia injury

Epilepsy—sensory stimulus
Epilepsy-stimulating states
- Narcolepsy and catalepsy
- Psychogenic
- Tetany from hypocalcemia, alkalosis

Hypoglycemic states
- Hyperinsulinism
- Hypopituitarism
- Adrenocortical insufficiency
- Hepatic disorders

Uremia
Allergy
Cardiovascular dysfunction or syncopal episodes
Migraine

(formerly known as partial), generalized, or unknown and unclassified (Fisher, Cross, French, et al., 2017). Focal seizures are divided into those with preserved awareness and those with impaired awareness and those with or without motor manifestations. Generalized onset seizures are also divided by their motor symptoms: tonic for the stiffening movements and clonic for the rhythmic jerking that may accompany tonic stiffening, and absence of nonmotor seizures. Unknown onset seizures are classified using the same motor criteria as generalized seizures.

The causes of seizures in children are many. Acute reactive seizures are caused by an acute condition such as electrolyte imbalance, acute stroke, head trauma, meningitis, or encephalitis. These seizures may continue and become epilepsy depending on the ability to treat the underlying condition. New-onset seizures may be the initial presentation of a child with a brain malformation. More than 100 genes have been found to cause epilepsy syndromes in children (Mikati & Tchapyjnikov, 2020). Many, but not all, of these genetic orders cause intellectual disability in addition to epilepsy. The proportion of seizures and epilepsy for which we have no identifiable cause becomes smaller each year as neuroimaging and genetic testing improve. Those children who do not have an identifiable cause for their seizures and epilepsy have a better prognosis for eventual resolution of their epilepsy.

Incidence

Epilepsy and seizures affect about 3 million Americans; it is the most common neurologic condition of children. The prevalence of epilepsy in children is consistently higher than the incidence and ranges from 3.2 to 5.5 in 1000 (Camfield & Camfield, 2015). The onset of epilepsy in children is highest during the first few months of life. The causative factors associated with childhood seizures are often linked to the child's age. In infants the most common causes are congenital brain malformations and genetic disorders, including metabolic disorders. Infections and epilepsy of unknown etiology are common causes of seizures in childhood. Children with intellectual disability, cerebral palsy, and/or autism spectrum disorder are more likely to have epilepsy than their typically developing peers.

Pathophysiology

Regardless of the etiologic factor or type of seizure, the basic mechanism is the same. Abnormal electrical discharges (1) may arise from the simultaneous activation of neurons in both hemispheres of the brain (generalized seizures); (2) may be restricted to one area of the cerebral cortex, producing manifestations characteristic of that particular anatomic focus; or (3) may begin in a localized area of the cortex as a focal seizure and spread to other portions of the brain and, if sufficiently extensive, produce generalized seizure activity.

A seizure occurs when there is sudden excessive excitation and loss of inhibition within neuronal circuits, allowing the circuits to amplify their discharges simultaneously. These discharges occur in response to the activity of sodium, potassium, calcium, and chloride ion channels. Normally these discharges are restrained by inhibitory mechanisms. In response to physiologic stimuli, such as brain injury or infection, genetic abnormalities, severe hypoglycemia, electrolyte imbalance, sleep deprivation, and toxic exposures, these abnormal neuronal discharges can spread to nearby cortex and subcortical structures. Primary generalized seizures begin with abnormal discharges in both hemispheres, which can involve connections between the thalamus and neocortex. On the basis of these characteristic neuronal discharges (manifested as stereotypical symptoms observed and reported during seizures and/or as recorded by the EEG), seizures are designated as focal, generalized, and unclassified epileptic seizures.

Seizure Classification and Clinical Manifestations

There are many different types of seizures, and each has unique clinical manifestations (Box 27.7). Seizures are classified into two major categories: (1) focal seizures (previously referred to as partial seizures), which have a local onset and involve a relatively small location in the brain; and (2) generalized seizures, which involve both hemispheres of the brain and are without local onset.

Focal Seizures (Formerly Known as Partial Seizures)

Focal seizures may arise from any area of the cerebral cortex, but the frontal, temporal, and parietal lobes are most often affected and are characterized by localized motor symptoms; somatosensory, psychic, or autonomic symptoms; or a combination of these. The abnormal EEG discharges begin unilaterally and are evident as focal spikes or sharp waves. Focal seizures are subdivided into three types:

Focal seizures without impaired awareness (formerly simple partial seizures)—Sensory symptoms that occur in one part of the brain and cause no alteration of consciousness, often referred to as aura. Sometimes accompanied by motor movements.

Focal seizures with impaired awareness (formerly complex partial seizures)—Sensory and/or motor symptoms that result in a change or loss of consciousness.

Focal to bilateral tonic-clonic seizures (formerly simple or complex seizures secondarily generalized)—Focal seizures with or without awareness that evolve into generalized seizures, usually a tonic-clonic event.

Focal seizures exhibit manifestations related to where they occur in the brain. A clear description of the seizure (***ictal state***) by an eyewitness is a valuable aid in localizing the brain area involved. Asking the child if he or she could hear, remember, and respond during the event is also helpful for localization. The initial event may provide the best clue for assessing the type of seizure and its localization. Correctly localizing the area of the brain involved with the seizure event is crucial for diagnostic and therapeutic reasons because many antiepileptic drugs are specific for each type of seizure.

In addition to the initial event, the circumstances that precipitated the episode are important. Identifying and eliminating triggering factors may be the only treatment needed. The ***postictal state*** (the period after a seizure) may be varied. The child may be drowsy, be uncoordinated, have transient aphasia or confusion, and display some sensory or motor impairment. Document neurologic changes. Weakness, hypotonia, or inactivity of a body part may indicate an epileptogenic focus in the corresponding contralateral cortical region.

Focal seizures without impaired awareness. Focal seizures with motor signs originate from the primary motor cortex, located in the temporal lobe, which is the area of the brain that controls muscle movement. They are the most frequent type of focal seizure. The simplest form of focal seizures with motor signs is ***clonus***, the rhythmic alternating contraction and relaxation of muscle groups.

Eye movements provide clues to the focus or origin of the seizure. Discharge in the cortex of one hemisphere tends to cause the eyes to deviate to the opposite side. Bilateral discharges tend to cause the eyes to move upward or straight ahead. While deviated, the eyes may rhythmically twitch.

Focal seizures with sensory symptoms are usually described as numbness, tingling, or pins and needles. This may be the only symptom of a seizure, or it may spread to involve an adjacent sensory cortex or motor cortex. Auditory seizures may manifest as sounds becoming painfully loud, humming, buzzing, or hissing. Visual seizures typically manifest as micropsia, macropsia, or flashes of light or colors. Focal seizures with autonomic symptoms may consist of feelings of nausea or epigastric rising. Flushing or pallor, sweating, or pupil dilation can

BOX 27.7 Classification and Clinical Manifestations of Partial and Generalized Seizures

Partial Seizures

Simple Partial Seizures With Motor Signs

Characterized by the following:

- Localized motor symptoms
- Somatosensory, psychic, autonomic symptoms
- Abnormal discharges remaining unilateral

Manifestations:

- Aversive seizure (most common motor seizure in children)—Eye or eyes and head turn away from the side of the focus; awareness of movement or loss of consciousness
- Rolandic (Sylvan) seizure—Tonic-clonic movements involving the face, salivation, arrested speech; most common during sleep
- Jacksonian march (rare in children)—Orderly, sequential progression of clonic movements beginning in a foot, hand, or face and moving, or "marching," to adjacent body parts

Simple Partial Seizures With Sensory Signs

Characterized by various sensations, including:

- Numbness, tingling, prickling, paresthesia, or pain originating in one area (e.g., face or extremities) and spreading to other parts of the body
- Visual sensations or formed images
- Motor phenomena such as posturing or hypertonia

Focal Seizures With Impaired Awareness

Observed more often in children from 3 years of age through adolescence

Characterized by the following:

- Period of altered behavior
- Amnesia for event (no recollection of behavior)
- Inability to respond to environment
- Impaired consciousness during event
- Drowsiness or sleep usually following seizure
- Confusion and amnesia possibly prolonged
- Complex sensory phenomena (aura)—Most frequent sensation is strange feeling in the pit of the stomach that rises toward the throat and is often accompanied by odd or unpleasant odors or tastes, complex auditory or visual hallucinations, ill-defined feelings of elation or strangeness (e.g., déjà vu, a feeling of familiarity in a strange environment), strong feelings of fear and anxiety, distorted sense of time and self, and in small children emission of a cry or attempt to run for help

Patterns of motor behavior:

- Stereotypic
- Similar with each subsequent seizure
- May suddenly cease activity, appear dazed, stare into space, become confused and apathetic, and become limp or stiff or display some form of posturing
- May be confused
- May perform purposeless, complicated activities in a repetitive manner (automatisms), such as walking, running, kicking, laughing, or speaking incoherently, most often followed by postictal confusion or sleep; may exhibit oropharyngeal activities, such as smacking, chewing, drooling, swallowing, and nausea or abdominal pain followed by stiffness, a fall, and postictal sleep; rarely manifests actions such as rage or temper tantrums; aggressive acts uncommon during seizure

Generalized Seizures

Tonic-Clonic Seizures (Formerly Known as Grand Mal)

Most common and most dramatic of all seizure manifestations

Occur without warning

Tonic phase lasts approximately 10 to 20 seconds

Manifestations:

- Eyes roll upward
- Immediate loss of consciousness
- If standing, falls to floor or ground
- Stiffens in generalized, symmetric tonic contraction of entire body musculature
- Arms usually flexed
- Legs, head, and neck extended
- May utter a peculiar piercing cry
- Apneic, may become cyanotic
- Increased salivation and loss of swallowing reflex

Clonic phase: lasts about 30 seconds but can vary from only a few seconds to a half-hour or longer

Manifestations:

- Violent jerking movements as the trunk and extremities undergo rhythmic contraction and relaxation
- May foam at the mouth
- May be incontinent of urine and feces

As event ends, movements less intense, occurring at longer intervals, then ceasing entirely

Status epilepticus—Series of seizures at intervals too brief to allow the child to regain consciousness between the time one event ends and the next begins:

- Requires emergency intervention
- Can lead to exhaustion, respiratory failure, and death

Postictal state:

- Appears to relax
- May remain semiconscious and difficult to arouse
- May awaken in a few minutes
- Remains confused for several hours
- Poor coordination
- Mild impairment of fine motor movements
- May have visual and speech difficulties
- May vomit or complain of severe headache
- When left alone, usually sleeps for several hours
- On awakening is fully conscious
- Usually feels tired and complains of sore muscles and headache
- No recollection of entire event

Absence Seizures (Formerly Called Petit Mal)

Characterized by the following:

- Onset usually between 4 and 12 years of age
- More common in girls than in boys
- Usually cease at puberty
- Brief loss of consciousness
- Minimum or no alteration in muscle tone
- May go unrecognized because of little change in child's behavior
- Abrupt onset; suddenly develops 20 or more attacks daily
- Event often mistaken for inattentiveness or daydreaming
- Events possibly precipitated by hyperventilation, hypoglycemia, stresses (emotional and physiologic), fatigue, or sleeplessness

Manifestations:

- Brief loss of consciousness
- Appear without warning or aura
- Usually last about 5 to 10 seconds
- Slight loss of muscle tone may cause child to drop objects
- Ability to maintain postural control; seldom falls
- Minor movements such as lip smacking, twitching of eyelids or face, or slight hand movements
- Not accompanied by incontinence
- Amnesia for episode
- May need to reorient self to previous activity

Continued

BOX 27.7 Classification and Clinical Manifestations of Partial and Generalized Seizures—cont'd

Atonic and Akinetic Seizures (Also Known as Drop Attacks)

Characterized by the following:

- Onset usually between 2 and 5 years of age
- Sudden, momentary loss of muscle tone and postural control
- Events recurring frequently during the day, particularly in the morning hours and shortly after awakening

Manifestations:

- Loss of tone causing child to fall to the floor violently; unable to break fall by putting out hand; may incur a serious injury to the face, head, or shoulder
- Loss of consciousness only momentary

Myoclonic Seizures

May be isolated as benign essential myoclonus

Characterized by the following:

- Sudden, brief contractures of a muscle or group of muscles
- Occur singly or repetitively
- No postictal state
- May or may not be symmetric
- May or may not include loss of consciousness

be observed. Focal seizures with psychic symptoms may include speech arrest or vocalizations, the sensation that an experience has occurred before (déjà vu), fear, displeasure, anger, or irritability. The affective symptoms associated with focal seizures last only a few minutes and are unprovoked.

Focal seizures with impaired awareness. During the period of impaired consciousness the child may look vacant, dazed, or frightened and be unable to respond when spoken to or to follow instructions and will not react when touched. Focal seizures with impaired awareness are the most common type of seizures. Focal seizures are observed in children of all ages and are the most common type in infants. These seizures may begin with an ***aura***—a sensation or sensory phenomenon that precedes the seizure activity. Common sensations include a strange feeling at the bottom of the stomach that rises toward the throat, odd or unpleasant odors or taste, complex auditory or visual hallucinations, or ill-defined feelings of strangeness (e.g., déjà vu). Small children may emit a cry as a manifestation of an aura. Strong feelings of fear and anxiety and a disturbed sense of time can be associated with an aura. The aura is part of the seizure event and is associated with EEG changes.

Another feature of a focal seizures may be ***automatisms*** (repetitive involuntary activities without purpose, carried out in a dreamy state). The predominant observations may be oropharyngeal activities such as lip smacking, chewing, drooling, swallowing, or picking at clothing or bed linens; ambulatory activities such as wandering or running; and verbal manifestations such as repeating words ("please, please," or "help, help"). These automatisms may appear to be antisocial behaviors, such as removing clothes in public or attempting to open the door of a moving car. The child may begin walking or running and unknowingly run out into traffic or into obstacles. It is important to realize that the child's consciousness is impaired and that these actions are not deliberate. It is sometimes difficult to determine whether such behavior is related to the seizure activity or to a behavioral deviation. If the behavior results from seizure activity, all attempts to control such behavior by physical restraint, with counseling, or with behavior plans will be ineffective. The child may suddenly cease activity, appear dazed, stare into space, become confused or apathetic, become limp or stiff, or display some form of posturing. Because the seizure starts in the same part of the brain each time, the child will do the same thing during every event. The term *psychomotor seizure* was formerly used because of the frequent association of psychic symptoms and motor automatisms with focal seizures.

If the seizure involves areas of the brain that control motor function, the child exhibits movements such as jerking of the hands and arms. Focal seizures generally last only a few minutes. After the seizure the postictal period occurs, with signs of confusion and lack of recollection of the ictal period. Depending on the area of the brain involved during the episode, the child may sleep for a time (see Table 27.3 for a comparison of focal seizures without and with impaired awareness).

Focal seizures that generalize. Focal seizures may spread and become generalized, usually into a tonic-clonic seizure. In such cases the focal seizure is considered the primary seizure event, and the generalized seizure is considered the secondary one. It would be stated that the tonic-clonic seizure was not generalized at the onset but was a focal seizure that became a bilateral tonic-clonic or secondarily generalized seizure.

Generalized Seizures

Generalized seizures without a focal onset indicate that the initial involvement is from both hemispheres. Loss of consciousness and impairment of motor function occur from the outset. Unlike focal seizures that become generalized, there is no aura. Seizures can occur at any time, day or night. The interval between events may be minutes, hours, weeks, or even years.

Tonic-clonic seizures. The generalized tonic-clonic seizure, formerly known as *grand mal,* is the most dramatic of all seizure manifestations of childhood. The seizure usually occurs without warning and consists of two distinct phases: tonic and clonic. In the tonic phase the child stiffens, the eyes roll upward, and the child loses consciousness. If standing, the child falls to the ground. The musculature stiffens in a generalized and symmetric tonic contraction of the entire body. The arms usually flex, and the legs, head, and neck extend. The mouth snaps shut, and the tongue may be bitten. The thoracic and abdominal muscles contract and sometimes produce a "tonic cry" as air is forced over the vocal cords. Parents often misinterpret this as an expression of pain. The average tonic phase lasts 10 to 30 seconds, during which the child's respirations become slow and shallow and the child may become cyanotic. Autonomic phenomena that may be observed include increased blood pressure, increased heart rate, flushing, and increased salivation.

In the clonic phase the tonic rigidity is replaced by intense jerking movements as the trunk and extremities undergo rhythmic contraction and relaxation. During this time the child cannot control oral secretions and may be incontinent of urine and feces. As the seizure ends, the movements become less intense and occur at less frequent intervals until they cease entirely. The average clonic phase lasts 30 to 50 seconds.

In the postictal phase the child may remain semiconscious and difficult to arouse. The postictal phase can last 30 minutes to several hours (Mikati & Tchapyjnikov, 2020). The child may remain confused or sleep. He or she may have mild impairment of fine motor movements, have visual and speech difficulties, and may vomit or complain

TABLE 27.3 Comparison of Focal and Absence Seizures

Clinical Manifestations	Focal Seizures Without Impaired Awareness	Focal Seizures With Impaired Awareness	Absence Seizures
Frequency (per day)	Variable	Rarely over 1-2 times	Multiple
Duration	Usually <30 sec	Usually >60 sec, rarely <10 sec	Usually <10 sec, rarely >30 sec
Aura	May be sole manifestation of seizure	Frequent	Never
Impaired consciousness	Never	Always	Always, brief loss of consciousness
Automatisms	No	Frequent	Frequent
Clonic movements	Frequent	Occasional	Occasional
Postictal impairment	Rare	Frequent	Never
Mental disorientation	Rare	Common	Unusual

of headache. On awakening, he or she is fully conscious but usually feels tired and may complain of sore muscles and a headache. The child has no recollection of the event.

Absence seizures. Absence seizures, formerly called *petit mal,* are generalized seizures. They have a sudden onset and are characterized by a brief loss of awareness, a blank stare, and automatisms. Absence seizures are divided into typical and atypical. These seizures almost always first appear during childhood, usually between the ages of 5 to 8 years, and often stop spontaneously in the teenage years (Mikati & Tchapyjnikov, 2020).

The onset of typical absence seizures is abrupt, with the child suddenly experiencing 20 or more events daily. Characteristically the brief loss of consciousness appears without warning and usually lasts 5 to 10 seconds. The child has a motionless blank stare that may be confused with inattentiveness or daydreaming. Slight loss of muscle tone may cause the child to drop objects, but he or she seldom falls. There may be automatisms such as lip smacking, twitching of the eyelids or face, or fumbling with the clothes. The sudden arrest of activity and consciousness is not accompanied by incontinence. Although the child will not recall the episode, when the seizure ends, the child may be aware and able to report that he or she has missed things that happened. There is no postictal sleepiness. Most children can immediately resume previous activities but may be momentarily confused. Atypical absence seizures are accompanied by head nods and sudden myoclonic jerks. Atypical absence seizures, unlike typical absence seizures, can be difficult to treat (Mikati & Tchapyjnikov, 2020).

Hyperventilation and photic stimulation are potent precipitators of absence seizures (Mikati & Tchapyjnikov, 2020). If the child is involved in a group activity, such as classroom reading or discussion, he or she may need help to catch up with the group after the seizure. Frequent episodes can result in slowed intellectual processes and deterioration in schoolwork and behavior. This is often the first indication of the problem. Absence seizures can be distinguished from daydreaming and attention-deficit/hyperactivity disorder by attempting to physically interrupt the episode by touching the face and eyelashes. Children who are daydreaming will respond to touch, whereas those who are having an absence seizure cannot. The abnormal EEG pattern in absence epilepsy is diagnostic and distinguishes absence seizures from focal seizures.

Atonic seizures. Atonic seizures are a sudden, momentary, and total loss of muscle tone. The onset is usually between 2 and 5 years of age. During a mild seizure the child may simply experience several sudden brief head drops. During a more severe episode the child suddenly falls to the ground, loses consciousness briefly, and after a few seconds gets up as if nothing happened. Because of the sudden loss of tone, the child is unable to break the fall by putting out a hand and can suffer injuries to the head, teeth, and face. Therefore if a child has frequent atonic seizures, wearing a helmet with a face guard when the child is up and walking around should be considered.

Myoclonic seizures. Myoclonic seizures are characterized by sudden, brief, shocklike movements of a muscle or group of muscles (Holmes, 2018). The seizures may involve only the face and trunk or one or more extremities. They may occur singly or repetitively. The seizures may or may not be symmetric. Myoclonic seizures often occur in combination with other seizure types. Myoclonic seizures should not be confused with myoclonic jerks that can occur normally in the course of falling asleep.

The myoclonic seizure can be confused with the exaggerated startle reflex often seen in children with severe developmental delays. The startle reflex occurs immediately after a stimulus such as a loud noise. The child will stiffly and rapidly extend all four extremities, sometimes with a cry, and then quickly return to his or her usual posture. An EEG with video recording can distinguish between the two events.

Tonic seizures. Tonic seizures are characterized by a sudden onset of increased tone. The child falls if standing. The child may involuntarily cry out because of contraction of the respiratory and abdominal muscles. Tonic seizures are longer than myoclonic seizures, with an average duration of 10 seconds. Postictal confusion, tiredness, and headache are common.

Clonic seizures. Clonic seizures are characterized by loss of consciousness and decreased tone followed by jerking movements of the extremities. These movements may be more predominant in one extremity. The duration is typically from 1 to several minutes and may be followed by a rapid recovery or may have a period of postictal confusion.

Unknown Onset Epileptic Seizures

Unknown onset epileptic seizures are seizures that lack sufficient information to classify. For example, the location of the onset of epileptic spasms, a type of seizure found predominantly in children younger than 2 years old, is often unknown. In addition to the seizures listed in the International Classification of Epileptic Seizures, several types of epileptic syndromes display a group of signs and symptoms that collectively characterize or indicate a particular condition. Several syndromes associated with epilepsy occur in infants and children. Two of these are West syndrome and Lennox-Gastaut syndrome (LGS).

Infantile Spasms (West syndrome). Infantile spasms are the most common epilepsy of infancy and are also known as West syndrome. It has a peak onset between 4 and 8 months of age and rarely occurs after 2 years of age (Singhal, Harini, & Sullivan, 2018). The etiology

can be genetic, metabolic, or structural but is unknown in about one-third of affected children. The pathophysiology is poorly understood. An abnormal EEG with hypsarrhythmia is pathognomonic. Nearly all children with infantile spasms have some degree of cognitive impairment (Singhal et al., 2018).

Flexor spasms consist of brief contractions of the neck, trunk, arms, and legs. The arms may either adduct or abduct, with the arms flexed at the elbow. Extensor spasms consist predominantly of extensor contractions resulting in abrupt extension of the neck and trunk with extensor adduction or abduction of the arms and legs. Eye deviation or nystagmus often occurs with infantile spasms. Infantile spasms may occur as a single event or in clusters, with as many as 150 seizures within a cluster. The infant often cries or is irritable during or after a cluster of spasms.

Adrenocorticotropic hormone (ACTH), an injectable hormonal treatment, is the first-line treatment recommended for infantile spasms. ACTH is more likely to provide short-term resolution of infantile spasms, but longer-term resolution is no different when prednisolone (oral hormonal treatment) is used (Jones, Snead, Boyd, et al., 2015). Due to the cost and difficulty obtaining ACTH, prednisone is considered to be a reasonable option by many epileptologists.

Vigabatrin is usually the choice of treatment for infantile spasms in tuberous sclerosis (Hancock, Osborne, & Edwards, 2013). There is evidence that it works as well as hormonal treatment in the rare children with infantile spasms and normal development (Jones, Go, Boyd, et al., 2015). Long-term use can damage the retinas, causing clinically asymptomatic peripheral visual field cuts. The risk of this visual field cut must be balanced with the benefit of controlling infantile spasms. New evidence suggests that combining vigabatrin with hormonal treatment is more effective than either treatment alone (O'Callaghan, Edwards, Alber, et al., 2017).

A Cochrane review of 18 randomized controlled studies found that no single treatment proved to be more efficacious than any other in the treatment of infantile spasms; hormonal treatments resolve spasms more often than vigabatrin, but the hormonal treatments may cause more long-term side effects (Hancock et al., 2013). Use of the ketogenic diet and other antiepileptic drugs as adjunctive therapy is increasing.

Lennox-Gastaut syndrome. Between 20% and 50% of infants who have infantile spasms eventually develop LGS (Germain & Maria, 2018). LGS is diagnosed on three criteria: (1) the presence of multiple seizure types (atonic, myoclonic, tonic, and atypical absence); (2) intellectual disability; and (3) slow spike wave discharges on EEG (Tenney & Glauser, 2018). Onset of LGS is between 1 and 8 years of age. Children with LGS typically have multiple seizures daily. Tonic seizures are the most common. There are many causes of LGS; about one-third of children with LGS have no known cause. Causes include brain malformations and injury, neurocutaneous disorders, brain infections, and genetic disorders. In addition to cognitive impairments, many of these children develop other problems, including hyperactivity, aggressive behavior, or autism spectrum disorder.

Treatment is challenging. Most children require more than one antiepileptic drug and even then many will continue to have some seizures. In addition, the ketogenic diet or implantation of a vagus nerve stimulator may be efficacious for some of these children. The prognosis of LGS is typically poor. Additional family support is often required to maintain the child at home.

Diagnostic Evaluation

Establishing a diagnosis is critical for establishing a prognosis and planning appropriate treatment. The process of diagnosis in a child suspected of having epilepsy includes first determining whether the events thought to be seizures are epileptic seizures or nonepileptic events and then identifying the underlying cause, if possible. The assessment and diagnosis rely heavily on a thorough history, skilled observation, and several diagnostic tests.

It is especially important to differentiate seizures from other brief alterations in consciousness or behavior. Clinical entities that mimic seizures include staring, migraine headaches, toxic effects of drugs, syncope (fainting), breath-holding spells in infants and young children, movement disorders (tics, tremor, chorea), prolonged QT syndrome and other cardiac arrhythmias, sleep disturbances (sleepwalking, night terrors), psychogenic seizures, rage attacks, and transient ischemic attacks (rare in children). The toxic effects of maternal drug use and withdrawal from these drugs should be considered in the differential diagnosis of new-onset seizure activity in a newborn.

A detailed description of the seizure should be obtained from the caregiver(s) who witnessed it. Ask questions about the child's behavior during the event, especially at the onset, and the time at which the seizure occurred (e.g., early morning, while awake, during sleep). Any factors that may have precipitated the seizure are important, including fever, infection, head trauma, anxiety, fatigue, sleep deprivation, menstrual cycle, alcohol, and activity (e.g., hyperventilation or exposure to strong stimuli such as bright flashing light or loud noises). Record any sensory phenomena that the child can describe and if the child was able to hear during the seizure. The duration and progression of the seizure (if any) and the postictal feelings and behavior (e.g., confusion, inability to speak, amnesia, headache, sleep) should also be noted. For children who have epilepsy, document how often they have seizures: daily, weekly, or monthly. Knowing the age at which the child had his or her first seizure is important. It is important to determine whether more than one seizure type exists. It is often more informative to ask the parents to show you what the seizure looked like rather than to rely on their verbal description. Demonstrating a seizure often reveals features, such as head turning, that would otherwise go unrecognized. Some seizures are overlooked by parents. For example, some parents may not identify brief head nods or brief single jerks as seizures unless specifically asked if their child has these symptoms.

A thorough medical history must be obtained, beginning with conception. Questions to consider include the following: Was the mother's pregnancy complicated by illness and drug use, either prescription or recreational? How old was the baby when discharged from the hospital after birth? Has the child had any overnight hospitalizations or surgeries? A complete history is designed to uncover possible risk factors for the development of seizures or epilepsy.

The family history should include whether other family members ever had a seizure of any kind, cognitive impairments, cerebral palsy, autism, or other neurologic disorders. Ask if there is a family history of sudden, unexpected deaths. A family history can offer clues to other paroxysmal disorders, such as migraine headaches, breath-holding spells, febrile seizures, or neurologic diseases.

A complete physical and neurologic examination, including developmental assessment of language, learning, behavior, and motor abilities, may provide clues to the cause of the seizures. A number of laboratory and neuroimaging tests may be ordered depending on the child's age, whether it is a new-onset seizure, characteristics of the seizure, and the history. Laboratory studies that may prove valuable include a white blood cell count (for signs of infection) and blood glucose measurements that may indicate hypoglycemic episodes. Serum electrolytes, blood urea nitrogen, calcium, serum amino acids, lactate, ammonia, and urine organic acids may indicate metabolic disturbances. Blood for chromosomal analysis may also be tested if a genetic etiology is suspected. A toxicology screen should

be performed if alcohol or drug ingestion or withdrawal is suspected. Lumbar puncture can confirm a suspected diagnosis of meningitis. CT may be done to detect a cerebral hemorrhage, infarctions, brain tumors, and gross malformations. MRI provides greater anatomic detail and is used to detect developmental malformations, tumors, and cortical dysplasias.

Most children with seizures will have an EEG. The EEG is the most useful tool for evaluating the child's risk of recurrent seizures, helping determine the type of seizure the child had, and diagnosing the type of epilepsy. The EEG confirms the presence of abnormal electrical discharges and provides information on the seizure type and the location of onset. The EEG is carried out under varying conditions: with the child asleep, awake, awake with provocative stimulation (flashing lights, noise), and hyperventilation. Stimulation may elicit abnormal electrical activity that is recorded on the EEG. Various seizure types produce characteristic EEG patterns; for example, a three-per-second spike and wave pattern is observed in absence epilepsy, and a slow spike and wave pattern is observed in LGS.

A normal EEG does not rule out seizures. The EEG is only a surface recording, lasts approximately 1 hour, and therefore may show normal interictal activity. If there is concern about whether a child has seizures or if the seizure type cannot be determined, a long-term video EEG may be done to record the child during wakefulness and sleep. The full-body image is recorded on video, with selected EEG channels displayed on the same screen for simultaneous recording and viewing. Amplitude-integrated electroencephalography (aEEG) monitoring is increasingly available in neonatal and pediatric intensive care units. This is a method of continuous monitoring of brain activity using recordings from a handful of leads compared with the 24 leads of standard EEGs. aEEG is useful for diagnosing seizures when standard EEG or a neurophysiologist to interpret it is unavailable. Although the EEG is valuable, it should not be used alone to determine the type of seizure. Rather, the EEG interpretation with a thorough clinical description of the child's behavior during the seizure will inform the correct classification of the seizure and the appropriate treatment choice.

Therapeutic Management

The goal of treatment of seizure disorders is to control the seizures or to reduce their frequency and severity, discover and correct the cause when possible, and help the child live as normal a life as possible. Discovering and, when possible, correcting the underlying cause of the seizures can lead to complete control of all seizures. If the seizure activity is a manifestation of an infectious, traumatic, or metabolic process, seizure therapy is instituted as part of the general therapeutic regimen. Management of epilepsy has four treatment options: drug therapy, the ketogenic diet, vagus nerve stimulation, and epilepsy surgery.

Drug Therapy

It is known that persons predisposed to epilepsy have seizures when their basal level of neuronal excitability exceeds a critical point; no event occurs if the excitability is maintained below this threshold. The administration of antiepileptic drugs serves to raise this threshold and prevent seizures. Consequently, the primary therapy for epilepsy is the administration of the appropriate antiepileptic drug or combination of drugs in a dosage that provides the desired effect without causing adverse side effects or toxicity. Antiepileptic drugs are believed to exert their effect primarily by reducing the responsiveness of neurons to the sudden, high-frequency nerve impulses that arise in the epileptogenic focus. Thus the seizure is effectively suppressed; however, the abnormal brain waves may or may not be altered. The chance of total control of seizures depends on the underlying cause of the seizures. Children with epilepsy without any underlying pathology such as brain malformations or genetic disorders and with normal development have the best prognosis.

The initiation of anticonvulsant therapy is based on several factors, including the child's age, type of seizure, risk of recurrence, and other comorbid or predisposing medical issues. For children who develop recurrent seizures or epilepsy, treatment is begun with a single drug known to be effective for the child's seizure type and have the lowest risk of adverse side effects. The dosage is gradually increased until the seizures are controlled. If a child develops intolerable side effects, the medication is stopped and another one tried. If the drug at maximum doses reduces but does not stop all seizures, a second drug is added in gradually increasing doses. When seizures are controlled, the first drug may be tapered to reduce the potential adverse effects and drug interactions of polytherapy. Monotherapy remains the treatment of choice for epilepsy, but a combination of medications may be a viable alternative for children who do not have total seizure control with only one medication (Mikati & Tchapyjnikov, 2020).

If complete seizure control is maintained on an antiepileptic drug for 2 years, it may be safe to slowly discontinue the drug for patients with no risk factors. Risk factors for recurrence of seizures include history of status epilepticus, older age at onset, duration of treatment before seizure control is achieved, presence of a neurologic dysfunction (e.g., motor or cognitive impairment), and abnormal EEG findings when the medication is stopped (Lee, Li, & Chen, 2017). Recurrence occurs most often within the first year of discontinuation (Braun & Schmidt, 2014). When seizure medications are discontinued, the dosage is decreased gradually over weeks or months. Sudden withdrawal of a drug is not recommended because it can cause seizures, which may be longer and more intense than previously, to recur.

Potential complications of drug therapy. The side effects of continued use of antiepileptic medications are often distressing to the child and family. Most side effects are transient and dose related, but drug reactions warrant immediate attention. A serious potential adverse side effect of antiepileptic medication is allergic drug rash. The rash can start with hives and is usually very pruritic. Allergic drug rashes from antiepileptic drugs can spread quickly and become severe, life-threatening events. The drug should be stopped with any signs of a rash. A physician or nurse practitioner should evaluate the child within 24 hours or sooner if the child develops edema or respiratory problems. Treatment includes antihistamines, epinephrine, glucocorticosteroids, anabolic steroids, and/or airway management, depending on the severity of the reaction (Blaszczyk, Lasoń, & Czuczwar, 2015).

Sleepiness, changes in mood or behavior, vision changes, and ataxia are some of the potential side effects of antiepileptic medications. These are very distressing to both children and families. They often disappear over time or when drug dosages are reduced. Blood cell counts, urinalysis, and liver function tests are obtained at regular intervals in children receiving some older antiepileptic medications that can affect organ function.

Knowledge of drug-to-drug interactions, including other medications such as antibiotics, is critical in caring for the child with epilepsy. Knowledge of potential adverse effects is also imperative. Severe, potentially life-threatening side effects can occur with specific antiepileptic medications. For example, carbamazepine, phenytoin, and lamotrigine may cause a severe, life-threatening rash. Valproic acid may cause liver toxicity, particularly in a child less than 2 years of age. To avoid possible complications of tissue damage and difficulties with administration of IV phenytoin, fosphenytoin should be used. Therefore critical thinking and careful monitoring are necessary in providing optimum care to the child with epilepsy.

DRUG ALERT

Fosphenytoin

Fosphenytoin is often used to treat seizures instead of intravenous (IV) phenytoin because of possible complications and drug interactions associated with IV phenytoin. If IV phenytoin is used, it should be administered via slow IV push and at a rate that does not exceed 50 mg/min. Because phenytoin precipitates when mixed with glucose, only normal saline is used to flush the tubing or catheter. Fosphenytoin may be given in saline or glucose solutions at a rate of up to 150 mg PE (phenytoin equivalent)/min, and it may be given intramuscularly if necessary.

Chronic treatment with phenytoin may cause gum hypertrophy. Surgical removal of the excess tissue may be needed in severe cases. Enlargement of the tonsillar and adenoidal tissue can cause partial airway obstruction, which produces snoring during sleep. Chronic treatment with antiepileptic medications, particularly enzyme-inducing medications, has been associated with decreased bone mineral density that worsened with prolonged use of antiepileptic medications (Ahmad, Petty, Gorelik, et al., 2017). Prophylactic administration of calcium and vitamin D supplements is recommended for all patients receiving antiepileptic medications, and bone mineral density testing is recommended for patients on long-term antiepileptic medications (Ahmad et al., 2017).

Children whose mothers took antiepileptic medications in the first trimester of pregnancy have a twofold increased risk of being born with congenital malformations compared with children not exposed in utero to these drugs (Ban, Fleming, Doyle, et al., 2015). Folic acid can prevent birth defects, but women taking antiepileptic medications tend to have low levels of serum folic acid. The Centers for Disease Control and Prevention and the American Academy of Neurology recommend that all females capable of childbearing take 400 to 800 mcg of folic acid daily prior to conception.

Ketogenic Diet

The ***ketogenic diet*** is a high-fat, very-low-carbohydrate, and adequate-protein diet that has shown effectiveness for treatment of epilepsy (Martin, Jackson, Levy, et al., 2016). It is also the first-line treatment for certain metabolic disorders, including pyruvate dehydrogenase deficiency, glucose transporter type I deficiency, and glutaric aciduria type I. Consumption of the ketogenic diet forces the body to shift from using glucose as the primary energy source to using fat, and the individual develops a state of ketosis. The diet is rigorous. All foods and liquids the child consumes must be carefully weighed and measured. A liquid formula is available for children who cannot take solid food. The diet is deficient in vitamins and minerals; therefore vitamin and mineral supplementation is necessary. Potential adverse side effects of the diet include constipation, hypoglycemia during initiation of the diet, acidosis, and lethargy. Less common but more serious side effects include urinary tract infections, kidney stones, and insufficient weight gain (Luat, Coyle, & Kamat, 2016).

The ketogenic diet (and its variations) has been shown to be an effective and tolerable treatment for medically refractory epilepsy with seizure control comparable to or better than that obtained with antiepileptic medications in some children (Martin et al., 2016).

Vagus Nerve Stimulation

Vagus nerve stimulation (VNS) was developed as palliative treatment for patients with seizures not controlled by drugs and who are not candidates for diet or surgical therapy (Moshe, Perucca, Ryvlin, et al., 2015). The results in children have been mixed, with a usually modest reduction in seizures (Dhamne, Kaye, & Rotenberg, 2018). A programmable signal generator is implanted subcutaneously in the chest. Electrodes tunneled underneath the skin deliver electrical impulses to the left vagus nerve (CN X). The device is programmed noninvasively to deliver a precise pattern of stimulation to the left vagus nerve. The patient or caregiver can activate the device using a magnet at the onset of a seizure. No long-term adverse effects have been reported with VNS, but dysphonia, throat or neck pain, and cough can occur during stimulation.

Surgical Therapy

When seizures are caused by a hematoma, vascular malformation, tumor, or other cerebral lesion, surgical removal is usually recommended. Epilepsy surgery is the most effective treatment for children with medically refractory epilepsy due to focal cortical dysplasia and mesial temporal sclerosis. About 80% of these patients will be seizure free 4 years after surgery (Moosa & Gupta, 2014).

Epilepsy surgery does not always eliminate the need for antiepileptic drug therapy. The goal is to improve seizure control without worsening or producing serious deficits. Some children will see improvements in their cognition, behavior, and quality of life (Ryvlin, Cross, & Rheims, 2014). Types of surgeries include focal resection of the epileptogenic focus, functional hemispherectomy, and corpus callosotomy, which severs the connection between the hemispheres.

Status Epilepticus

Status epilepticus is a continuous seizure that lasts more than 30 minutes or a series of seizures from which the child does not regain a premorbid level of consciousness (Fernandez, Abend, & Loddenkemper, 2018). The term *impending status epilepticus* is used for a continuous seizure or series of seizures lasting between 5 and 30 minutes with the designation that treatment should begin within 5 minutes (Fernandez et al., 2018).

The initial treatment is directed toward support of vital functions (i.e., the CAB of life support), measuring blood glucose, administrating oxygen, and gaining IV access, immediately followed by IV administration of antiepileptic agents. Simultaneously with life support measures and emergency medications, the underlying cause of the status epilepticus is identified and corrected (Fernandez et al., 2018).

Buccal or intranasal midazolam and rectal diazepam are simple, effective, and safe treatments for home or prehospital management of prolonged seizures and impending status epilepticus (Brigo, Nardone, Tezzon, et al., 2015). Time to cessation of the seizure with midazolam was 4 minutes shorter than with rectal diazepam (Brigo et al., 2015). Respiratory depression is a potential side effect of these medications when more than two doses are given (Abend & Loddenkemper, 2014); however, respiratory depression is not a side effect of rectal diazepam when it is administered as recommended. Intranasal midazolam is safe and effective for stopping seizures but also is easier to administer than rectal diazepam (Glauser, Shinnar, Gloss, et al., 2016).

For in-hospital management of status epilepticus, IV diazepam or lorazepam (Ativan) is the first-line drug of choice (Glauser et al., 2016). If IV access has not been established, rectal diazepam or intramuscular, intranasal, or buccal midazolam should be given. It appears that the exact medication chosen is less important than choosing the one that can be administered fastest (Fernandez et al., 2018). The child must be closely monitored during administration to detect early alterations in vital signs that may indicate impending respiratory depression. When a benzodiazepine (diazepam or lorazepam) is ineffective, IV phenytoin or fosphenytoin followed by phenobarbital is given as the next line of treatment. Fosphenytoin is preferred over phenytoin because of better

tolerability (Glauser et al., 2016). This combination of therapy places the child at high risk for apnea, and therefore respiratory support is generally necessary. Children may also receive other antiepileptic medications, including IV valproate or levetiracetam.

Children who continue to have seizures despite drug treatment may require general anesthesia with a continuous infusion of midazolam, propofol, or pentobarbital (Fernandez et al., 2018). In this situation the patient may need to be intubated, and continuous EEG monitoring is typically done to monitor for and treat electrographic seizures (Fernandez et al., 2018).

DRUG ALERT

Diazepam

Diazepam is incompatible with many drugs. To give intravenously, inject slowly and directly into the vein or through tubing as close as possible to the vein insertion site.

Nursing care of a child with status epilepticus includes, in addition to the CAB of life support, monitoring blood pressure and body temperature. During the first 30 to 45 minutes of the seizure, the blood pressure may be elevated. Thereafter the blood pressure typically returns to normal but may be decreased depending on the medications being administered for seizure control. Hyperthermia requiring treatment may occur as a result of increased motor activity.

Status epilepticus is a medical emergency that requires immediate intervention to prevent possible brain injury or death. Diagnosis and correction of the underlying cause of the status epilepticus is essential.

Prognosis

Only about half of children who experience a first seizure will have additional seizures (El-Radhi, 2015). Children who have cognitive impairments and/or cerebral palsy are at highest risk for developing epilepsy. Prognosis for eventual remission of childhood epilepsy depends on the etiology and epilepsy syndrome diagnosis. Some syndromes almost always remit, whereas others almost never do (Camfield & Camfield, 2015). ***Intractable seizures*** are defined as failure to control seizures after two appropriately selected antiepileptic medications are trialed (Wassenaar, Leijten, Egberts, et al., 2013). ***Refractory seizures*** are usually defined as the persistence of seizures despite adequate trials of three antiepileptic medications, alone or in combination (Téllez-Zenteno, Hernández-Ronquillo, Buckley, et al., 2014).

Most deaths in children with epilepsy are due to factors associated with a child's coexisting neurologic conditions and poorly controlled seizures (Berg & Rychlik, 2015). Deaths from epilepsy in children who have no other neurologic conditions occur at the same rate as childhood deaths from other causes, with the exception of drowning

BOX 27.8 General Observations of the Child During a Seizure

Observations During Seizure

General Description

Order of events (before, during, and after)
Duration of seizure
- Tonic-clonic—from first signs of event until jerking stops
- Absence—from loss of consciousness until consciousness is regained
- Focal seizures with impaired awareness—from first sign of unresponsiveness, motor activity, automatisms until there are signs of responsiveness to environment

Onset

Time of onset
Significant precipitating events—missed medication dosage, illness, stress, sleep deprivation, menses

Behavior

Change in facial expression
Cry or other sound
Stereotypic or automatous movements
Random activity (wandering)
Position of eyes, head, body, extremities
Unilateral or bilateral posturing of one or more extremities

Movement

Change of position, if any
Site of commencement—hand, thumb, mouth, generalized
Tonic phase—length, parts of body involved
Clonic phase—twitching or jerking movements, parts of body involved, sequence of parts involved, generalized, change in character of movements
Lack of movement or muscle tone of body part or entire body

Face

Color change—pallor, cyanosis, flushing
Perspiration
Mouth—position, deviating to one side, teeth clenched, tongue bitten, frothing at mouth
Lack of expression
Asymmetric expression

Eyes

Position—straight ahead, deviation upward or outward, conjugate or divergent gaze
Pupils—change in size, equality, reaction to light

Respiratory Effort

Presence and length of apnea

Other

Incontinence

Postictal Observations

Duration of postictal period
State of consciousness
Orientation
Arousability
Motor ability
- Any change in motor function
- Ability to move all extremities
- Paresis or weakness

Speech
Sensations
- Complaint of discomfort or pain
- Any sensory impairment
- Recollection of preseizure sensations or aura

(Franklin, Pearn, & Peden, 2017). The phenomenon of sudden unexpected death in epilepsy (SUDEP) is drawing increasing attention in child neurology and epilepsy clinics. It is an extremely rare condition in children with a risk of between 1.1 and 3.4 per 10,000 patient-years (Morse & Kothare, 2016). The major risk factor for SUDEP is uncontrolled generalized tonic-clonic seizures, particularly in sleep (Harden, Tomson, Gloss, et al., 2017).

Nursing Care Management

An important nursing responsibility is to observe the seizure episode and accurately document the events. Record and note any alterations in behavior preceding the seizure and the characteristics of the episode, such as sensory-hallucinatory phenomena (e.g., an aura), motor effects (e.g., eye movements, muscular contractions), alterations in consciousness, and postictal state (Box 27.8). The nurse should describe only what is observed rather than try to label a seizure type. Note the time that the seizure began and the duration of the seizure.

Generalized seizures and other types with clear manifestations are easy to detect, but absence seizures may present more difficulties. They are easily misinterpreted as inattention. Any unusual behavior, even seemingly inconsequential, such as a momentary interruption of activity, staring, or mental blankness, should be described. The more detailed these descriptions, the more valuable they are for assessment (see the Next-Generation NCLEX® Examination-Style Unfolding Case Study and Quality Patient Outcomes boxes).

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

The Child With Seizures

Day 1, 10:00 am

1. A 7-year-old boy who was playing during physical education class at school when he suddenly stopped his activity, stared into space, repetitively moved his left arm up and down, and smacked his lips. After approximately 1 minute, he stopped the behavior and was drowsy but responsive to his environment. He had no memory of the event. He was accompanied by his teacher to the school nurse for further assessment. While waiting for the parents to arrive, what are the most important subjective and objective data that the nurse would document? **Select all that apply.**

From the boy:

A. Aura
B. Sensory phenomena that the child can describe during the event (i.e., ability to hear)
C. Postictal feelings (i.e., confusion, inability to speak, amnesia, headache, sleepiness)

From the person who observed the seizure:

A. Duration of seizure
B. Time of onset of seizure
C. Other students who have the same symptoms
D. Change in level of consciousness (LOC) before, during, and after the seizure
E. Movements (ask for demonstration of the seizure rather than relying on verbal description)

Day 1, 11:30 am

2. The child is seen in the Emergency Department after the mother picked him up from school. The physician wants to observe the child while tests results are pending. Blood work and an electroencephalogram (EEG) was done. **Indicate which nursing action listed in the far-left column is appropriate to prevent the potential complication following a seizure listed in the middle column. Indicate the nursing action number in the far-right column. Note that ONLY one nursing action can be used for each potential complication and that NOT all nursing actions will be used.**

Nursing Action	Potential Complication	Nursing Action to Prevent Complication
1. Monitor time (onset and duration), movements, and LOC during seizure.	Child experiences anxiety and fear	
2. If child is at risk of falling, ease child to floor. Prevent child from hitting head on objects. Do not attempt to restrain child or use force.	An accurate description of the seizure is not obtained	
3. During seizure, place child in a side-lying position on a flat surface such as floor. Do not put anything in child's mouth.	Parents unable to cope with the diagnosis and management of their son	
4. Stay with the child and reassure the child when awakening from seizure.	Physical harm occurs	
5. Involve child and parents in discussion of fears, anxieties, and resources and support options available to patient and family.	Aspiration can occur	
	Lack of description of the postictal state	
	Further seizures occur	

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—cont'd

1 week later, 11:00 am

3. A 7-year-old boy who was playing during physical education class at school a week ago had a seizure. The work-up revealed an abnormal EEG and the physical examination and clinical history supported the decision to begin anticonvulsant therapy with a single medication. This morning he has another seizure while playing with his siblings in the backyard. His brother ran inside to get help and his mother ran outside to see him staring into space with his head turned to the side and his left arm moving rhythmically up and down. This activity stopped for a few seconds and then started again. His mother called for emergency assistance (911), and he was transported to the hospital. Which of the signs and symptoms experienced by this 7-year-old child would the nurse expect to find with a focal seizure? **Select all that apply.**
   - A. Automatisms
   - B. Aura experienced
   - C. Mental disorientation
   - D. Postictal impairment
   - E. Lasted less than a minute
   - F. Occurs multiple times a day
   - G. Seizure lasted for 45 minutes

1 week later, 11:30 am

4. The child was transferred by ambulance to the hospital. He had not regained consciousness during the transport. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.**

   Since the child is not regaining a premorbid level of consciousness (LOC) between seizures is concerning and meets criteria for a diagnosis of_____1_____. The child's _____2_____ should be monitored closely, and supportive measures (i.e., cardiopulmonary resuscitation) should be initiated as indicated. Simple, effective, and safe treatments for home or prehospital management of prolonged seizures and impending status epilepticus include _____3_____ midazolam and rectal diazepam.

Options for 1	Options for 2	Options for 3
simple partial seizure	blood pressure	intrathecal
complex partial seizure	seizure activity	intravenous
status epilepticus	circulation, airway, and breathing (CAB)	rectal
absence seizure	blood levels	buccal

1 week later, 1:00 pm

5. The child is admitted to the hospital after the seizure was stopped in the Emergency Department by administering intravenous lorazepam. The child has gained consciousness and is being monitored closely with his parents at the bedside. He is undergoing a comprehensive neurological examination with neuroimaging studies. The child had no history of signs of infection or head trauma. **For each nursing action, use an X to indicate whether it was Effective (helped to meet expected patient outcomes), Ineffective (did not help to meet expected patient outcomes), or Unrelated (not related to the patient outcomes).**

Nursing Action	Effective	Ineffective	Unrelated
Monitor circulation, airway, and breathing closely.			
Ensure antiepileptic drugs are being administered as directed.			
Monitor and record characteristics, onset, and duration of any new seizures, including motor effects, alterations in consciousness, and postictal state.			
Attempt to stop the seizure if one occurs again; keep the child upright.			
Do not place anything in child's mouth during the seizure.			
Place child in a side-lying position; suction the oral cavity and posterior oropharynx as needed.			
Closely monitor hemoglobin and platelet count.			
Observe for hyperthermia, hypertension and respiratory depression.			

Three days later, 11:00 am

6. The child is stabilized and has completed the comprehensive neurological evaluation. The evaluation revealed no definitive etiology for the seizures. However, the EEG remains abnormal and the MRI study was also abnormal. He will remain on seizure medications at home and be followed by the neurology team. The child's parents are anxious and upset and concerned about taking their son home. The nurse caring for him is to begin discharge teaching today. What are the most important aspects of home care to discuss with his parents at this time? **Select all that apply.**
   - A. Have the child wear a helmet to school.
   - B. Have child wear medical identification.
   - C. Arrange for a class presentation to all students to help with observation while at school.
   - D. Educate family about characteristics of seizures, including aura, seizure activity, and postictal state.
   - E. Educate family about safety precautions before and during a seizure, including side-lying positioning, padding area if needed, and not placing items in mouth or attempting to stop the seizure.
   - F. Educate family about medication administration, including scheduled and as necessary (prn) medications and potential side effects of medications.
   - G. Arrange for social worker to meet with family to assess emotional and financial needs.
   - H. Consider consultation with child life specialist to assist with education of school personnel and classmates.
   - I. Have eyes-on supervision when swimming in pools and an adult within arm's reach in natural bodies of water.
   - J. Use protective helmet and padding during bicycle riding, skateboarding, and in-line skating.

QUALITY PATIENT OUTCOMES: Seizures
- Etiology of seizure determined
- Seizures controlled or reduced in frequency and severity
- Family and child receive education to manage seizures
- Child adhering to treatment
- Side effects of treatment minimized

The child must be protected from injury during the seizure. Nursing observations made during the event provide valuable information for diagnosis and management of the disorder (see Emergency Treatment box).

It is impossible to physically stop a seizure once it has begun, and no attempt should be made to do so. The nurse must remain calm, stay with the child, and prevent the child from injury during the seizure. If possible, isolate the child from the view of others by closing a door or curtain. A seizure can be upsetting to the child, other visitors, and their families. If other persons are present, reassure them that everything is being done for the child. After the seizure, they can be given a simple explanation about the event as needed.

If the nurse is able to reach the child in time, a child who is standing or seated in a chair is eased to the floor immediately. Do not remove a child from a wheelchair. During (and sometimes after) a tonic-clonic seizure, the swallowing reflex is lost, salivation increases, and the tongue is hypotonic. Therefore the child is at risk for aspiration and airway occlusion. Placing the child on the side facilitates drainage and helps maintain a patent airway. Suctioning of the oral cavity and posterior oropharynx may be necessary. Take vital signs and allow the child to rest. When feasible, the child is integrated into the environment as soon as possible. Sending a child with a chronic seizure disorder home from school is not necessary unless requested by the parents.

! NURSING ALERT

Do not move or forcefully restrain the child during a tonic-clonic seizure, and do not place a solid object between the child's teeth.

Seizure precautions are required for children who are known to have seizures or who are under observation for seizures. The extent of these measures depends on the type and frequency of the seizure (Box 27.9).

Long-Term Care

Care of the child with epilepsy involves physical care and instruction on the importance of adherence to the treatment plan. Probably more significant is support and education on the potential for the development of psychosocial, educational, and emotional problems in children with epilepsy and their families. Few diseases generate as much anxiety among family, friends, and school personnel as epilepsy (Jones & Reilly, 2016). Fears and misconceptions about the disease and its treatment are common. Nursing care is directed toward educating the child and family about epilepsy and helping them develop strategies to cope with the psychologic and sociologic problems related to epilepsy.

EMERGENCY TREATMENT

Seizures

Tonic-Clonic Seizure

During the Seizure

Remain calm.
Time seizure episode.
If child is standing or seated, ease child to the floor.
Place pillow or folded blanket under child's head.
Loosen restrictive clothing.
Remove eyeglasses.
Clear area of any hazards or hard objects.
Allow seizure to end without interference.
If vomiting occurs, turn child to one side.
Do *not:*
- Attempt to restrain child or use force.
- Put anything in child's mouth.
- Give any food or liquids.

After the Seizure

Time postictal period.
Check for breathing. Check position of head and tongue.
Reposition if head is hyperextended.
If breathing is not present, give rescue breathing and call emergency medical service (EMS).
Keep child on side.
Remain with child.
Do not give food or liquids until child is fully alert and swallowing reflex has returned.
Look for medical identification, and determine what factors occurred before onset of seizure that may have been triggering factors.
Check head and body for possible injuries.
Check inside of mouth to see if tongue or lips have been bitten.

Focal Seizure With Impaired Consciousness

During the Seizure

Do not restrain the child's movements.
Remove harmful objects from area.
Redirect to safe area.
Do not agitate; instead, talk in calm, reassuring manner.
Do not expect child to follow instructions.
Watch to see if seizure generalizes.

After the Seizure

Stay with child and reassure until fully conscious.

Call EMS If

Child stops breathing.
There is evidence of injury or child is diabetic or pregnant.
Seizure lasts for more than 5 minutes (unless seizures typically last longer than 5 minutes) and written medical order is present.
Status epilepticus occurs.
Pupils are not equal after seizure.
Child vomits continuously 30 minutes after seizure has ended (sign of possible acute problem).
Child cannot be awakened and is unresponsive to pain after seizure has ended.
Seizure occurs in water.
This is child's first seizure.

Data from Epilepsy Foundation. (2017). *Seizure first aid,* Retrieved from http://www.epilepsyfoundation.org/aboutepilepsy/firstaid/index.cfm.

BOX 27.9 Seizure Precautions

The extent of precautions depends on type, severity, and frequency of seizures. Precautions may include the following:

- Side rails raised when child is sleeping or resting
- Side rails and other hard objects padded
- Waterproof mattress or pad on bed or crib

Appropriate precautions during potentially hazardous activities may include the following:

- Swimming with a companion
- Showers preferred; bathing only with close supervision
- Use of protective helmet and padding during bicycle riding, skateboarding, and skating
- Supervision during use of hazardous machinery or equipment

Have child carry or wear medical identification.

Alert other caregivers to need for any special precautions.

Child may not drive or operate hazardous machinery or equipment unless seizure free for designated period (varies by state).

Children with epilepsy are prescribed antiepileptic medications, which are administered at regular intervals to maintain adequate levels in the blood. The nurse can help the parents plan the administration of the medication at convenient times, usually breakfast and dinner or bedtime, to make taking the medication as easy as possible. It is important to talk with the family about the importance of giving the antiepileptic medication as scheduled to prevent recurrent seizures. Using a pill box can prevent accidentally missing doses. The seizure threshold may be lowered during any illness but particularly with fever. Therefore parents should be aware that if their child has an illness he or she may be at increased risk for seizures. Parents should contact their health professional if their child misses medications due to vomiting.

Rectal preparations of some antiepileptic medications are highly effective when a child is unable to take oral medications because of repeated vomiting, surgery, or status epilepticus. Parents can learn to administer rectal antiepileptic medication for home treatment. Buccal and intranasal midazolam and rectal diazepam are useful adjunctive home treatments for children at risk for prolonged seizures or clusters of seizures and can minimize the need for hospitalization while enhancing parental confidence.

Usually antiepileptic medications are continued until the child has been seizure free for 2 years (Lee et al., 2017). The medication is then slowly tapered over a period of weeks to decrease the chances of precipitating a seizure.

DRUG ALERT

Vitamin D and Folic Acid Deficiency

Children taking phenobarbital or phenytoin should receive adequate vitamin D and folic acid because deficiencies of both have been associated with these drugs. Phenytoin should not be taken with milk.

Nurses should educate the child and parents about the possible adverse reactions to the medications used to treat seizures. Parents must understand the rare but potentially serious side effect of allergic reaction to the medication. They must immediately report rashes to the child's health care provider. More common but less serious potential side effects include excessive sleepiness, changes in appetite, and worsening behavior and mood. Parents should be encouraged to share their observations with their child's health care provider. Parents should understand that the child needs periodic physical assessment. Depending on the medication prescribed, some children will need regular testing of their complete blood count and liver functions. Possible adverse effects on the hematopoietic system, liver, and kidneys may be reflected in symptoms such as fever, sore throat, enlarged lymph nodes, jaundice, and bleeding (e.g., abnormally easy bruising, petechiae, ecchymosis, and epistaxis). The most common cause of status epilepticus in children taking antiepileptic medications is missed medication.

Children with epilepsy are not at increased risk for injury with the exception of head injury (Baca, Vickrey, Vassar, et al., 2013). The degree to which activities are restricted is individualized for each child and depends on the type, frequency, and severity of the seizures; the child's response to therapy; and the length of time the seizures have been controlled. To prevent head injuries, children should always wear helmets and other safety devices when participating in sports, such as biking, skiing, skateboarding, horseback riding, and skating. Only children with frequent seizures must avoid these activities. Children with epilepsy should avoid activities involving heights, such as climbing on play structures taller than they are. Submersion injuries are a serious risk for children with a history of seizures. Children should never be left alone in the bathtub, even for a few seconds. Older children and adolescents should be encouraged to use a shower and reminded not to lock the bathroom door when showering. They must have eyes-on supervision at all times when swimming.

Because the child is encouraged to attend school, camp, and other normal activities, the school nurse and teachers should be made aware of the child's condition and therapy. They can help ensure regularity of medication administration and provision of any special care the child might need. Teachers, child care providers, camp counselors, youth organization leaders, coaches, and other adults who assume responsibility for children should be instructed on care of the child during a seizure so that they can react calmly, provide for the child's safety, and influence the attitude of the child's peers.

DRUG ALERT

Rectal Antiepileptic Medications

Rectal preparations of some antiepileptic medications are highly effective when a child is unable to take oral medications because of repeated vomiting, gastrointestinal surgery, or status epilepticus. Parents can learn to administer rectal antiepileptic medication for home treatment. Rectal diazepam is a useful adjunctive home treatment for children at risk for prolonged seizures or clusters of seizures. It also minimizes hospitalization and enhances parental confidence.

Triggering Factors

Careful and detailed documentation of seizures over time may indicate a pattern of seizures. About half of people age 12 years and older with epilepsy can recognize at least one trigger for their seizures (Wassenaar, Kasteleijn-Nolst Trenite, de Haan, et al., 2014). When this occurs, the child, nurse, or responsible adult can intervene to make changes in the lifestyle or environment that may prevent seizures or decrease their frequency. Often the necessary changes are simple but can make an enormous difference in the lives of the child and family.

The most precipitating factors for seizures in children include physical and psychologic stress, sleep deprivation, fever, and illness (Novakova, Harris, Ponnusamy, et al., 2013). Other precipitating factors include flickering lights, menstrual cycle, stimulant recreational

drugs, and alcohol (Wassenaar et al., 2014). Some individuals have pattern-sensitive or photosensitive epilepsy, that is, seizures precipitated by changes in dark-light patterns, such as those that occur with a flash on a camera, automobile headlights, reflections of light on snow or water, sunlight filtered through leafy trees, or rotating blades on a fan. Most of these individuals have absence, myoclonic, or generalized tonic-clonic seizures. A small minority of children have seizures while playing video games. Only these children need to be restricted from playing video games (see Critical Thinking Case Study).

CRITICAL THINKING CASE STUDY

Seizures

Jane is a 14-year-old girl with focal epilepsy with focal seizures with impaired awareness. Her seizures have been well controlled for the past 6 years on monotherapy, with only an occasional breakthrough seizure every 3 or 4 months, often in association with a concurrent illness. Six months ago she entered high school. She is active with cheerleading and practices for 2 hours after school each day. In addition, she is taking honors English and math classes, both of which have daily homework. Jane typically does homework until midnight and gets up at 6 AM for school. For the past 3 months she has had an increasing number of seizures and is now having at least one seizure per week. She has not had any recent illnesses. Her physical and neurologic examination is normal.

Initial Assessment. Should there be concern for the increase in seizures? What could be causing this?

Clinical Reasoning. What interventions should be explored and how will you include Jane in the plans?

Teaching Points

- Precipitating factors for seizures include physical and psychologic stress, sleep deprivation, fever, and illness.
- Careful and detailed documentation of seizures over time may indicate a pattern of seizures.
- Adolescents can often identify the triggers that cause their seizures.

Critical Thinking Answers

Initial Assessment. Changes with starting high school could be a precipitating factor for the increased number of seizures Jane is experiencing. Exploring this further with her will be important, and working together to establish ways to decrease her stress is important. Her sleep pattern has changed, and strategies to improve sleep hygiene should be explored.

Clinical Reasoning. Common precipitating factors for seizures in children and adolescents include physical and psychologic stress. Jane is now in high school with many new experiences that could be new stressors for her.

Family Support

Parental attitudes and management of a child with a seizure disorder vary. Whether the seizures result from illness, injury, or unknown cause, the parents may feel guilt, anxiety, and even humiliation. They want to know if the seizures will affect their child's ability to learn and develop. Many persons erroneously associate epilepsy with mental deficiency. Seizures commonly accompany other manifestations of severe brain damage from disease or injury, but children with seizures, like any population of healthy children, display a wide range of intelligence.

Parents also wonder how the illness will affect their child's future. The answer to this question depends on the cause of the seizures and other comorbid conditions. In many cases parents can be reassured that the illness will not shorten their child's life and that their child can attend school, marry, and have children. The child may need vocational guidance. Parents need to become familiar with the laws in their state regarding any limitations imposed on people with epilepsy. For children who are severely impaired, the family needs to become familiar with local early childhood programs. The nurse should emphasize that the seizures can be controlled or greatly reduced in the large majority of affected children.

Encourage a healthy attitude toward the child and the condition and help the parents feel competent in their ability to meet their responsibilities to their child. The child should be reared in the same manner as any normal child, with natural concern tempered by understanding of the need not to overprotect. Many parents refrain from correcting or punishing their child, especially if the child has had a seizure after being disciplined. The child must not be made to feel different in any way. Encourage parents to be honest and open about the disorder with their child and with others. Some parents try to conceal the nature of their child's illness because of their belief that the disorder is shameful or a disgrace to the family.

Educational materials and support groups may prove beneficial for families. The Epilepsy Foundation[b] is a national organization that works for the welfare of persons with epilepsy and their families; helps with employment and legal problems; and provides education to patients, families, and communities.

Febrile Seizures

A febrile seizure is a seizure associated with a febrile illness in the absence of a CNS infection. By definition, children who have a febrile seizure cannot have a history of afebrile seizures, must have a temperature of at least 38°C (100.4°F), and must be between the age of 6 and 60 months (Mikati & Tchapyjnikov, 2020). Febrile seizures are the most common type of seizure, affecting 2% to 4% of children (Weiss, Masur, Shinnar, et al., 2016).

There is evidence for both genetic and environmental causes of febrile seizures. Children with a family history of febrile seizures are at increased risk for both a single febrile seizure (10% to 46%) and recurrent febrile seizures (Saghazadeh, Matrangelo, & Rezaei, 2014). In some families the predisposition to febrile seizures is inherited as an autosomal dominant trait. In most families, though, the predisposition involves multiple genes that have not yet been found (Mikati & Tchapyjnikov, 2020). Environmental factors include viral illness and age under 18 months (Mewasingh, 2014).

! NURSING ALERT

If a febrile seizure lasts more than 5 minutes, parents should seek medical attention immediately. Instruct parents to call for emergency assistance (911) and not to place the child who is actively having a seizure in the car.

Most febrile seizures have stopped by the time the child is taken to a medical facility and require no treatment. There is no benefit of antiepileptic prophylaxis in these children; patients who were started on medication are exposed to several potential adverse side effects (Offringa, Newton, Cozijnsen, et al., 2017). Parents may be given a prescription to take home for a benzodiazepine for as-needed acute treatment of prolonged recurrent febrile seizures. If the child has recurrent febrile seizures that last more than 5 minutes, acute treatment

[b]8301 Professional Place, Landover, MD 20785; 800-332-1000; http://www.epilepsyfoundation.org/. In Canada: Epilepsy Canada, 2255B Queen St. E., Suite 336, Toronto, Ontario, Canada M4E 1G3; 877-734-0873; http://www.epilepsy.ca.

with rectal diazepam, buccal lorazepam, or intranasal midazolam is recommended (Silverman, Sporer, Lemieux, et al., 2017). The child whose seizure does not stop within 10 minutes of administration of acute treatment will need treatment for febrile status epilepticus with IV administration of both short-acting and long-acting antiepileptic medications.

Antipyretic therapy during febrile illness offers symptomatic relief for fever-associated symptoms but appears to be ineffective in preventing seizures (Patel, Ram, Swiderska, et al., 2015). Parental education and emotional support are important interventions. Parents need reassurance regarding the benign nature of febrile seizures. Several large studies show no difference in intelligence, memory, behavior, or academic performance in children with febrile seizures compared with either population or sibling controls (Weiss et al., 2016).

Parents need education on what to do during a seizure, that is, turn the child on his or her side, never put anything in the child's mouth, and time the seizure. Attempts to lower the temperature will not prevent a seizure. Tepid sponge baths are not recommended for several reasons: they are ineffective in significantly lowering the temperature, the shivering effect further increases metabolic output, and cooling causes discomfort to the child. Parental education and emotional support are important interventions, and information may need to be repeated, depending on the parents' anxiety and education level.

Long-term antiepileptic therapy is usually not required for children with simple febrile seizures. Children whose initial simple febrile seizure becomes febrile status epilepticus have an increased risk of subsequent febrile status epilepticus. Risk of recurrence of a simple febrile seizure is about 30% (Hesdorffer, Shinnar, Lax, et al., 2016). The risk of developing epilepsy after having simple febrile seizures is less than 3%, whereas the risk increases to 12% to 22% if the child has had prolonged febrile seizures and febrile status epilepticus. The risk of developing epilepsy for children with simple febrile seizures is increased if they have a family history of seizures (Seinfeld, Pellock, Kjeldsen, et al., 2016).

HEADACHE

Headaches are a common complaint of children. They can be either primary or secondary. Primary headaches are classified as migraine, tension-type headache, trigeminal autonomic cephalalgias, and other primary headache disorders by the International Headache Society (2018). A secondary headache is caused from another condition and should resolve once the underlying cause is treated. Headaches can be the result of a variety of conditions, including TBI, brain tumor, brain infections, cerebrovascular disorders, withdrawal from or exposure to substances, vision problems, hunger, psychiatric disorders, and medication overuse.

ASSESSMENT

It is important to determine the pattern of the headache—acute, acute recurrent, chronic progressive, or chronic nonprogressive (Langdon & DiSabella, 2017). Other assessment information includes the presence of seizures, ataxia, lethargy, weakness, nausea or vomiting, or any personality changes. Factors related to early development and past illnesses and a family history of headaches may also be pertinent. A "headache diary," which includes time of onset and termination of headaches, intensity, associated events, and actions taken and their effects, can be helpful for the patient and provider.

Clues to etiology may be found in the family history, including information about the home or social situation (e.g., divorce, separation, alcoholism, school avoidance). Thorough physical and neurologic examinations are performed. An abnormal neurologic examination or unusual neurologic symptoms indicate the need for further diagnostic tests (e.g., CT, MRI, EEG) (Hershey, Kabbouche, O'Brien, et al., 2020).

! NURSING ALERT

During the health history and neurologic assessment, the following abnormal signs require immediate follow-up for children:

- The headache progresses in frequency and severity over a brief period (2 to 3 weeks).
- It awakens the child from sleep (may also be migraine).
- It occurs in early morning.
- It is worse on arising.
- It is characterized by persistent, occipital, or frontal pain.
- It is accompanied by unexplained vomiting.
- It is associated with a change in gait, personality, or behavior.
- It is exacerbated by Valsalva maneuver (intensified by lowering head and straining, such as during a bowel movement, coughing, or sneezing).

Tension-type headaches are common in children. They are typically frontal, the pain is described as a pressing or tightness and nonthrobbing in character, and they are not typically accompanied by nausea or vomiting.

Management of tension-type headaches begins with headache hygiene or prevention (Gofshteyn & Stephenson, 2016). This includes adequate sleep, appropriate hydration, and regular meals and exercise. If headaches continue after the child is following a headache hygiene plan, ibuprofen is usually the most effective pharmacologic intervention. To prevent medication overuse headache, children with headaches should take no more than three doses of these medications per week (Kacperski, Kabbouche, O'Brien, et al., 2016). Biofeedback, cognitive-behavioral therapy, and relaxation techniques may be useful nonpharmacologic interventions in children with recurrent tension-type headaches (Langdon & DiSabella, 2017).

MIGRAINE HEADACHE

Migraine is in the top five common childhood diseases. Migraines can have their onset in very young children, including infants where they may manifest as colic. The onset tends to be earlier in boys than girls until puberty, when girls have a twofold increase over boys in migraines. This is thought to be due to the effects of estrogen (Langdon & DiSabella, 2017).

The exact pathophysiology of migraines is not completely known. Genetics, neurotransmitters, and neurophysiologic mechanisms appear to be involved to varying degrees (Puledda, Messina, & Goadsby, 2017). Familial hemiplegic migraine has an identified autosomal dominant genetic cause. A number of other genes have been identified in diseases that that are often accompanied by migraine (Sutherland & Griffiths, 2017). Previously, it was thought that migraine headaches were caused by dilation of cerebral blood vessels; however, this is no longer thought to be correct. There is much attention on the specific vulnerability factors of the individual that leads to neuron dysfunction and the generation of the acute attack.

Revisions in the classification of migraine headaches introduced some new terms and eliminated, renamed, or reclassified others. Migraine headaches are now classified as migraine without aura and migraine with aura; the latter category includes the following subtypes: auras and prodrome, familial hemiplegic migraine, sporadic hemiplegic migraine, and basilar-type migraine (International Headache Society, 2018).

Migraines are paroxysmal. The symptoms vary depending on age. Typical symptoms include nausea, vomiting, and abdominal pain, which are relieved by sleep. Toddlers may be seen with episodic pallor, decreased activity, and vomiting. In children the onset may be bifrontal, temporal, and bilateral or unilateral. As children and adolescents advance in age, many will develop phonophobia and/or photophobia. Compared with adults, migraine headaches in children are generally shorter in duration. If the child falls asleep during the headache, the amount of time the child is asleep is counted as part of the duration (Hershey et al., 2020). A family history of migraine is elicited in up to 90% of children with migraine; 28% of all children who have migraines experience a headache before age 15 years (Hershey et al., 2020).

Like tension-type headaches, migraine management begins with headache hygiene. Keeping a headache diary can help with identifying triggers so that they can be avoided. If these measures fail to prevent migraines, both abortive and prophylactic treatment may be needed. At the onset of the headache, the child should rest or sleep in a quiet, dark room when feasible. Migraine therapy, if administered early in the course of the headache, may provide rapid relief. Ibuprofen appears to be the safest and most effective treatment if given early (Patniyot & Gelfand, 2016). Prophylactic mediation can be considered if a child is having a migraine or more per week. Riboflavin and magnesium have helped some children (Merison & Jacobs, 2016). Topiramate, an antiepileptic drug, has been approved by the US Food and Drug Administration for use in children to prevent migraine (Kacperski et al., 2016).

DRUG ALERT

Triptans

Triptans are serotonin agonists and are effective in the abortive treatment of migraines. Almotriptan, zolmitriptan, and sumatriptan are approved by the US Food and Drug Administration for use in children ages 12 to 17 years, and rizatriptan is approved for children ages 6 years and older (Patniyot & Gelfand, 2016).

The outlook for a child with migraine is good, but the child and parents should be informed that predisposition to the headaches may be lifelong. Severe headaches can adversely affect the child's routine activities of daily living, including family relations and school. Many children and families will benefit from psychotherapy.

THE CHILD WITH CEREBRAL MALFORMATION

HYDROCEPHALUS

Hydrocephalus is a condition caused by an imbalance in the production and absorption of CSF in the ventricular system. The causes of hydrocephalus are varied and include either congenital (e.g., myelomeningocele, intrauterine viral infection [cytomegalovirus, toxoplasmosis], aqueduct stenosis) or acquired conditions (e.g., intraventricular hemorrhage, tumor, CSF infection, head injury). The result is either (1) impaired absorption of CSF fluid within the subarachnoid space, obliteration of the subarachnoid cisterns, or malfunction of the arachnoid villi (nonobstructive or communicating hydrocephalus); or (2) obstruction to the flow of CSF through the ventricular system (obstructive or noncommunicating hydrocephalus) (Kinsman & Johnston, 2020).

Any imbalance of secretion and absorption causes an increased accumulation of CSF in the ventricles, which become dilated (ventriculomegaly) and compress the brain tissue against the surrounding rigid bony cranium. When this occurs before fusion of the cranial sutures, it causes enlargement of the skull and dilation of the ventricles. In children younger than 12 years old, previously closed sutures, especially the sagittal suture, may become diastatic or opened. After 12 years old, the sutures are fused and will not open.

Pathophysiology

To appreciate the condition, an understanding of the dynamics of CSF, and the relationship between the various structures that make up the ventricular and subarachnoid spaces is necessary. The two mechanisms by which CSF is formed are secretion by the choroid plexuses and lymphatic-like drainage by the extracellular fluid of the brain. CSF circulates throughout the ventricular system and is then absorbed within the subarachnoid spaces by a mechanism that is not entirely clear.

Ventricular Circulation

The fluid flows from the lateral ventricles through the foramen of Monro to the third ventricle, where it combines with fluid secreted into the third ventricle. From there CSF flows through the aqueduct of Sylvius into the fourth ventricle, where more fluid is formed; it then leaves the fourth ventricle by way of the lateral foramen of Luschka and the midline foramen of Magendie and flows into the cisterna magna. From the cisterna magna, CSF flows to the cerebral and cerebellar subarachnoid spaces where it is absorbed. A large portion is absorbed through the arachnoid villi, but the sinuses, veins, brain substance, and dura also participate in absorption.

The terms *communicating* and *noncommunicating hydrocephalus* traditionally referred to obstructive and nonobstructive types of hydrocephalus. Because other diagnostic methods are now used, the terms may be used only as a reference point in the diagnosis. Hydrocephalus can also be classified according to the cause as either congenital or acquired hydrocephalus.

Etiology

Rarely, a tumor of the choroid plexus causes increased CSF secretion. Most cases of hydrocephalus are a result of developmental malformations. Although the defect usually is apparent in early infancy, it may become evident at any time from the prenatal period to late childhood or early adulthood. Other causes include neoplasms, CNS infections (e.g., meningitis, encephalitis), and trauma (e.g., shaken baby syndrome). An obstruction to the normal flow can occur at any point in the CSF pathway to produce increased pressure and dilation of the pathways proximal to the site of obstruction.

Developmental defects (e.g., Chiari malformation [see following discussion], aqueductal stenosis, aqueductal gliosis, atresia of the foramina of Luschka and Magendie [Dandy-Walker malformation]) account for most cases of hydrocephalus from birth to 2 years of age. Dandy-Walker malformation involves dilation of the fourth ventricle, partial or complete absence of the cerebellar vermis, and enlargement of the posterior fossa resulting in hydrocephalus in about 80% of children with Dandy-Walker (Shankar, Zamora, & Castillo, 2016).

Hydrocephalus is so often associated with myelomeningocele that all such infants should be observed for its development. In the remaining cases there is a history of intrauterine infection (e.g., toxoplasmosis, cytomegalovirus), hemorrhage (e.g., posthemorrhagic hydrocephalus in preterm infants), and neonatal meningoencephalitis (bacterial or viral). In older children hydrocephalus is most often a result of intracranial masses (e.g., vascular anomalies, cysts, tumors), preexisting developmental defects, intracranial infections, trauma, or hemorrhage.

Chiari I and II Malformations

Chiari malformations are structural defects in the base of the skull and cerebellum. They occur when the lower cerebellum extends below the foramen magnum and into the upper spinal canal (Chiari I) or when the

lower cerebellum and brain stem protrude into the spinal canal through an enlarged foramen magnum (Chiari II). Chiari I malformation does not usually cause hydrocephalus. It is usually asymptomatic until adolescence, when it can cause headaches, neck pain, frequent urination, and lower limb progressive spasticity (Kinsman & Johnston, 2020). Type II Chiari malformation is seen almost exclusively with myelomeningocele and results in obstruction of CSF flow causing the hydrocephalus.

Clinical Manifestations

The three factors that influence the clinical picture in hydrocephalus are the acuity of onset, timing of onset, and associated structural malformations. In infancy, before closure of the cranial sutures, head enlargement (increasing occipitofrontal circumference [OFC]) is the predominant sign. The signs and symptoms in early to late childhood are caused by increased ICP. Specific manifestations are related to the location of the lesion.

Infancy

In infants with hydrocephalus, the head grows at an abnormal rate, although the first signs may be bulging fontanels with or without head enlargement (Fig. 27.7). The anterior fontanel is tense, often bulging, and nonpulsatile. Scalp veins are dilated, especially when the infant cries. With the increase in intracranial volume, the bones of the skull become thin and the sutures become palpably separated to produce the cracked-pot sound (***Macewen sign***) on percussion of the skull. In severe cases there may be frontal protrusion, or ***frontal bossing***, with depressed eyes, and the eyes may be rotated downward, producing a ***setting-sun sign***, in which the sclera may be visible above the iris. Pupils are sluggish, with unequal response to light.

The infant is irritable and lethargic, feeds poorly, and may display changes in LOC, opisthotonos (often extreme), and lower extremity spasticity. The infant cries when picked up or rocked and quiets when allowed to lie still. Early infantile reflexes may persist, and normally expected responses may not appear, indicating failure in the development of normal cortical inhibition.

Infants with Chiari malformations may exhibit behaviors that reflect cranial nerve dysfunction as a result of brainstem compression, including swallowing difficulties, stridor, apnea, aspiration, respiratory difficulties, and arm weakness.

The preterm infant with posthemorrhagic hydrocephalus may not exhibit any clinical signs and symptoms other than a gradual increase in head circumference. Alternatively, the nurse may note subtle seizure activity and alternating levels of consciousness. Ventricular size can be assessed by ultrasonography or CT scanning in preterm infants at high risk for intraventricular hemorrhage.

If hydrocephalus is allowed to progress, development of lower brainstem functions is disrupted, as manifested by difficulty in sucking and feeding and a shrill, brief, high-pitched cry. Eventually the skull becomes enlarged, and the cortex is destroyed. If the hydrocephalus is rapidly progressive, symptoms may include emesis, somnolence, seizures, and cardiopulmonary distress.

Childhood

The signs and symptoms in early to late childhood are caused by increased ICP, and specific manifestations are related to the location of the focal lesion. Most commonly resulting from posterior fossa neoplasms and aqueduct stenosis, the clinical manifestations are primarily those associated with space-occupying lesions (i.e., headache on awakening with improvement after emesis, papilledema, strabismus, extrapyramidal tract signs such as ataxia). As with infants, the child is irritable, lethargic, apathetic, confused, and often incoherent. In one of the congenital defects with later onset (by age 3 months), Dandy-Walker syndrome, characteristic manifestations are a bulging occiput, nystagmus, ataxia, and cranial nerve palsies.

Manifestations of Chiari malformation in children older than 3 years of age are related to spinal cord dysfunction rather than brainstem compression as observed in infants. Scoliosis proximal to the level of the myelomeningocele (usually associated with Chiari malformation) and development of upper extremity spasticity, which may progress to weakness and atrophy, are common. Cranial nerve deficits are rare.

Diagnostic Evaluation

Antenatal diagnosis of fetal ventriculomegaly, which is associated with postnatal hydrocephalus, is possible with fetal ultrasonography as early as 14 to 15 weeks of gestation, often followed by fetal MRI (Pisapia, Sinha, Zarnow, et al., 2017). There are ongoing trials in carefully selected pregnant women of fetal surgery for prevention of in utero brain damage from in utero hydrocephalus. Initial results were not

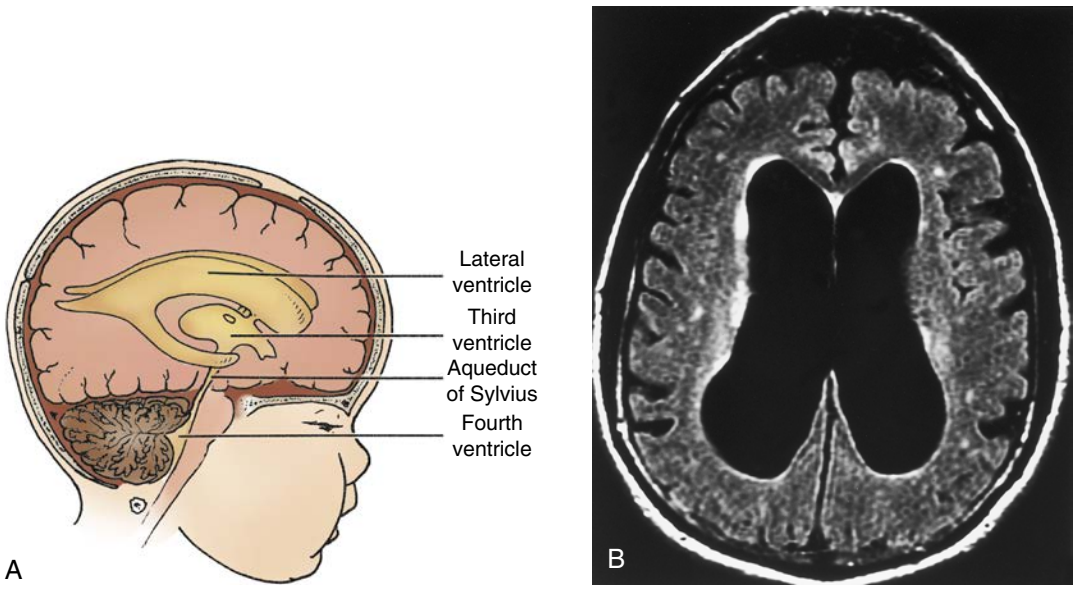

Fig. 27.7 Hydrocephalus: a block in flow of cerebrospinal fluid (CSF). **A,** Patent CSF circulation. **B,** Enlarged lateral and third ventricles caused by obstruction of circulation—stenosis of aqueduct of Sylvius.

promising, but recently outcomes have improved (Elbabaa, Gildehaus, Pierson, et al., 2017). Delivery is not currently recommended until fetal lung maturity has been achieved.

In infancy the diagnosis of hydrocephalus is based on head circumference that crosses one or more percentile lines on the head measurement chart within a period of 2 to 4 weeks and on associated neurologic signs that are progressive. However, other diagnostic studies are needed to localize the site of CSF obstruction. Routine daily head circumference measurements are carried out in infants with myelomeningocele, hemorrhage, or intrauterine viral or CNS infections. In evaluation of a preterm infant, specially adapted head circumference charts are consulted to distinguish abnormal head growth from rapid but normal head growth.

The primary diagnostic tools for detecting hydrocephalus in older infants and children are CT and MRI. Mild sedation or general anesthesia is usually required for children under age 8 years or with neurodevelopmental disabilities because the child must remain absolutely still for an accurate study. Diagnostic evaluation of children who have symptoms of hydrocephalus after infancy is similar to that used in those with a suspected intracranial tumor. In the neonate, echoencephalography is useful in comparing the ratio of lateral ventricle to cortex.

Problems in differential diagnosis are related to the child whose head circumference is greater than the 95th percentile but whose head growth parallels the normal growth curve. It is sometimes valuable to measure the parental OFC to detect a possible normal familial characteristic (benign familial megalencephaly) (see Table 27.1 for diagnostic tests for neurologic evaluation).

Therapeutic Management

The treatment of hydrocephalus is directed toward relief of ventricular pressure, treatment of the cause of the ventriculomegaly, treatment of associated complications, and management of problems related to the effect of the disorder on psychomotor development. The treatment is, with few exceptions, surgical.

Surgical Treatment

Improved neurosurgical techniques have established surgical treatment as the therapy of choice in almost all cases of hydrocephalus. This is accomplished by direct removal of an obstruction, such as resection of a neoplasm, cyst, or hematoma, or, in rare instances of fluid overproduction, by choroid plexus extirpation (plexectomy or electric coagulation). However, most children require a shunt procedure that provides primary drainage of the CSF from the ventricles to an extracranial compartment, usually the peritoneum.

Most shunt systems consist of a ventricular catheter, a flush pump, a unidirectional flow valve, and a distal catheter. All are radiopaque for easy visualization after placement, and all are tested for accuracy before insertion. A reservoir is frequently added to allow direct access to the ventricular system for administration of medications and removal of fluid. In all models the valves are designed to open at a predetermined intraventricular pressure and close when the pressure falls below that level, thus preventing backflow of fluid. Most shunts now in use have differential pressure and adjustable programmable valves with capability for changing the pressures with an external magnet, thus avoiding additional surgery.

! NURSING ALERT

Tablet computers, such as iPads, and magnetic toys may interfere with magnetically programmable shunt valve settings. They should be kept at least 2.5 cm from the shunt's valve (Strahle, Selzer, Muraszko, et al., 2012)

The standard procedure for many years has been the ***ventriculoperitoneal (VP) shunt***, especially in neonates and young infants (Fig. 27.8). There is greater allowance for excess tubing, which minimizes the number of revisions needed as the child grows. Because it requires repeated lengthening, the ventriculoatrial (VA) shunt (ventricle to right atrium) is reserved for older children who have attained most of their somatic growth and children with abdominal pathologic conditions. The VA shunt is contraindicated in children with cardiopulmonary disease or elevated CSF protein.

The initial shunt is placed when indicated based on individual assessment. The timing of revisions varies widely. In most instances, revisions are performed when physical signs indicate shunt malfunction (i.e., signs of elevated ICP). Sometimes revisions are planned for specific times during development. The initial success rate is relatively high. However, shunts are associated with complications that interfere with continued shunt function or that threaten the child's life.

Endoscopic third ventriculostomy (ETV) is a procedure that has potential for allowing greater independence from VA or VP shunting in children with obstructive hydrocephalus. ETV involves creating a small opening in the floor of the third ventricle, allowing CSF to flow freely through the previously blocked ventricle. Studies to date have not demonstrated improved short-term outcomes with ETV compared with VP shunting (Kulkarni, Sgouros, Constantini, et al., 2016). Long-term outcomes need to be studied. VP shunts have a risk of infection and shunt failure, whereas ETV does not; however, for the foreseeable future, placement of a VP shunt for treatment of hydrocephalus remains a frequent neurosurgical procedure (Venable, Rossi, Morgan Jones, et al., 2016).

Complications

The major complications of VP shunts are infection and malfunction. All shunts are subject to mechanical difficulties, such as kinking, plugging, or separation and migration of tubing. Malfunction is most often caused by mechanical obstruction either within the ventricles from particulate matter (tissue or exudate) or at the distal end from thrombosis or displacement as a result of growth. Functional obstruction of a shunt's antisiphon device remains a common complication. About 22% of shunt failures are reported within the first 90 days, the majority of these within the first month (Venable et al., 2016). The child with a shunt obstruction often is seen in an emergency visit with clinical manifestations of increased ICP, such as nausea, vomiting, irritability, and a bulging fontanel, that are frequently accompanied by worsening neurologic status.

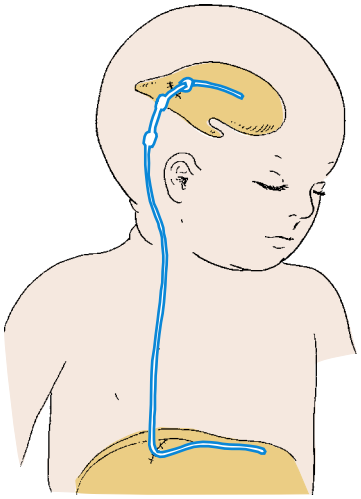

Fig. 27.8 Ventriculoperitoneal shunt. Catheter is threaded beneath skin.

One of the most common and serious complications, shunt infection, can occur at any time, but the period of greatest risk is within the first month after placement (Månsson, Johansson, Ziebell, et al., 2017). Within 2 years, shunt infection rates are reported to be approximately 5% to 10% (Månsson et al., 2017). Infections include sepsis, bacterial endocarditis, wound infection, shunt nephritis, meningitis, and ventriculitis, and may be a result of intercurrent infections at the time of shunt placement. Brain abscess associated with colonic perforation and infection with a gram-negative enteric organism suggests an ascending shunt infection in a child who has a VP shunt. Meningitis and ventriculitis are of greatest concern because any complicating CNS infection is a significant predictor of future intellectual disability. Infection is treated with antibiotics administered intravenously or intrathecally for a minimum of 7 to 10 days. The use of perioperative antibiotic prophylaxis or antibiotic-impregnated shunts has significantly decreased shunt infection rates, particularly acute infections, among all age ranges of patients and all types of shunts (Månsson et al., 2017). In addition, measures to reduce the number of people in the operating room and strictly enforced hand washing can help. A persistent infection may require removal of the shunt until the infection is controlled, and an EVD is used until CSF is sterile. EVD allows removal of CSF from a tube placed in the child's ventricle that flows by gravity into a collection device.

The primary reasons for inserting an EVD include unstable status, increased ICP that is difficult to stabilize, or infection from an existing VP shunt. The EVD may drain CSF intermittently or continuously according to need. The EVD is a closed system made up of transparent pliable tubing that should be labeled, a collection bag, and at times a drip chamber between the tubing and the collection bag. The EVD is placed at the level of the child's external auditory meatus with the head at a 20- to 30-degree elevation, depending on physician preference. Elevating the EVD above this level decreases the flow of CSF, and placing the device below the level of the external meatus increases the flow. Ambulation or sitting up in bed or a chair usually requires that the tubing be clamped to prevent imbalance in CSF drainage. In addition, the EVD is a closed sterile system. Aseptic technique should be used during any manipulation or maintenance of the EVD system, such as in relation to emptying the device or changing the scalp dressing (Hepburn-Smith et al., 2016). Accurate and frequent documentation of the incision site; amount, color, and consistency of drainage into the device; and the child's vital and neurologic signs are an important part of the nursing care.

Another serious shunt-related complication is subdural hematoma caused by too-rapid reduction of ICP and, in some cases, tentorial herniation as a result of imbalance in CSF drainage. These complications can be averted by careful assessment of ICP before insertion of the shunt and use of correct valvular pressure. Other complications that may occur include peritonitis, abdominal abscesses, perforation of abdominal organs by catheter or trocar (at the time of insertion), fistulas, hernias, and ileus. Some children require shunt lengthening as body growth occurs. This procedure usually involves replacing the distal catheter below the valve.

Prognosis

The prognosis of children with treated hydrocephalus depends largely on the cause of the dilated ventricles before shunt placement and the amount of irreversible brain damage before shunting (Kinsman & Johnston, 2020). Those children with isolated aqueductal stenosis usually function cognitively like their typically developing peers (Kahle, Kulkarni, Limbrick, et al., 2016). The neurologic disorders seen in children after shunting for hydrocephalus are most often due to the underlying cause of the hydrocephalus rather than the hydrocephalus itself (Paulsen, Lundar, & Lindegaard, 2015).

Survivors have a high incidence of intellectual disability and learning disorders, including challenges with memory, processing, and visual-spatial skills requiring special education services. Tumors, meningitis, and intraventricular hemorrhage are the conditions most closely associated with hydrocephalus accompanied by intellectual disability (Paulsen et al., 2015). Children with myelomeningocele or intraventricular hemorrhage often have motor disabilities. As with all pediatric neurologic conditions, social and behavior problems are common, including attention-deficit/hyperactivity disorder. Up to a third of children with hydrocephalus will have epilepsy (Kahle et al., 2016).

Surgically treated hydrocephalus in patients with little or no evidence of irreversible brain damage has a survival rate of about 80%, with most deaths occurring within the first year of treatment (Paulsen et al., 2015). Those with poor outcomes included children shunted for posthemorrhagic hydrocephalus or meningitis. Most children who require shunting must depend on the shunt for the remainder of their life.

Nursing Care Management

The infant with suspected or confirmed hydrocephalus is observed carefully for signs of increasing ventricular size and increasing ICP. In infants the head is measured daily at the point of largest measurement—the OFC (see Chapter 4 for technique). To avoid the likelihood of wide discrepancies, the point at which the measurements are taken is indicated on the head with a marking pen. Fontanels and suture lines are palpated for size, signs of bulging, tenseness, and separation. Irritability, lethargy, seizure activity, and altered vital signs and feeding behavior may indicate an advancing pathologic condition.

In older children, who are usually admitted to the hospital for elective or emergency shunt revision, the most valuable indicators of increasing ICP are an alteration in the child's LOC, complaint of headache, and changes in interaction with the environment. Changes are identified by observing and comparing present behavior with customary behavior, sleep patterns, developmental capabilities, and habits obtained through a detailed history and a baseline assessment. This baseline information serves as a guide for postoperative assessment and evaluation of shunt function.

The nurse is responsible for preparing the child for diagnostic tests such as MRI or a CT scan and for assisting with procedures such as a ventricular tap, which is often performed to relieve excessive pressure and to obtain CSF during the preoperative period. Sedation is required because the child must remain absolutely still during diagnostic testing. A variety of drugs are available for sedation (see Chapter 22 for preparing children for procedures). If surgery is anticipated, IV infusions should not be placed in a scalp vein.

Postoperative Care

In addition to routine postoperative care and observation, the infant or child is positioned carefully on the unoperated side to prevent pressure on the shunt valve. The child remains flat to help avert complications resulting from too-rapid reduction of intracranial fluid. The surgeon indicates the position to be maintained and the extent of activity allowed.

The nurse continues observation for signs of increased ICP that indicate obstruction of the shunt. Neurologic assessment includes pupil dilation (pressure causes compression or stretching of the oculomotor nerve, producing dilation on the same side as the pressure) and blood pressure (hypoxia to the brainstem causes variability in these vital signs). The nurse also observes for abdominal distention and constipation because CSF may cause peritonitis or a postoperative ileus as a complication of distal catheter placement.

Because infection is the greatest hazard of the postoperative period, nurses are continually on the alert for the usual manifestations of CSF infection, including elevated temperature, poor feeding, vomiting, decreased responsiveness, and seizure activity. There may be signs of local inflammation at the operative sites and along the shunt tract. Antibiotics are administered by the IV route as ordered, and the nurse may need to assist with intraventricular instillation. Inspect the incision site for leakage, and test any suspected drainage for glucose, an indication of CSF.

Family Support

Specific needs and concerns of parents during periods of hospitalization are related to the reason for the child's hospitalization (e.g., shunt revision, infection, diagnosis) and the diagnostic and surgical procedures to which the child must be subjected. Parents may have little understanding of anatomy; therefore they need further explanation and reinforcement of information that was given to them by the physician, neurosurgeon, and nurse practitioners, including information about what to expect. They are especially frightened of any procedure that involves the brain. The fear of disability or brain damage is real and pervasive. Nurses can calm their anxiety with explanations of the rationale underlying the various nursing and medical activities such as positioning or testing and by simply being available and willing to listen to their concerns.

To prepare for the child's discharge and home care, instruct the parents on how to recognize signs that indicate shunt malfunction or infection. Active children may have injuries, such as a fall, that can damage the shunt, and the tubing may pull out of the distal insertion site or become disconnected during normal growth. Contact sports such as football, rugby, boxing, and wrestling are usually prohibited if a person has a VP shunt; other sports such as swimming, soccer, and track are acceptable and even encouraged for the child's physical and emotional health. Families should consult with their child's neurosurgeon or neurosurgery nurse practitioner about activities after discharge, as providers vary in their recommendations. Helmets must be worn for skating, skiing, biking, and skateboarding. It is also important for the nurse to encourage families to enroll infants and toddlers with hydrocephalus into an early childhood development program to monitor their development and quickly address any signs that they are not keeping up with their typically developing peers.

The management of hydrocephalus in a child is a demanding task for both the family and health professionals. Helping the family cope with the child's difficulties is an important nursing responsibility. Children with hydrocephalus have lifelong special health care needs. The nurse can provide optimum primary health care, including teaching families hand hygiene and hand washing, advice on immunizations, treatments for common infectious conditions, or child care and school precautions. The overall aim is to establish realistic goals and an appropriate educational program that will assist the child in achieving the maximum potential. Families can be referred to community agencies for support and guidance. The National Hydrocephalus Foundation[c] and the Hydrocephalus Association[d] in the United States and the Spina Bifida and Hydrocephalus Association of Canada[e] provide information on the condition for families; the National Hydrocephalus Foundation also assists interested groups in establishing local organizations.

Anticipatory guidance will prepare parents for possible problems and help them avoid being overprotective of the child. Few restrictions need be placed on the child's activities (mainly contact sports), and the child is encouraged to live as would any other youngster of the same age and abilities. Parents need support and encouragement in coping with the child and problems the child may encounter in relationships with peers and others. Reactions of other children when the child has a noticeably enlarged head or requires special restrictions are stressful for both the child and the parents (see Chapter 19 for problems and coping with a child with a disability).

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. A nurse is assigned to complete the initial assessment for a 5-year-old child with a basilar skull fracture from a fall this morning. He was taken by ambulance to the Emergency Department after his older brother found him; he had tried to climb a tree in their yard and fell backwards onto the ground. When he arrived at the Emergency Department, he was awake and knew his name. Because of the severity of this type of fracture the nurse completes a comprehensive history and assessment, and findings are found below. Which are clinical manifestations of severe acute head injury and need **immediate** intervention**? Select all that apply.**
   - **A.** Retinal hemorrhages
   - **B.** Bleeding from the ear
   - **C.** Respiration = 16 breaths/min
   - **D.** Pulse oximetry 96% room air
   - **E.** Clear fluid leaking from the nose
   - **F.** Oral temperature = 100.4 F (38 C)
   - **G.** Unsteady gait when moving from wheelchair to stretcher

2. A 7-year-old child is hospitalized with fever, chills, headache and vomiting the past 2 days. She is irritable when awake but sleeps most of the time and is extremely sensitive to the light in the room. On examination she exhibits nuchal rigidity with + Kernig and Brudzinski signs. A lumbar puncture was performed to confirm the diagnosis. **Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.** This child's diagnosis most likely is _____1_____. Because of this diagnosis initial therapeutic management includes____2____. There are routine vaccinations available to prevent bacterial meningitis and includes the _____3_____ vaccine for all children beginning at 2 months of age.

Options for 1	Options for 2	Options for 3
Aplastic crisis	Intubation	meningococcal
Bacterial meningitis	Suctioning	pneumococcal
Acute chest syndrome	Isolation	polio
Reye syndrome	Vaccination	tetanus
COVID 19	blood transfusion	pertussis

3. You are working with a pediatric nurse who has just transferred to the pediatric clinic from adult surgery. You are role-playing phone triage with a mother of a 10-month-old infant with a head injury. The infant was seen in the emergency center yesterday and sent home after observation. You ascertain that the nurse needs more teaching based on what response? **Select all that apply.**
   - **A.** "Another physical examination should take place in 1 or 2 days."
   - **B.** "After initial physical examination, if there was no loss of consciousness with the head injury the infant is observed at home."
   - **C.** "If there is a language barrier, written instructions can be given, followed by discharge."
   - **D.** "Parents should call the doctor if their child has any of these signs: blurred vision, walking unsteadily, or is hard to awaken."
   - **E.** "An ultrasound of the head is needed to provide important follow-up to determine if your child had bleeding into the head."
   - **F.** "Parents should give only clear liquids to the infant for the next 24 hours."

4. The nurse is caring for an infant with hydrocephalus who is postoperative day 1 from a shunt revision. A complete assessment is performed by the nurse and findings are below. Which history and assessment findings require **immediate** follow-up for this infant. **Select all that apply.**
   - **A.** Pupil dilation
   - **B.** Abdominal distention
   - **C.** Easily awakened and cries
   - **D.** Sleeping quietly
   - **E.** Temperature of 38.2°C (100.8°F)
   - **F.** Decrease in heart rate over the last hour

CONCEPTS

- Cellular Regulation
- Glucose Regulation
- Patient Education
- Health Promotion

THE ENDOCRINE SYSTEM

The endocrine system controls and regulates metabolism; this includes energy production, growth, fluid and electrolyte balance, response to stress, and sexual development (Gardner & Shoback, 2011). This system has three components: (1) the cell that sends a chemical message using a hormone; (2) the target cells or organs, which receive the chemical message; and (3) the environment through which the chemical is transported from the site of synthesis to the site of cellular action (e.g., blood, lymph, extracellular fluids). The endocrine glands, which are distributed throughout the body, are listed in Table 28.1; also listed are several additional structures sometimes considered endocrine glands, although they are not usually included. The pathophysiology review in Fig. 28.1 provides a summary of the principle pituitary hormones and their target organs.

HORMONES

A hormone is a complex chemical substance produced and secreted into body fluids by a cell or group of cells that exerts a physiologic controlling effect on other cells (Garibaldi & Chemaitilly, 2016). These effects may be local or distant and may affect either most cells of the body or specific "target" tissues. Most hormones are released by the endocrine glands into the bloodstream, and production is regulated by a feedback mechanism (see Table 28.1). The master gland of the endocrine system is the anterior pituitary. The pituitary is responsible for stimulation and inhibition of tropic hormones. Other hormones, such as insulin, are not regulated by the pituitary gland.

DISORDERS OF PITUITARY FUNCTION

The pituitary gland is divided into two lobes: the anterior pituitary (adenohypophysis) and the posterior pituitary (neurohypophysis). It is controlled by hormones secreted from the hypothalamus. Each lobe of the pituitary is responsible for secreting different hormones. The cause of pituitary dysfunction may be organic or idiopathic and may involve one hormone or a combination of hormones. The clinical manifestations of pituitary dysfunction depend on the hormones involved and the age of the patient. Combined pituitary hormone deficiency (CPHD) is defined as the loss of more than one anterior pituitary hormone function (Gangat & Radovick, 2017). *Panhypopituitarism* is defined clinically as the loss of all anterior pituitary hormone function, leaving only posterior function intact (Toogood & Stewart, 2008).

! NURSING ALERT

Children with panhypopituitarism should wear medical identification, such as a bracelet.

HYPOPITUITARISM

Hypopituitarism or CPHD is the diminished secretion of one or more anterior pituitary hormones. The consequences of this condition depend on the degree of dysfunction and are often associated with increased risk of morbidity and mortality (Gangat & Radovick, 2017).

- Gonadotropin deficiency (decrease in luteinizing hormone [LH] or follicle-stimulating hormone [FSH]) where children show an absence or regression in secondary sex characteristics
- Growth hormone (GH) deficiency in which children display stunted somatic growth
- Thyroid-stimulating hormone (TSH) deficiency, which causes hypothyroidism
- Adrenocorticotropic hormone (ACTH) deficiency, which results in adrenal hypofunction

Hypopituitarism can result from any of the conditions listed in Box 28.1. The most common organic cause of pituitary undersecretion is a tumor in the pituitary or hypothalamic region. Craniopharyngiomas are tumors well known to invade these regions of the brain and cause panhypopituitarism. Clinical manifestations of panhypopituitarism are listed in Box 28.1. Children with panhypopituitarism should be advised to wear medical identification at all times.

Congenital hypopituitarism can be seen in newborn infants and can run in families, suggesting a genetic cause; however the majority of cases have no genetic association (Gangat & Radovick, 2017). Neonates may have symptoms of hypoglycemia and seizure activity (Schoenmaker, Alatzoglou, Chatterjee, et al., 2015). A child with combined GH deficiency and hypothyroidism should be screened for congenital pituitary defects and genetic mutations (Pine-Twaddell, Romero, & Radovick, 2013).

Idiopathic hypopituitarism, or idiopathic pituitary growth failure, is usually related to GH deficiency, which inhibits somatic growth in all cells of the body (Amin, Mushtaq, & Alvi, 2015). Isolated GH deficiency is seen in children, but these patients should be closely monitored for

TABLE 28.1 Hormones and Their Function

Hormone	Effect	Hypofunction	Hyperfunction
Adenohypophysis (Anterior Pituitary)[a]			
STH or GH (somatotropin) *Target tissue:* Bones	Promotes growth of bone and soft tissues Has main effect on linear growth Maintains a normal rate of protein synthesis Conserves carbohydrate use and promotes fat mobilization Is essential for proliferation of cartilage cells at epiphyseal plate Is ineffective for linear growth after epiphyseal closure Has hyperglycemic effect (anti-insulin action)	Epiphyseal fusion with cessation of growth Prepubertal dwarfism Pituitary cachexia (Simmonds disease) Generalized growth retardation Hypoglycemia	Prepubertal gigantism Acromegaly (after full growth is attained) DM Postpubertal hypoproteinemia
Thyrotropin (TSH) *Target tissue:* Thyroid gland	Promotes and maintains growth and development of thyroid gland Stimulates TH secretion	Hypothyroidism Marked delay of puberty Juvenile myxedema	Hyperthyroidism Thyrotoxicosis Graves disease
ACTH *Target tissue:* Adrenal cortex	Promotes and maintains growth and development of adrenal cortex Stimulates adrenal cortex to secrete glucocorticoids and androgens	Acute adrenocortical insufficiency (Addison disease) Hypoglycemia Increased skin pigmentation	Cushing syndrome
Gonadotropins *Target tissue:* Gonads	Stimulate gonads to mature and produce sex hormones and germ cells	Absent or incomplete spontaneous puberty	Precocious puberty Early epiphyseal closure
FSH *Target tissue:* Ovaries, testes	*Male:* Stimulates development of seminiferous tubules; initiates spermatogenesis *Female:* Stimulates Graafian follicles to mature and secrete estrogen	Hypogonadism Sterility Absence or loss of secondary sex characteristics Amenorrhea	Precocious puberty Primary gonadal failure Hirsutism Polycystic ovary Early epiphyseal closure
LH[b] *Target tissue:* Ovaries, testes	*Male:* Stimulates differentiation of Leydig cells, which secrete androgens, principally testosterone *Female:* Produces rupture of follicle with discharge of mature ovum; stimulates secretion of progesterone by corpus luteum	Hypogonadism Sterility Impotence Absence or loss of secondary sex characteristics Ovarian failure Eunuchism	Precocious puberty Primary gonadal failure Hirsutism Polycystic ovary Early epiphyseal closure
Prolactin (luteotropic hormone) *Target tissue:* Ovaries, breasts	Stimulates milk secretion Maintains corpus luteum and progesterone secretion during pregnancy	Inability to lactate Amenorrhea	Galactorrhea Functional hypogonadism
MSH *Target tissue:* Skin	Promotes pigmentation of skin	Diminished or absent skin pigmentation	Increased skin pigmentation
Neurohypophysis (Posterior Pituitary)			
ADH (vasopressin) *Target tissue:* Renal tubules	Acts on distal and collecting tubules, making them more permeable to water, thus increasing reabsorption and decreasing excretion of urine	DI	SIADH Fluid retention Hyponatremia
Oxytocin *Target tissue:* Uterus, breasts	Stimulates powerful contractions of uterus Causes ejection of milk from alveoli into breast ducts (letdown reflex)		
Thyroid			
THs: T_4 and T_3	Regulate metabolic rate; control rate of growth of body cells Especially important for growth of bones, teeth, and brain Promote mobilization of fats and gluconeogenesis	Hypothyroidism Myxedema Hashimoto thyroiditis General growth greatly reduced; extent dependent on age at which deficiency occurs Intellectual disability in infant	Exophthalmic goiter (Graves disease) Accelerated linear growth Early epiphyseal closure
Thyrocalcitonin	Regulates calcium and phosphorus metabolism Influences ossification and development of bone		
Parathyroid Glands			
PTH	Promotes calcium reabsorption from blood, bone, and intestines Promotes excretion of phosphorus in kidney tubules	Hypocalcemia (tetany)	Hypercalcemia (bone demineralization) Hypophosphatemia

TABLE 28.1 Hormones and Their Function—cont'd

Hormone	Effect	Hypofunction	Hyperfunction
Adrenal Cortex			
Mineralocorticoids Aldosterone	Stimulate renal tubules to reabsorb sodium, thus promoting water retention but potassium loss	Adrenocortical insufficiency	Electrolyte imbalance Hyperaldosteronism
Sex hormones: Androgens, estrogens, progesterone	Influence development of bone, reproductive organs, and secondary sex characteristics	Male feminization	Adrenogenital syndrome
Glucocorticoids Cortisol (hydrocortisone and compound F) Corticosterone (compound B)	Promote normal fat, protein, and carbohydrate metabolism Mobilize body defenses during periods of stress Suppress inflammatory reaction	Addison disease Acute adrenocortical insufficiency Impaired growth and sexual function	Cushing syndrome Severe impairment of growth with slowing in skeletal maturation In excess, tend to accelerate gluconeogenesis and protein and fat catabolism
Adrenal Medulla			
Epinephrine (adrenaline), norepinephrine (noradrenaline)	Produce vasoconstriction of heart and smooth muscles (raise blood pressure) Increase blood glucose via glycolysis Inhibit GI activity Activate sweat glands		Hyperfunction caused by: • Pheochromocytoma • Neuroblastoma • Ganglioneuroma
Islets of Langerhans of Pancreas			
Insulin (β cells)	Promotes glucose transport into the cells Increases glucose use, glycogenesis, and glycolysis Promotes fatty acid transport into cells and lipogenesis Promotes amino acid transport into cells and protein synthesis	DM	Hyperinsulinism
Glucagon (α cells)	Acts as antagonist to insulin, thereby increasing blood glucose concentration by accelerating glycogenolysis Able to inhibit secretion of both insulin and glycogen		Hyperglycemia May be instrumental in genesis of DKA in DM
Somatostatin (δ cells)	Able to inhibit secretion of both insulin and glycogen		
Ovaries			
Estrogen	Accelerates growth of epithelial cells, especially in uterus after menses Promotes protein anabolism Promotes epiphyseal closure of bones Promotes breast development during puberty and pregnancy Plays role in sexual function Stimulates water and sodium reabsorption in renal tubules Stimulates ripening of ova	Lack of or repression of sexual development	Precocious puberty, early epiphyseal closure
Progesterone	Prepares uterus for nidation of fertilized ovum and aids in maintenance of pregnancy Aids in development of alveolar system of breasts during pregnancy Inhibits myometrial contractions Has effect on protein catabolism Promotes salt and water retention, especially in endometrium		
Testes			
Testosterone	Accelerates protein anabolism for growth Promotes epiphyseal closure Promotes development of secondary sex characteristics Plays role in sexual function Stimulates testes to produce spermatozoa	Delayed sexual development or eunuchoidism	Precocious puberty, early epiphyseal closure

ACTH, Adrenocorticotropic hormone; *ADH,* antidiuretic hormone; *DI,* diabetes insipidus; *DKA,* diabetic ketoacidosis; *DM,* diabetes mellitus; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GI,* gastrointestinal; *LH,* luteinizing hormone; *MSH,* melanocyte-stimulating hormone; *PTH,* parathyroid hormone; *SIADH,* syndrome of inappropriate antidiuretic hormone secretion; *STH,* somatotropin hormone; T_3, triiodothyronine; T_4, thyroxine; *TH,* thyroid hormone; *TSH,* thyroid-stimulating hormone.

[a]For each anterior pituitary hormone there is a corresponding hypothalamic-releasing factor. A deficiency in these factors caused by inhibiting anterior pituitary hormone synthesis produces the same effects. (See text for more detailed information.)

[b]In males, LH is sometimes known as interstitial cell–stimulating hormone (ICSH).

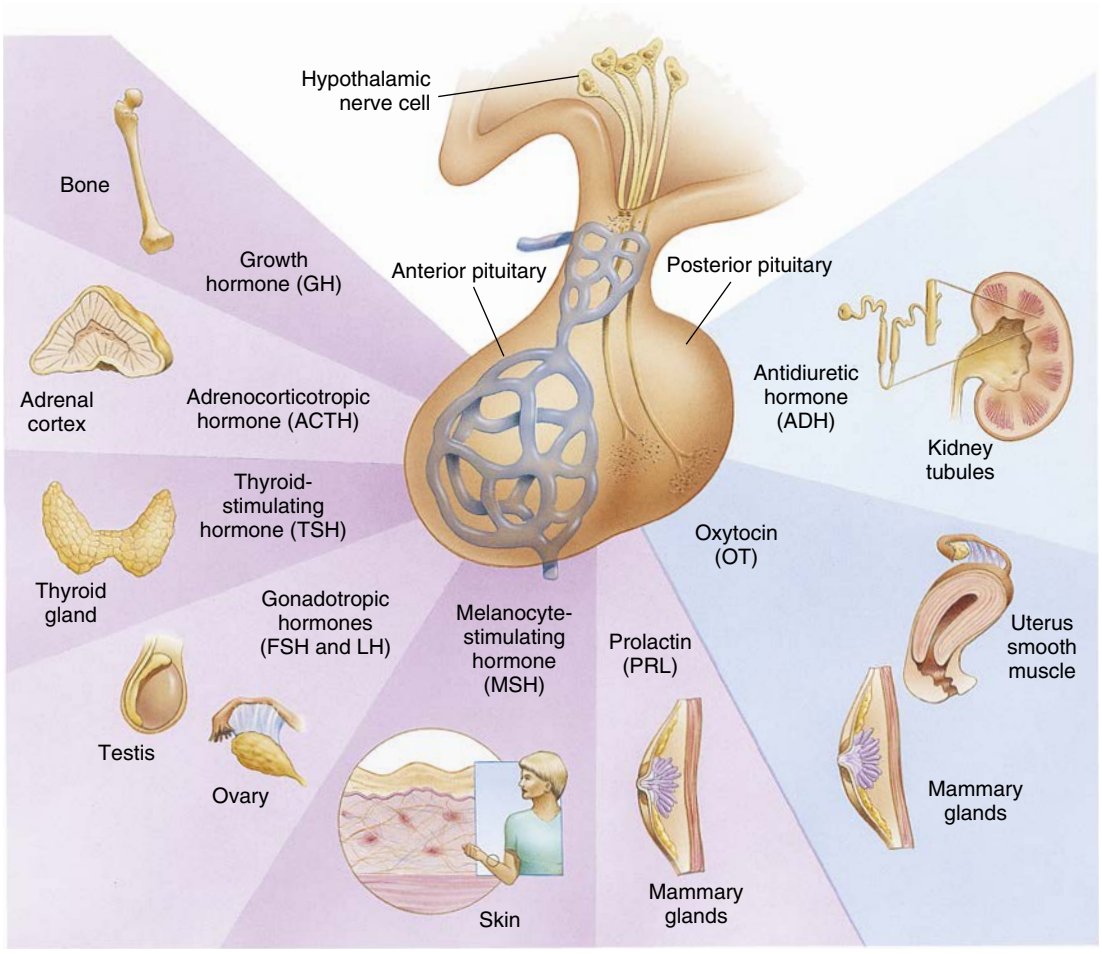

Fig. 28.1 Principal anterior and posterior pituitary hormones and their target organs. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone. (From Patton, K. T., & Thibodeau, G. A. [2013]. *Anatomy and physiology* [8th ed.]. St. Louis, MO: Mosby/Elsevier.)

BOX 28.1 Clinical Manifestations of Panhypopituitarism

Growth Hormone
Short stature but proportional height and weight
Delayed epiphyseal closure
Retarded bone age proportional to height
Premature aging common in later life
Increased insulin sensitivity

Thyroid-Stimulating Hormone
Short stature with infantile proportions
Dry, coarse skin; yellow discoloration, pallor
Cold intolerance
Constipation
Somnolence
Bradycardia
Dyspnea on exertion
Delayed dentition, loss of teeth

Gonadotropins
Absence of sexual maturation or loss of secondary sexual characteristics
Atrophy of genitalia, prostate gland, breasts
Amenorrhea without menopausal symptoms
Decreased spermatogenesis

Adrenocorticotropic Hormone
Severe anorexia, weight loss
Hypoglycemia
Hypotension
Hyponatremia, hyperkalemia
Adrenal apoplexy, especially in response to stress
Circulatory collapse

Antidiuretic Hormone
Polyuria
Polydipsia
Dehydration

Melanocyte-Stimulating Hormone
Decreased pigmentation

the development of other pituitary hormone deficiencies (Cerbone & Datanni, 2017). Growth failure is defined as an absolute height of less than −2 standard deviation (SD) for age or a linear growth velocity consistently less than −1 SD for age. When this occurs without the presence of hypothyroidism, systemic disease, or malnutrition, an abnormality of the GH–insulin-like growth factor (IGF-I) axis should be considered (Grimberg, Divall, Polychronakos, et al., 2016).

However, not all children with short stature have GH deficiency. In most instances, the cause is considered idiopathic. Most children with idiopathic short stature (ISS) have either familial short stature or constitutional growth delay. **Familial short stature** refers to otherwise healthy children who have ancestors with adult height in the lower percentiles. **Constitutional delay of growth and puberty** refers to individuals (usually boys) with delayed linear growth, with skeletal and sexual maturation that is behind that of age-mates (Amin et al., 2015). GH therapy in children with ISS continues to be debated frequently by pediatric endocrinologists (Murray, Dattani, & Clayton, 2016). New guidelines recommend the clinical management of children with growth failure related to GH deficiency and ISS. They now include recombinant IGF-1 therapy for primary IGF-1 deficiency (Grimberg et al., 2016).

Clinical Manifestations

Children with GH deficiency generally grow normally during the first year and then follow a slowed growth curve that is below the 3rd percentile. These children may appear overweight or obese due to stunted height in combination with good nutrition. A nourished appearance is an important diagnostic clue that may differentiate patients with GH deficiency from patients with failure to thrive. Sexual development is usually delayed but is otherwise normal unless the gonadotropin hormones are deficient. Growth may extend into the third or fourth decade of life, but permanent height is usually diminished if the disorder is left untreated. Because of an underdeveloped jaw, teeth may be crowded or malpositioned.

Diagnostic Evaluation

Only a small number of children with delayed growth or short stature have hypopituitary dysfunction. Diagnostic evaluation is aimed at isolating organic causes, which, in addition to GH deficiency, may include tumor growth, hypothyroidism, oversecretion of cortisol, gonadal aplasia, chronic illness, nutritional inadequacy, Russell-Silver dwarfism, or hypochondroplasia. A detailed family history, growth history and previous health status, physical examination, and psychosocial evaluation are important. Specific radiographic imaging, including magnetic resonance imaging (MRI), endocrine studies, and genetic testing, may be warranted (Stanley, 2012). Accurate measurement of height and weight and comparison of these measures with standard growth charts are essential. Multiple height measures reflect a more accurate assessment of abnormal growth patterns (Box 28.2). Parental height and familial patterns of growth are important clues to diagnosis. A skeletal survey in children younger than 3 years old and radiographic examination of the hand and wrist for centers of ossification (bone age) (Box 28.3) in older children are important in evaluating growth.

A definitive diagnosis of GH deficiency is based on absent or subnormal reserves of pituitary GH. Because GH levels are variable in children, GH stimulation testing is usually required for diagnosis. It is recommended that GH stimulation tests be reserved for children with low serum IGF-I and insulin-like growth factor binding protein 3 (IGFBP3) levels and poor growth who do not have other causes for short stature (Hokken-Koelega, 2011). GH stimulation testing involves the use of pharmacologic agents such as levodopa, clonidine, arginine, insulin, propranolol, or glucagon, followed by the measurement of GH blood levels (Patterson & Felner, 2020). Children with poor linear growth, delayed bone age, and abnormal GH stimulation tests are considered GH deficient. New reference standards that decrease the lower limit of normal GH levels have been proposed and continue to be debated (Murray et al., 2016).

BOX 28.2 Evaluating the Growth Curve

Ensure reliability of measurements: Accurately obtain and plot height and weight measurements.

Determine absolute height: The child's absolute height bears some relationship to the likelihood of a pathologic condition. However, most children who have a height below the lowest percentile (either the 3rd or 5th percentile on the height curve) do not have a pathologic growth problem.

Assess height velocity: The most important aspect of a growth evaluation is the observation of a child's height over time, or height velocity. Accurate determination of height velocity requires at least 4 and preferably 6 months of observation. A substantial deceleration in height velocity (crossing several percentiles) between 3 and 12 or 13 years of age indicates a pathologic condition until proven otherwise.

Determine weight-to-height relationship: Determination of the weight-to-height ratio has some diagnostic value in ascertaining the cause of growth retardation in a short child.

Project target height: The height of a child can be judged inappropriately short only in the context of his or her genetic potential. Determine the target height of the child with the formula:

$$[\text{Father's height (cm)} + \text{Mother's height (cm)} + 13] / 2 \text{ for boys}$$

or

$$[\text{Father's height (cm)} + \text{Mother's height (cm)} - 13] / 2 \text{ for girls}$$

Most children achieve an adult stature within approximately 10 cm (4 inches) of the target height.

Modified from Vogiatzi, M. G., & Copeland, K. C. (1998). The short child. *Pediatrics in Review, 19*(3), 92–99.

BOX 28.3 Bone Age for Evaluating Growth Disorders

Bone age refers to a method of assessing skeletal maturity by comparing the appearance of representative epiphyseal centers obtained on x-ray examination with age-appropriate published standards.

Most conditions that cause poor linear growth also cause a delay in skeletal maturation and a retarded bone age. Observation of even a profoundly delayed bone age is never diagnostic or even indicative of a specific diagnosis. A delayed bone age merely indicates that the associated short stature is to some extent "partially reversible" because linear growth will continue until epiphyseal fusion is complete. In comparison, a bone age that is not delayed in a short child is of much greater concern and may, in fact, be of some diagnostic value under certain circumstances.

Modified from Vogiatzi, M. G., & Copeland, K. C. (1998). The short child. *Pediatrics in Review, 19*(3), 92–99.

Therapeutic Management

Treatment of GH deficiency caused by organic lesions is directed toward correction of the underlying disease process (e.g., surgical removal or irradiation of a tumor). The definitive treatment of GH deficiency is replacement of GH, which is successful in 80% of affected

children. Biosynthetic GH is administered subcutaneously on a daily basis. Growth velocity increases in the first year of treatment and then declines in subsequent years (Patterson & Felner, 2020). Final height is likely to remain less than normal (Bryant, Baxter, Cave, et al., 2007; Deodati & Cianfarani, 2011), and early diagnosis and intervention are essential.

The decision to stop GH therapy is made jointly by the child, family, and health care team. Growth rates of less than 1 inch per year and a bone age of more than 14 years in girls and more than 16 years in boys are often used as criteria to stop GH therapy (Patterson & Felner, 2020).

Nursing Care Management

The principal nursing consideration is identifying children with growth problems. Even though the majority of growth problems are not a result of organic causes, any delay in normal growth and sexual development may pose special emotional adjustments for these children.

The nurse may be a key person in helping establish a diagnosis. For example, if serial height and weight records are not available, the nurse can question parents about the child's growth compared with that of siblings, peers, or relatives. Preparation of the child and family for diagnostic testing is especially important if a number of tests are being performed, and the child requires particular attention during testing. Blood samples are usually taken every 30 minutes for a 3-hour period. Children also have difficulty overcoming hypoglycemia generated by tests with insulin, so they must be observed carefully for signs of hypoglycemia. Those receiving glucagon are at risk of nausea and vomiting. Clonidine may cause hypotension, requiring administration of intravenous (IV) fluids.

Child and Family Support

Children undergoing hormone replacement require additional support. The nurse should provide education for patient self-management during the school-age years. Nursing functions include family education concerning medication preparation and storage, injection sites, injection technique, and syringe disposal (see Chapter 20). Administration of GH is facilitated by family routines that include a specific time of day for the injection.

> **NURSING TIP:** Optimum dosing is often achieved when growth hormone (GH) is administered at bedtime. The pituitary release of GH occurs during the first 45 to 90 minutes after the onset of sleep.

Even when hormone replacement is successful, these children attain their eventual adult height at a slower rate than their peers; therefore they need assistance in setting realistic expectations regarding improvement. Because these children appear younger than their chronologic age, others may relate to them in infantile or childish ways. Families should be counseled to set realistic expectations for the child based on age and abilities. For example, in the home, such children should have the same age-appropriate responsibilities as their siblings. As they approach adolescence, they should be encouraged to participate in group activities with peers. If abilities and strengths rather than physical size are emphasized, such children are more likely to develop a positive self-image.

Professionals and families can find resources for research, education, support, and advocacy from the Human Growth Foundation.[a]

[a]997 Glen Cove Ave., Suite 5, Glen Head, NY 11545; 800-451-6434; email: hgf1@hgfound.org; http://www.hgfound.org.

Treatment is expensive, but the cost is often partially covered by insurance if the child has a documented deficiency.

PITUITARY HYPERFUNCTION

Excess GH before closure of the epiphyseal shafts results in proportional overgrowth of the long bones until the individual reaches a height of 2.4 m (8 feet) or more. Vertical growth is accompanied by rapid and increased development of muscles and viscera. Weight is increased but is usually in proportion to height. Proportional enlargement of head circumference also occurs and may result in delayed closure of the fontanels in young children. Children with a pituitary-secreting tumor may also demonstrate signs of increasing intracranial pressure, especially headache.

If oversecretion of GH continues after epiphyseal closure (growth plate), growth occurs in the transverse direction, producing a condition known as **acromegaly**. Typical facial features include overgrowth of the head, lips, nose, tongue, jaw, and paranasal and mastoid sinuses; separation and malocclusion of the teeth in the enlarged jaw; disproportion of the face to the cerebral division of the skull; increased facial hair; thickened, deeply creased skin; and an increased tendency toward hyperglycemia and diabetes mellitus (DM). Acromegaly can develop slowly, leading to delays in diagnosis and treatment. Patients with acromegaly have a higher mortality rate due to an increased risk of cardiovascular, metabolic, skeletal, and pulmonary complications (Pivonello, Auriemma, Grasso, et al., 2017).

Diagnostic Evaluation

Excessive secretion of GH by a pituitary adenoma causes most cases of acromegaly (Colao, Grasso, Giustina, et al., 2019). Diagnosis is based on a history of excessive growth during childhood and evidence of increased levels of GH and IGF-1 (Colao et al., 2019). MRI may reveal a tumor or an enlarged sella turcica, normal bone age, enlargement of bones (e.g., the paranasal sinuses), and evidence of joint changes. Endocrine studies to confirm excess of other hormones, specifically thyroid, cortisol, and sex hormones, should also be included in the differential diagnosis.

Therapeutic Management

If a pituitary lesion is present, surgery may be performed to remove the tumor. Other therapies aimed at destroying pituitary tissue include external irradiation and radioactive implants. Pharmacologic agents, including somatostatin receptor ligands, dopamine agonists, or GH receptor antagonists, have been used individually or in combination with other treatment modalities to treat acromegaly (Colalo et al., 2019).

Nursing Care Management

Nurses can actively assist in the identification of children with excessive growth rates. Although medical management is unable to reduce a patient's height, further growth can be prevented. If treatment for acromegaly is initiated early, it improves a patient's chance of maintaining normal adult height. Nurses should also observe for signs of a tumor, especially headache, and evidence of concurrent hormonal excesses, particularly the gonadotropins, which cause sexual precocity. Children with excessive growth rates require as much emotional support as those with short stature.

PRECOCIOUS PUBERTY

It is now accepted that puberty is occurring earlier than in previous generations likely due to changes in hormonal, genetic, environmental, and nutritional factors over time (Alotaibi, 2019). Traditionally,

BOX 28.4 Causes of Precocious Puberty

Central Precocious Puberty

Idiopathic, with or without hypothalamic hamartoma

Secondary

- Congenital anomalies
- Postinflammatory: Encephalitis, meningitis, abscess, granulomatous disease
- Radiotherapy
- Trauma
- Neoplasms

After effective treatment of long-standing pseudosexual precocity

Peripheral Precocious Puberty

Familial male-limited precocious puberty

Albright syndrome

Gonadal or extragonadal tumors

Adrenal

- Congenital adrenal hyperplasia (CAH)
- Adenoma, carcinoma
- Glucocorticoid resistance

Exogenous sex hormones

Primary hypothyroidism

Incomplete Precocious Puberty

Premature thelarche

Premature menarche

Premature pubarche or adrenarche

Modified from Root, A. W. (2000). Precocious puberty. *Pediatrics in Review, 21*(1), 10–19.

sexual development before 9 years old in boys and 8 years old in girls is considered precocious, warranting further evaluation (Brito, Spinola-Castro, Kochi et al., 2016). New guidelines define puberty as precocious if it occurs in Caucasian girls younger than 7 years old and African-American girls younger than 6 years old (Brito, Spinola-Castro, Kochi, et al., 2016). Although previous data suggest that boys may be beginning maturation earlier as well (Herman-Giddens, 2006; Slyper, 2006), no changes have been made to the guidelines for evaluation of precocious puberty in boys (Brito et al., 2016).

Normally, the hypothalamic-releasing factors stimulate secretion of the gonadotropic hormones from the anterior pituitary at the time of puberty. In boys, interstitial cell–stimulating hormone stimulates Leydig cells of the testes to secrete testosterone; in girls, FSH and LH stimulate the ovarian follicles to secrete estrogens (Nebesio & Eugster, 2007). This sequence of events is known as the **hypothalamic-pituitary-gonadal axis**. If for some reason the cycle undergoes premature activation, the child will display evidence of advanced or precocious puberty. Causes of precocious puberty are found in Box 28.4.

Most children with precocious puberty have **central precocious puberty (CPP)**, in which pubertal development is stimulated by hypothalamic gonadotropin-releasing hormone (GnRH), following the same pattern as in normal puberty (Aguirre & Eugster, 2018). This produces early maturation and development of the gonads with secretion of sex hormones, development of secondary sex characteristics, and sometimes production of mature sperm and ova (Garibaldi & Chemaitilly, 2020). CPP may be the result of congenital anomalies; infectious, neoplastic, or traumatic insults to the central nervous system (CNS); or treatment of long-standing sex hormone exposure (Trivin, Couto-Silva, Sainte-Rose, et al, 2006). CPP occurs more frequently in girls and is usually idiopathic, with 90% to 95% demonstrating no causative factor (Aguirre & Eugster, 2018; Greiner & Kerrigan, 2006; Li, Li, & Yang, 2014; Nebesio & Eugster, 2007).

Peripheral precocious puberty (PPP) includes early puberty resulting from hormone stimulation other than the hypothalamic GnRH–stimulated pituitary gonadotropin release. Isolated manifestations that are usually associated with puberty may be seen as variations in normal sexual development (Brito et al., 2016). They appear without other signs of pubescence and are caused by excess secretion of sex hormones through the gonads or adrenal glands and may be isosexual or contrasexual. Included are premature thelarche (development of breasts in prepubertal girls), premature pubarche (premature adrenarche, early development of sexual hair), and premature menarche (isolated menses without other evidence of sexual development).

Therapeutic Management

Identification of precocious puberty warrants a referral to an endocrinologist for evaluation. Early exposure of growth plates to sex hormones can cause premature closure of the epiphyses, resulting in short stature. The goal of treatment is to prevent exposure and allow a child to achieve adult height (Chen & Eugster, 2015). Treatment of precocious puberty is directed toward the specific cause when known. In 50% of cases, precocious pubertal development regresses or stops advancing without any treatment (Carel & Léger, 2008). CPP usually is managed with monthly injections of a synthetic analog of **luteinizing hormone–releasing hormone (Lupron Depot)** in the United States (Chen & Eugster, 2015). The available preparation, leuprolide acetate (Lupron Depot), is given once every 4 to 12 weeks depending on the preparation. An alternative treatment is the GnRH analog (GnRHa) histrelin implant, which is placed subcutaneously in the upper arm and suppresses LH and testosterone levels for 1 to 2 years (Chen & Eugster, 2015; Garibaldi & Chemaitilly, 2020). Studies suggest that not all patients attain adult target heights with these treatments. The use of GH to improve adult height is being investigated in children with precocious puberty and advanced bone age (Garibaldi & Chemaitilly, 2020). Treatment for precocious puberty is discontinued at a chronologically appropriate time, allowing pubertal changes to resume.

Nursing Care Management

Both parents and the affected child should be taught to perform injections using return demonstration if possible. Psychological support and guidance of the child and family are the most important aspects of management. Parents need anticipatory guidance, support, information resources, and reassurance. GnRH agonists are associated with side effects such as headache, emotional lability, and vasodilation causing hot flashes (Harrington & Palmert, 2016). Nurses are essential in providing medical education to the patient and family. Dress and activities for the physically precocious child should be appropriate to the chronologic age. Sexual interest is not usually advanced beyond the child's chronologic age, and parents need to understand that the child's mental age is congruent with the chronologic age.

DIABETES INSIPIDUS

The principal disorder of posterior pituitary hypofunction is diabetes insipidus (DI), also known as **neurogenic DI** or **central DI**, which results from undersecretion of **antidiuretic hormone (ADH)**, or **vasopressin** (Pitressin), producing a state of uncontrolled diuresis (polyuria) and excessive thirst and water intake (polydipsia) (Levy, Prentice, & Wass, 2019). This disorder is not to be confused with nephrogenic DI, a rare hereditary disorder affecting primarily males and caused by unresponsiveness of the renal tubules to vasopressin. Nephrogenic DI

can also be cause by electrolyte disturbance, renal disease, or medications such as lithium (Levy et al., 2019).

Central DI may result from a number of different causes. Primary causes are familial or idiopathic; of the total cases, approximately 20% to 50% are idiopathic (Di Iorgi, Allegri, Napoli, et al., 2014). Secondary causes include trauma (accidental or surgical), tumors, granulomatous disease, infections (meningitis or encephalitis), and vascular anomalies (aneurysm). Certain drugs, such as alcohol and phenytoin (diphenylhydantoin), can cause a transient polyuria. DI may be an early sign of an evolving cerebral process (Di Iorgri, Napoli, Allegri, et al., 2012).

The cardinal signs of DI are polyuria and polydipsia. In older children, signs such as excessive urination accompanied by a compensatory insatiable thirst may be so intense that the child does little more than go to the toilet and drink fluids. Frequently, the first sign is enuresis. In infants, the initial symptom is irritability that is relieved with feedings of water but not milk. These infants are also prone to dehydration, electrolyte imbalance, hyperthermia, azotemia, and potential circulatory collapse.

Dehydration is usually not a serious problem in older children, who are able to drink larger quantities of water. However, any period of unconsciousness (such as after trauma or anesthesia) may be life threatening because the voluntary demand for fluid is absent. During such instances, careful monitoring of urine volumes, blood concentration, and IV fluid replacement is essential to prevent dehydration.

! NURSING ALERT

Children with diabetes insipidus (DI) complicated by congenital absence of the thirst center must be encouraged to drink sufficient quantities of liquid to prevent electrolyte imbalance.

Diagnostic Evaluation

The simplest test used to diagnose this condition is restriction of oral fluids using the water deprivation test and observation of consequent changes in urine volume and concentration. Normally, reducing fluid intake results in concentrated urine and diminished volume. In DI, fluid restriction has little or no effect on urine formation and urine osmolality (Levy et al., 2019). If urine output decreases and urine osmolality increases during the water deprivation test, DI may be excluded (Levy et al., 2019). Accurate results from this procedure require strict monitoring of fluid intake and urinary output, measurement of urine concentration (specific gravity or osmolality), and frequent weight checks. A weight loss between 3% and 5% indicates significant dehydration and requires termination of the fluid restriction. An MRI should be performed to look for secondary causes of central DI, such as a tumor or central brain anomaly (Di Iorgi et al., 2012).

! NURSING ALERT

Small children require close observation during fluid deprivation to prevent them from drinking, even from toilet bowls, flower vases, and other unlikely sources of fluid.

If a water deprivation test is positive, the child should be given a test dose of **desmopressin (DDAVP)**, which should alleviate the polyuria and polydipsia. Unresponsiveness to exogenous vasopressin usually indicates nephrogenic DI. An important diagnostic consideration is to differentiate DI from other causes of polyuria and polydipsia, especially DM.

Therapeutic Management

The usual treatment for DI is hormone replacement using DDAVP, which is a synthetic analog of the endogenous hormone arginine vasopressin (AVP). DDAVP can be administered orally, intranasally, or parentrally. The intranasal and oral forms of DDAVP are most commonly used in children. Oral DDAVP has few complications and is easier to give, which likely increases compliance (Di Iorgi et al., 2012).

NURSING TIP: To be effective, injectable desmopressin must be thoroughly resuspended before administration. If this is not done, the oil may be injected minus the antidiuretic hormone (ADH). Small brown particles, which indicate drug dispersion, must be seen in the suspension.

Nursing Care Management

An early sign of DI may be sudden enuresis in a child who is toilet trained. Excessive thirst with concurrent bedwetting indicates further investigation. Another clue is persistent irritability and crying in an infant that is relieved only by bottle feedings of water. After head trauma or certain neurosurgical procedures, the development of DI can be anticipated; therefore these patients must be closely monitored.

Nursing assessment includes frequent measurements of a patient's weight, serum electrolytes, blood urea nitrogen (BUN), hematocrit, and urine specific gravity. Fluid intake and output should be measured frequently and recorded. Alert patients are able to adjust fluid intake, but unconscious or very young patients require closer fluid observation. In children who are not toilet trained, collection of urine specimens may require application of a urine-collecting device.

After confirmation of DI, parents need comprehensive teaching. Specific clarification that DI is a different condition from DM should be reinforced. Parents and children must realize that treatment is lifelong. Caregivers should be taught the correct procedure for preparation and administration of vasopressin. When children are old enough, they should be encouraged to assume full responsibility for their care.

For emergency purposes, children with DI should wear medical alert identification. Older children should carry the nasal spray with them for temporary relief of symptoms. School personnel need to be aware of a child's diagnosis so that they can grant children unrestricted use of the lavatory. When admitted to the hospital, close attention should be paid to the scheduled doses of vasopressin. Missed doses or dosing errors could cause severe electrolyte abnormalities, causing significant harm or even death (Levy et al., 2019).

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

The disorder that results from hypersecretion of ADH from the posterior pituitary hormone is known as syndrome of inappropriate antidiuretic hormone secretion (SIADH). It is observed with increased frequency in a variety of conditions, including infections, tumors, CNS disease, trauma, or medication use, and it is one of the most common causes of hyponatremia in hospitalized children (Moritz, 2019).

The manifestations are directly related to fluid retention and hyponatremia. Excess ADH causes most of the filtered water to be reabsorbed from the kidneys back into central circulation. Serum osmolality is low, and urine osmolality is inappropriately elevated. When serum sodium levels are diminished to 120 mEq/L, affected children may display anorexia, nausea, vomiting, stomach cramps, irritability, weakness, confusion, and personality changes. With progressive

reduction in sodium, other neurologic signs, including stupor and seizure, may occur. When hyponatremia occurs acutely, swelling of the brain may occur. This is a medical emergency and can cause irreversible brain damage or even death (Giuliani & Peri, 2014). Children are at increased risk for developing hyponatremic encephalopathy when compared to adults (Moritz, 2019).

Fluid restriction is the first management of SIADH. Subsequent management depends on the cause and severity. Fluids continue to be restricted to one-fourth to one-half maintenance. When there are no fluid abnormalities but SIADH can be anticipated, fluids are often restricted expectantly at two-thirds to three-fourths maintenance.

! NURSING ALERT

Early symptoms of SIADH can be easily attributed to other causes: headache, nausea, vomiting, weakness, and general malaise (Moritz, 2019). These symptoms may precede the onset of more severe stages, such as disorientation, confusion, coma, and seizures (Gardner & Shoback, 2011).

Nursing Care Management

The first goal of nursing management is recognizing the presence of SIADH from symptoms described in patients at risk.

Accurately measuring intake and output, noting daily weight, and observing for signs of fluid overload are primary nursing functions and are essential when children are receiving IV fluids. Seizure precautions and neurologic checks may be implemented when a hospitalized child has SIADH. Hyponatremic encephalopathy is a medical emergency requiring hypertonic sodium chloride (3%) administration (Moritz, 2019). Patients and families need education on the rationale for fluid restrictions. The rare child with chronic SIADH will be placed on long-term ADH-antagonizing medication, and the child and family will require instructions for administration.

DISORDERS OF THYROID FUNCTION

The thyroid gland secretes two types of hormones: **thyroid hormone (TH)**, which consists of the hormones **thyroxine (T_4) and triiodothyronine (T_3)**, and **calcitonin**. The secretion of THs is controlled by TSH from the anterior pituitary, which in turn is regulated by thyrotropin-releasing factor (TRF) from the hypothalamus as a negative feedback response. Consequently, hypothyroidism or hyperthyroidism may result from a defect in the target gland or from a disturbance in the secretion of TSH or TRF. Because the functions of T_3 and T_4 are qualitatively the same, the term *thyroid hormone* is used throughout the discussion.

The synthesis of TH depends on available sources of dietary iodine and tyrosine. The thyroid is the only endocrine gland capable of storing excess amounts of hormones for release as needed. During circulation in the bloodstream, T_4 and T_3 are bound to carrier proteins (T_4-binding globulin). They must be unbound before they are able to exert their metabolic effect.

The main physiologic action of TH is to regulate the basal metabolic rate and thereby control the processes of growth and tissue differentiation. Unlike GH, TH is involved in many more diverse activities that influence the growth and development of body tissues. Therefore a deficiency of TH exerts a more profound effect on growth than that seen in GH deficiency.

Calcitonin helps maintain blood calcium levels by decreasing the calcium concentration. Its effect is the opposite of parathyroid hormone (PTH) in that it inhibits skeletal demineralization and promotes calcium deposition in the bone.

JUVENILE HYPOTHYROIDISM

Hypothyroidism is one of the most common endocrine problems of childhood. It may be either congenital (see Chapter 8) or acquired and represents a deficiency in secretion of TH (Patterson & Felner, 2020).

Beyond infancy, primary hypothyroidism may be caused by a number of defects. For example, a congenital hypoplastic thyroid gland may provide sufficient amounts of TH during the first year or two but be inadequate when rapid body growth increases demands on the gland. A partial or complete thyroidectomy for cancer or thyrotoxicosis can leave insufficient thyroid tissue to furnish hormones for body requirements. Radiotherapy for Hodgkin disease or other malignancies may lead to hypothyroidism (Metzger, Krasin, Choi, et al., 2016). Infectious processes may cause hypothyroidism. It can also occur when dietary iodine is deficient, although it is now rare in the United States because iodized salt is a readily available source of the nutrient.

Clinical manifestations depend on the extent of dysfunction and the child's age at onset. Primary congenital hypothyroidism is characterized by low levels of circulating THs and raised levels of TSH at birth (Kaplowitz, 2019). If left untreated, congenital hypothyroidism causes severe neurocognitive dysfunction (Wassner, 2018). Improvements in newborn screening have led to earlier detection and prevention of complications (American Academy of Pediatrics, Rose, Section on Endocrinology and Committee on Genetics of the American Thyroid Association, et al, 2006; Wassner, 2018). Children with acquired hypothyroidism, which occurs after the newborn period, may have decelerated growth from chronic deprivation of TH, or thyromegaly (enlargement of the thyroid) (Leung & Leung, 2019). Impaired growth and development are less severe when hypothyroidism is acquired at a later age, and because brain growth is nearly complete by 2 to 3 years old, intellectual disability and neurologic sequelae are not associated with juvenile hypothyroidism. Other manifestations are myxedematous skin changes (dry skin, puffiness around the eyes, sparse hair), constipation, lethargy, and mental decline (Box 28.5).

Therapy is TH replacement, the same as for hypothyroidism in infants, although the prompt treatment needed in infants is not required in children. Levothyroxine is administered over a period of 4 to 8 weeks to avoid symptoms of hyperthyroidism.

Nursing Care Management

The importance of early recognition in the infant is discussed in Chapter 8. Growth cessation or retardation in a child whose growth has previously been normal should alert the observer to the possibility of hypothyroidism. Treatment is daily oral TH replacement. The

BOX 28.5 Clinical Manifestations of Juvenile Hypothyroidism

Decelerated growth
- Less when acquired at later age

Myxedematous skin changes
- Dry skin
- Puffiness around eyes
- Sparse hair
- Constipation
- Sleepiness
- Mental decline

importance of daily compliance and the need for periodic monitoring of serum thyroid levels should be stressed to patients and their families.

GOITER

A goiter is an enlargement or hypertrophy of the thyroid gland. It may occur with deficient (hypothyroid), excessive (hyperthyroid), or normal (euthyroid) TH secretion. It can be congenital or acquired. Congenital disease occurs as a result of maternal administration of antithyroid drugs or iodides during pregnancy or as an inborn error of TH production (Leung & Leung, 2019). Acquired disease can result from increased secretion of pituitary TSH in response to decreased circulating levels of TH or from infiltrative neoplastic or inflammatory processes. In areas where dietary iodine (essential for TH production) is deficient, goiter can be endemic.

Enlargement of the thyroid gland may be mild and noticeable only when there is an increased demand for TH (e.g., during periods of rapid growth). Enlargement of the thyroid at birth can be sufficient to cause severe respiratory distress. Sporadic goiter is usually caused by lymphocytic thyroiditis or chronic autoimmune thyroiditis, otherwise known as Hashimoto thyroiditis (Leung & Leung, 2019). TH replacement is necessary to treat resulting hypothyroidism and reverse the TSH effect on the gland.

Nursing Care Management

Large goiters are identified by their obvious appearance. Smaller nodules may be evident only on palpation. Benign enlargement of the thyroid gland may occur during adolescence and should not be confused with pathologic states. Nodules rarely are caused by a cancerous tumor but always require evaluation. Nurses should be aware of the possibility of goiters and report findings. Questions regarding radiation exposure should be included in patient assessments.

! NURSING ALERT

If an infant is born with a goiter, immediate precautions are instituted for emergency ventilation, such as supplemental oxygen and a tracheostomy set nearby. Hyperextension of the neck often facilitates breathing.

Immediate surgery to remove part of the gland may be life-saving in infants born with a goiter. When thyroid replacement is necessary, parents have the same needs regarding its administration as discussed for the parents of children who have hypothyroidism.

LYMPHOCYTIC THYROIDITIS

Lymphocytic thyroiditis (**Hashimoto disease**, **chronic autoimmune thyroiditis**) is the most common cause of thyroid disease and goiter in children and adolescents and accounts for the largest percentage of juvenile hypothyroidism in iodine-sufficient parts of the world (Leung & Leung, 2019). Although lymphocytic thyroiditis can occur during the first 3 years of life, it occurs more frequently after 6 years old, with peak incidence occurring during adolescence. Some children may have subclinical hypothyroidism, but the presence of a goiter and elevated thyroglobulin antibody, with progressive increase in both thyroid peroxidase antibody and TSH, are predictive factors for future development of hypothyroidism (Hanley, Lord, & Bauer, 2016).

An enlarged thyroid gland is often detected during routine examination. Parents may notice it when a child swallows. In most children, the entire gland is enlarged symmetrically (although it may be asymmetric) and is firm, freely movable, and nontender. There may be manifestations of moderate tracheal compression (sense of fullness, hoarseness, and dysphagia). Many patients are euthyroid and asymptomatic (Leung & Leung, 2019). It is extremely rare for a nontoxic, diffuse goiter to cause airway obstruction. Other signs suggestive of thyroiditis are found in Box 28.6.

BOX 28.6 Clinical Manifestations of Lymphocytic Thyroiditis

Enlarged Thyroid Gland
Usually symmetric
Firm
Freely movable
Nontender

Tracheal Compression
Sense of fullness
Hoarseness
Dysphagia

Hyperthyroidism (Possible)
Nervousness
Irritability
Increased sweating
Hyperactivity

Diagnostic Evaluation

Thyroid function test results are usually normal, although TSH levels may be slightly or moderately elevated. With progressive thyroiditis, the T_4 decreases, followed by a decrease in T_3 levels and an increase in TSH. Many children have antithyroid antibody titers (Caturegli, De Remiqis, & Rose, 2014). However, levels in children are lower than in adults; therefore repeated measurements may be needed in doubtful cases. The identification of genes involved in this disease has led to improved diagnostic testing and may lead to new treatments in the future (Tomer, 2014).

Therapeutic Management

In many cases, the goiter is transient and asymptomatic and regresses spontaneously within a year or two. Therapy of a nontoxic diffuse goiter is usually simple, uncomplicated, and effective. Oral administration of TH provides the feedback needed to suppress TSH stimulation and decrease the size of the thyroid gland. TSH levels should be monitored, with the goal of restoring normal growth and development. Surgery is contraindicated in this disorder. Untreated patients should be evaluated periodically.

Nursing Care Management

Nurses help identify children with thyroid enlargement and provide reassurance and education regarding therapy and positive outcome.

HYPERTHYROIDISM

Graves disease (GD) is the most common cause of hyperthyroidism in children (Leger & Carel, 2018). This disease often runs in families. GD-associated hyperthyroidism is caused by autoantibodies to the TSH receptor causing excess secretion of TH. Most cases of GD in children occur in adolescence, with a peak incidence between 12 and 14 years old. Transient GD may be present at birth in children of thyrotoxic mothers. The incidence is higher in girls than boys (Léger & Carel, 2013). There is no cure for GD, and treatment options

BOX 28.7 Clinical Manifestations of Hyperthyroidism (Graves Disease)

Cardinal Signs
Emotional lability
Physical restlessness, characteristically at rest
Decelerated school performance
Voracious appetite with weight loss in 50% of cases
Fatigue

Physical Signs
Tachycardia
Widened pulse pressure
Dyspnea on exertion
Exophthalmos (protruding eyeballs)
Wide-eyed, staring expression with eyelid lag
Tremor
Goiter (hypertrophy and hyperplasia)
Warm, moist skin
Accelerated linear growth
Heat intolerance (may be severe)
Hair fine and unable to hold a curl
Systolic murmurs

Thyroid Storm
Acute onset:
- Severe irritability and restlessness
- Vomiting
- Diarrhea
- Hyperthermia
- Hypertension
- Severe tachycardia
- Prostration

May progress rapidly to:
- Delirium
- Coma
- Death

continue to be debated among pediatric endocrinologists (Leger & Carel, 2018).

Signs and symptoms of GD develop gradually, with an interval between onset and diagnosis of approximately 6 to 12 months. Clinical features include irritability, hyperactivity, short attention span, tremors, insomnia, emotional lability, poor concentration, nervousness, and palpitations or tremor (Leger & Carel, 2018). Because of the variety of symptoms, some children may see many different subspecialists before consulting an endocrinologist (Leger & Carel, 2018). Clinical manifestations are presented in Box 28.7.

Exophthalmos (protruding eyeballs), which is observed in many children, is accompanied by a wide-eyed staring expression, increased blinking, eyelid lag, lack of convergence, and absence of wrinkling of the forehead when looking upward. As exophthalmos progresses, the eyelid may not fully cover the cornea. Visual disturbances may include blurred vision and loss of visual acuity. Eye disease associated with hyperthyroidism can develop before or after the clinical diagnosis.

Diagnostic Evaluation

Graves disease is established based on increased levels of T_4 and T_3. TSH is suppressed to unmeasurable levels (Leger & Carel, 2018).

Therapeutic Management

Therapy for hyperthyroidism is controversial, but the end goal is the same—decrease the circulating TH. The three acceptable modes available are antithyroid drugs, subtotal thyroidectomy, and ablation with radioiodine (^{131}I iodide) (Lee & Hwang, 2014; Leger & Carel, 2018). Each therapy has advantages and disadvantages.

When affected children exhibit signs and symptoms of hyperthyroidism (e.g., increased weight loss, pulse, pulse pressure, and blood pressure), their activity should be limited to classwork only. Vigorous exercise is restricted until thyroid levels are decreased to normal or near-normal values.

Thyrotoxicosis (thyroid "crisis" or thyroid "storm") may occur from sudden release of TH. Although thyrotoxicosis is unusual in children, it can be life threatening. Clinical signs of thyroid storm are acute onset of severe irritability and restlessness, vomiting, diarrhea, hyperthermia, hypertension, severe tachycardia, and prostration. There may be rapid progression to delirium, coma, and even death. A crisis may be precipitated by acute infection, surgical emergencies, or discontinuation of antithyroid therapy. In addition to antithyroid drugs, beta-blockers are used to control symptoms until normal thyroid function is achieved (Leger & Carel, 2018). Therapy is usually required for 2 to 3 weeks.

The American Thyroid Association[b] has an extensive website with information related to prevention, treatment, and cure of thyroid disease.

Nursing Care Management

Because the clinical manifestations often appear gradually, the goiter and ophthalmic changes may not be noticed, and the excessive activity may be attributed to behavioral problems. Nurses in ambulatory settings, particularly schools, need to be alert to signs that suggest this disorder. Weight loss despite an excellent appetite, academic difficulties resulting from a short attention span, inability to sit still, unexplained fatigue and sleeplessness, and difficulty with fine motor skills such as writing can all be signs of this disease. Exophthalmos may develop long before the onset of the signs and symptoms and may be the only presenting sign.

Nursing care focuses on treating physical symptoms before a response to drug therapy is achieved. Children with hyperthyroidism need a quiet, unstimulating environment that is conducive to rest. Increased metabolic rate may cause heat intolerance and increased food intake in these patients. Mood swings and irritability can disrupt relationships, creating difficulties within and outside the home. Nurses can help parents understand the medical reason for behavior changes and offer ways to minimize them. A school consultation is important to provide education and suggest ways to assist a child after diagnosis.

Nurses should know the side effects of antithyroid drug therapy, including urticarial rash, fever, arthralgias, vasculitis, liver dysfunction, and agranulocytosis. Lymphadenopathy, edema, and diminished taste can also occur. Parents must understand the signs of hypothyroidism, which can occur from overdose.

! NURSING ALERT

Children being treated with propylthiouracil or methimazole must be carefully monitored for side effects of the drug. Because sore throat and fever accompany the grave complication of leukopenia, these children should be seen by a practitioner if such symptoms occur. Parents and children should be taught to recognize and report symptoms immediately.

! NURSING ALERT

The earliest indication of hypoparathyroidism may be anxiety and mental depression followed by paresthesia and evidence of heightened neuromuscular excitability, such as:

Chvostek sign: Facial muscle spasm elicited by tapping the facial nerve in the region of the parotid gland

Trousseau sign: Carpal spasm elicited by pressure applied to nerves of the upper arm

Tetany: Carpopedal spasm (sharp flexion of wrist and ankle joints), muscle twitching, cramps, seizures, and stridor

[b]6066 Leesburg Pike, Suite 550, Falls Church, VA 22041; 800-THYROID; email: thyroid@thyroid.org; http://www.thyroid.org.

DISORDERS OF PARATHYROID FUNCTION

The parathyroid glands secrete **parathyroid hormone (PTH)**. Along with vitamin D and calcitonin, PTH regulates the homeostasis of serum calcium concentrations (Lal & Clark, 2011). The effect of PTH on calcium is opposite that of calcitonin. PTH and vitamin D work together to maintain serum calcium levels within a narrow normal range. They are required for bone mineralization. Secretion of PTH is controlled by a negative feedback system involving the serum calcium ion concentration. Low ionized calcium levels stimulate PTH secretion, causing absorption of calcium by the target tissues; high ionized calcium concentrations suppress PTH.

HYPOPARATHYROIDISM

Hypoparathyroidism can be inherited or acquired and is rare in children (Al-Azem & Khan, 2012; Cusano, Rubin, & Bilezikian, 2015). Impaired secretion of PTH results in hypocalcemia and hyperphosphatemia (Snyder, 2015). **Congenital hypoparathyroidism** may be caused by genetic defects in the synthesis or cellular processing of PTH or by aplasia or hypoplasia of the gland (Al-Azem & Khan, 2012; Lal & Clark, 2011). Hypoparathyroidism may occur secondary to other causes, including infection, radiation, low levels of magnesium, and autoimmune syndromes (Al-Azem & Khan, 2012; Snyder, 2015). Postoperative hypoparathyroidism may be a result of thyroid surgery and be due to damage or removal of the parathyroid glands or disruption of their blood supply (Monis & Monnstadt, 2015). Two forms of transient hypoparathyroidism may be present in newborns, both of which are the result of PTH deficiency. One type is caused by maternal hyperparathyroidism. A more common form appears almost exclusively in infants fed a milk formula with a high phosphate-to-calcium ratio.

Pseudohypoparathyroidism occurs when there is a genetic defect in the cellular receptors to PTH and a resistance to the hormone (Al-Azem & Khan, 2012; Linglart, Levine, & Juppner, 2018). The result is normal parathyroid gland and normal PTH levels (Linglart et al., 2018). Calcium and phosphorus levels are not affected by administration of PTH. These children typically have a short, stocky build; a round face; and abnormally shaped hands and fingers. Other endocrine dysfunction may be found concurrently (Shoback, 2008).

Clinical signs of hypoparathyroidism are found in Box 28.8. Muscle cramps are an early symptom, progressing to numbness, stiffness, and tingling in the hands and feet. A positive Chvostek or Trousseau sign or laryngeal spasms may be present. Convulsions with loss of consciousness may occur. These episodes may be preceded by abdominal discomfort, tonic rigidity, head retraction, and cyanosis. Headaches and vomiting with increased intracranial pressure and papilledema may occur and may suggest a brain tumor (Doyle, 2020a). Hypoparathyroidism is associated with poor growth in children (Waller, 2011).

Diagnostic Evaluation

The diagnosis of hypoparathyroidism is made based on clinical manifestations associated with **decreased serum calcium** and **increased serum phosphorus**. Levels of plasma PTH are low in hypoparathyroidism but high in pseudohypoparathyroidism. End-organ responsiveness is tested by the administration of PTH with measurement of urinary cyclic adenosine monophosphate (cAMP). Kidney function tests are included in the differential diagnosis to rule out renal insufficiency. Magnesium levels should also be tested. Although bone radiograph findings are usually normal, they may demonstrate increased bone density and suppressed growth.

BOX 28.8 Clinical Manifestations of Hypoparathyroidism

Pseudohypoparathyroidism

Short stature
Round face
Short, thick neck
Short, stubby fingers and toes
Dimpling of skin over knuckles
Subcutaneous soft tissue calcifications
Intellectual disability a prominent feature

Idiopathic Hypoparathyroidism

None of the above physical characteristics observed
May include papilledema
May have intellectual disability

Both Types

Dry, scaly, coarse skin with eruptions
Hair often brittle
Nails thin and brittle with characteristic transverse grooves
Dental and enamel hypoplasia
Muscle contractions:
- Tetany
- Carpopedal spasm
- Laryngospasm (laryngeal stridor)
- Muscle cramps and twitching
- Positive Chvostek or Trousseau sign
- Paresthesias, tingling

Neurologic:
- Headache
- Seizures (generalized, absence, or focal)
- Swings of emotion
- Loss of memory
- Depression
- Confusion possible

Gastrointestinal:
- Muscle cramps
- Diarrhea
- Vomiting
- Retarded skeletal growth

Therapeutic Management

The objective of treatment is to maintain normal serum calcium and phosphate levels with minimum complications. Acute or severe tetany is corrected immediately by IV and oral administration of calcium and follow-up daily doses to achieve normal levels. Twice-daily serum calcium measurements are taken to monitor the efficacy of therapy and prevent hypercalcemia. When diagnosis is confirmed, **vitamin D therapy** is begun (Snyder, 2015). Vitamin D therapy is somewhat difficult to regulate because the drug has a prolonged onset and a long half-life. Some advocate beginning with a lower dose with stepwise increases and careful monitoring of serum calcium until stable levels are achieved. Others prefer rapid induction with higher doses and rapid reduction to lower maintenance levels (Doyle, 2020a).

Long-term management usually consists of vitamin D and oral calcium supplementation. Blood calcium and phosphorus are monitored frequently until the levels have stabilized. Renal function, blood pressure, and serum vitamin D levels are measured every 6 months. Serum magnesium levels are measured to permit detection of hypomagnesemia, which may raise the requirement for vitamin D. The US Food

BOX 28.9 Clinical Manifestations of Hyperparathyroidism

Gastrointestinal
Nausea
Vomiting
Abdominal discomfort
Constipation

Central Nervous System
Delusions
Confusion
Hallucinations
Impaired memory
Lack of interest and initiative
Depression
Varying levels of consciousness

Neuromuscular
Weakness
Easy fatigability
Muscle atrophy (especially proximal muscles of lower limbs)
Tongue twitching
Paresthesias in extremities

Skeletal
Vague bone pain
Subperiosteal resorption of phalanges
Spontaneous fractures
Absence of lamina dura around teeth

Renal
Polyuria
Polydipsia
Renal colic
Hypertension

and Drug Administration has approved a daily subcutaneous injection of recombinant human PTH for use in adults, and clinical trials are studying its use in children (Snyder, 2015).

Nursing Care Management

Unexplained convulsions, irritability (especially to external stimuli), gastrointestinal symptoms (diarrhea, vomiting, cramping), and positive signs of tetany are signs of hypocalcemia related to hypoparathyroidism. Nursing care includes institution of seizure and safety precautions; reduction of environmental stimuli; and observation for signs of laryngospasm, such as stridor, hoarseness, and a feeling of tightness in the throat. A tracheostomy set and injectable calcium gluconate should be available for emergency use. The administration of calcium gluconate requires precautions against extravasation of the drug and tissue destruction.

The nurse educates the family about continuous daily calcium and vitamin D. Because vitamin D toxicity can be a serious consequence of therapy, parents are advised to watch for signs that include weakness, fatigue, lassitude, headache, nausea, vomiting, and diarrhea. Polyuria, polydipsia, and nocturia are signs of early renal impairment.

HYPERPARATHYROIDISM

Hyperparathyroidism is rare in childhood but can be primary or secondary. The most common cause of primary hyperparathyroidism is adenoma of the gland (Doyle, 2020b). The most common causes of secondary hyperparathyroidism are chronic renal disease, renal osteodystrophy, and congenital anomalies of the urinary tract. The most common symptom is hypercalcemia. The clinical signs of hyperparathyroidism are listed in Box 28.9.

Diagnostic Evaluation

Blood studies to identify elevated calcium and decreased phosphorus levels are routinely performed. Measurement of PTH and tests to isolate the cause of the hypercalcemia, such as renal function studies, should be included. If a parathyroid adenoma is suspected, imaging using ultrasound and a sestamibi nuclear subtraction study are recommended (Pashtan, Grogan, Kaplan, et al., 2013). Other procedures used to substantiate the physiologic consequences of the disorder include electrocardiography and radiographic bone surveys.

Therapeutic Management

Treatment depends on the cause of hyperparathyroidism. The treatment of primary hyperparathyroidism is medication, but if this fails, surgical removal of the tumor or radioactive iodine is used (Doyle, 2020b). Treatment of secondary hyperparathyroidism is directed at the underlying contributing cause, which subsequently restores the serum calcium balance. However, in some instances (such as in chronic renal failure), the underlying disorder is irreversible. In this case, treatment is aimed at raising serum calcium levels to inhibit the stimulatory effect of low levels on the parathyroids. This includes oral administration of calcium salts, high doses of vitamin D to enhance calcium absorption, a low-phosphorus diet, and administration of a phosphorus-mobilizing aluminum hydroxide to reduce phosphate absorption.

Nursing Care Management

The initial nursing objective is recognition of the disorder. Because secondary hyperparathyroidism is a consequence of chronic renal failure, the nurse is always alert to signs that suggest this complication, especially bone pain and fractures. Because urinary symptoms are the earliest indication, assessment of other body systems for evidence of high calcium levels is indicated when polyuria and polydipsia coexist. Clues to the possibility of hyperparathyroidism include change in behavior, especially inactivity; unexplained gastrointestinal symptoms; and cardiac irregularities.

DISORDERS OF ADRENAL FUNCTION

The **adrenal cortex** secretes three main groups of hormones collectively called **steroids** and classified according to their biologic activity: (1) **glucocorticoids** (cortisol, corticosterone), (2) **mineralocorticoids** (aldosterone), and (3) **sex steroids** (androgens, estrogens, and progestins). The glucocorticoids and mineralocorticoids affect metabolism and stress. The sex steroids influence sexual development but are not essential because the gonads secrete the major supply of these hormones.

The **adrenal medulla** secretes the **catecholamines epinephrine** and **norepinephrine**. Both hormones have the same effects on various organs as those caused by direct sympathetic stimulation, except that the hormonal effects last several times longer. Catecholamine-secreting tumors are the primary cause of adrenal medullary hyperfunction. Primary adrenal insufficiency (PAI) is a group of disorders of the adrenal cortex that impair secretion of glucocorticoids and may be accompanied by mineralocorticoid and androgen deficiency or overproduction (Kirkgoz & Guran, 2018). This condition is usually inherited in children (Kirkgoz & Guran, 2018). Central adrenal insufficiency (CAI) is life threatening, involves impaired communication of hormone secretion from the pituitary or hypothalamus in the brain, and can be seen in children with genetic or malformative syndromes (Patti, Guzzeti, Di Iorgi, et al., 2018). In each case, the adrenal cortex will not secrete appropriate steroids in response to stress

ACUTE ADRENOCORTICAL INSUFFICIENCY

The acute form of adrenocortical insufficiency (**adrenal crisis**) may have a number of causes during childhood. Acute causes of adrenal insufficiency in children include hemorrhage into the adrenal gland from trauma or childbirth; infections, such as meningococcemia; abrupt withdrawal of exogenous sources of cortisone; failure to increase exogenous steroids during stress; or congenital adrenogenital hyperplasia of the salt-losing type.

Early symptoms of acute adrenocortical insufficiency may include increased irritability, poor feeding, headache, abdominal pain,

BOX 28.10 Clinical Manifestations of Acute Adrenocortical Insufficiency

Early Symptoms
Increased irritability
Headache
Diffuse abdominal pain
Weakness
Nausea and vomiting
Diarrhea

Generalized Hemorrhagic Manifestations (Waterhouse-Friderichsen Syndrome)
Fever (increases as condition worsens)
Central nervous system (CNS) signs:
- Nuchal rigidity
- Seizures
- Stupor
- Coma

Shocklike State
Weak, rapid pulse
Decreased blood pressure
Shallow respirations
Cold, clammy skin
Cyanosis
Circulatory collapse (terminal event)

Newborn
Hyperpyrexia
Tachypnea
Cyanosis
Seizures
Gland evident as palpable retroperitoneal mass (hemorrhagic)

weakness, nausea, vomiting, and diarrhea. Other clinical signs are found in Box 28.10. In newborns, adrenal crisis may be accompanied by high fever, tachypnea, cyanosis, and seizures. Usually there is no evidence of infection or clinical signs of bleeding. However, hemorrhage into the adrenal gland may be evident as a palpable retroperitoneal mass.

Diagnostic Evaluation

There is no rapid, definitive test to confirm acute adrenocortical insufficiency. Diagnosis is often made based on clinical presentation, especially when a fulminating sepsis is accompanied by hemorrhagic manifestations and signs of circulatory collapse despite adequate antibiotic therapy. Because there is no real danger in administering a cortisol preparation for a short period, treatment is instituted immediately. Improvement with cortisol therapy confirms the diagnosis.

Therapeutic Management

Acutely, treatment involves replacement of cortisol, replacement of body fluids to combat dehydration and hypovolemia, administration of glucose solutions to correct hypoglycemia, and specific antibiotic therapy in the presence of infection. Initially, IV hydrocortisone (Solu-Cortef) is administered. Normal saline containing 5% glucose is given parenterally to replace lost fluid, electrolytes, and glucose. If hemorrhage has been severe, whole blood may be replaced. In the event that these measures do not reverse the circulatory collapse, vasopressors are used for immediate vasoconstriction and elevation of blood pressure.

After the child's condition has been stabilized, oral doses of cortisone, fluids, and salt are given, similar to the regimen used for chronic adrenal insufficiency. To maintain sodium retention, aldosterone is replaced by synthetic salt-retaining steroid. Once a patient is stable, if central adrenal insufficiency is suspected, morning serum cortisol levels should be measured, and a stimulation test to measure cortisol release may be warranted (Patti et al., 2018).

Nursing Care Management

Because of the abrupt onset and potentially fatal outcome of this condition, prompt recognition is essential. Vital signs and blood pressure are taken every 15 minutes. Seizure precautions are instituted. The nurse should monitor the child's response to fluid and cortisol replacement. Rapid administration of fluids can precipitate cardiac failure, and overdosage with cortisol may cause hypotension and a sudden fall in temperature.

When the acute phase is over and the hypovolemia has been corrected, the child is given oral fluids in small quantities. Rapid ingestion of oral fluids may induce vomiting, which increases dehydration. Therefore the nurse should plan a gradual schedule for reintroducing liquids.

! NURSING ALERT

Monitor serum electrolyte levels and observe for signs of hypokalemia or hyperkalemia (e.g., weakness, poor muscle control, paralysis, cardiac dysrhythmias, apnea). The condition is rapidly corrected with intravenous (IV) or oral potassium replacement.

NURSING TIP: When an oral potassium preparation is given, it should be mixed with a small amount of strongly flavored fruit juice to disguise its bitter taste.

The sudden, severe nature of this disorder necessitates a great deal of emotional support for the child and family. The child may be placed in an intensive care unit where the surroundings are strange and frightening. Despite the need for emergency intervention, the nurse must be sensitive to the family's psychologic needs and prepare them for each procedure even if this is a brief statement, such as "The IV infusion is necessary to replace fluid that the child is losing." Because recovery within 24 hours is often dramatic, the nurse should keep the parents apprised of the child's condition, emphasizing signs of improvement, such as a lowered temperature and elevated blood pressure.

PRIMARY ADRENAL INSUFFICIENCY (ADDISON DISEASE)

Chronic primary adrenal insufficiency is rare in children and is usually caused by a genetic disorder causing one of the following: abnormal development of the adrenal gland, dysfunctional synthesis of adrenal hormones, resistance to ACTH, or damage to the adrenal cortex (Kirkgoz & Guran, 2018). Other causes include infection, a destructive lesion of the adrenal gland, or an autoimmune process. Because 90% of adrenal tissue must be nonfunctional before signs of insufficiency are manifested, onset of symptoms is often gradual. However, during periods of stress, when demands for additional cortisol are increased, symptoms of acute adrenal insufficiency may appear in a previously well child (Box 28.11).

Definitive diagnosis is based on measurements of functional cortisol reserve. The fasting serum cortisol and urinary 17-hydroxycorticosteroid levels are low and fail to rise, and plasma **adrenocorticotropic**

BOX 28.11 Clinical Manifestations of Chronic Adrenocortical Insufficiency

Neurologic Symptoms
Muscular weakness
Mental fatigue
Irritability, apathy, and negativism
Increased sleeping, listlessness

Pigmentary Changes
Previous scars
Palmar creases
Mucous membranes
Hair
Hyperpigmentation over pressure points (elbows, knees, or waist)
Less frequently, vitiligo (loss of pigmentation)

Gastrointestinal Symptoms
Dehydration
Anorexia
Weight loss

Circulatory Symptoms
Hypotension
Small heart size
Dizziness
Syncopal (fainting) attacks

Hypoglycemia
Headache
Hunger
Weakness
Trembling
Sweating

Other Signs (Seen in Some Children)
Recurrent, unexplained seizures
Intense craving for salt
Acute abdominal pain
Electrolyte imbalances

hormone (ACTH) levels are elevated with corticotropin (ACTH) stimulation, the definitive test for the disease.

Therapeutic Management

Treatment involves replacement of glucocorticoids (cortisol) and mineralocorticoids (aldosterone). Some children are able to be maintained solely on oral supplements of cortisol (cortisone or hydrocortisone preparations) with a liberal intake of salt. During stressful situations (such as fever, infection, emotional upset, or surgery), the dosage must be tripled to accommodate the body's increased need for glucocorticoids. Failure to meet this requirement will precipitate an acute crisis. Overdosage produces appearance of cushingoid signs.

Children with more severe states of chronic adrenal insufficiency require mineralocorticoid replacement to maintain fluid and electrolyte balance. Other forms of therapy include monthly injections of desoxycorticosterone acetate or implantation of desoxycorticosterone acetate pellets subcutaneously every 9 to 12 months. Continuous subcutaneous hydrocortisone infusions via a pump have also been used, but are associated with higher costs and potential risk of complications (Kirkgoz & Guran, 2018).

Nursing Care Management

After the disorder is diagnosed, parents need guidance concerning drug therapy. They must be aware of the continuous need for cortisol replacement. Sudden termination of the drug because of inadequate supplies or inability to ingest the oral form because of vomiting places the child in danger of an acute adrenal crisis. Parents should always have a spare supply of medication. Ideally, families will have a prefilled syringe of hydrocortisone and have training to administer this drug during a crisis. Unnecessary administration of cortisone will not harm the child, but if it is needed, it may be life-saving. Any evidence of acute insufficiency should be reported to the practitioner immediately.

Undesirable side effects of cortisone include gastric irritation, which is minimized by ingestion with food or the use of an antacid; increased excitability and sleeplessness; weight gain, which may require dietary management to prevent obesity; and occasionally behavioral changes, including depression or euphoria. Parents should be aware of signs of overdose and report these to the practitioner. In addition, the drug has a bitter taste, which creates a challenge.

Because the body cannot supply endogenous sources of cortical hormones during times of stress, the home environment should be stable and relatively unstressful. Parents need to be aware that during periods of emotional or physical crisis, the child requires additional hormone replacement. The child should wear a medical identification bracelet, to notify medical personnel during emergency care.

BOX 28.12 Etiology of Cushing Syndrome

Pituitary: Cushing syndrome with adrenal hyperplasia, usually attributed to an excess of ACTH
Adrenal: Cushing syndrome with hypersecretion of glucocorticoids, generally a result of adrenocortical neoplasms
Ectopic: Cushing syndrome with autonomous secretion of ACTH, most often caused by extrapituitary neoplasms
Iatrogenic: Cushing syndrome, frequently a result of administration of large amounts of exogenous corticosteroids
Food dependent: Inappropriate sensitivity of adrenal glands to normal postprandial increases in secretion of gastric inhibitory polypeptide

Adapted from Magiakou, M. A., Mastorakos, G., Oldfield, E. H., et al. (1994). Cushing's syndrome in children and adolescents: Presentation, diagnosis, and therapy. *New England Journal of Medicine, 331*(10), 629–636.
ACTH, Adrenocorticotropic hormone.

CUSHING SYNDROME

Cushing syndrome (CS) is a characteristic group of conditions caused by excessive circulating free cortisol. This can result from a variety of causes, which generally fall into one of five categories (Box 28.12).

Cushing syndrome is uncommon in children. When seen, it is often caused by excessive or prolonged steroid therapy that produces a cushingoid appearance (Fig. 28.2). When caused by excess exogenous steroid therapy, CS is reversible after the steroids are gradually discontinued (Stratakis, 2016). Abrupt withdrawal will precipitate acute adrenal insufficiency. Gradual withdrawal of exogenous supplies is necessary to allow the anterior pituitary an opportunity to secrete increasing amounts of ACTH to stimulate the adrenals to produce cortisol.

Clinical Manifestations

Because the actions of cortisol are widespread, clinical manifestations are equally profound and diverse. The symptoms that produce changes in physical appearance occur early in the disorder and are of considerable concern to school-age and older children. The physiologic disturbances, such as hyperglycemia, susceptibility to infection, hypertension, and hypokalemia, may have life-threatening consequences unless they are recognized early and treated successfully. Children with short stature may be responding to increased cortisol levels, resulting in Cushing syndrome. Cortisol inhibits the action of GH.

Diagnostic Evaluation

Several tests are helpful in confirming Cushing syndrome. Serum cortisol levels should be measured at midnight and in the morning along with corticotropin hormone, urinary free cortisol, fasting blood glucose levels for hyperglycemia, serum electrolyte levels for hypokalemia and alkalosis, and 24-hour urinary levels of elevated 17-hydroxycorticoids and 17-ketosteroids (Lowitz & Keil, 2015). Imaging of the pituitary and

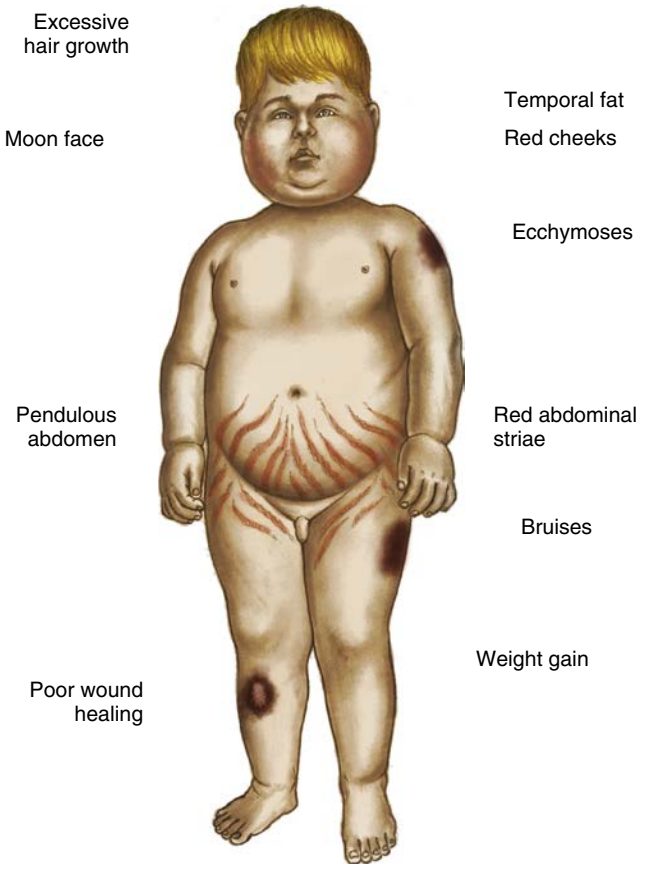

Fig. 28.2 Characteristics of Cushing syndrome.

adrenal glands to assess for tumors, bone density studies for evidence of osteoporosis, and skull radiographs to determine enlargement of the sella turcica may also aid in the diagnosis. Another procedure used to establish a more definitive diagnosis is the dexamethasone (cortisone) suppression test (Ceccato & Boscaro, 2016). Administration of an exogenous supply of cortisone normally suppresses ACTH production. However, in individuals with Cushing syndrome, cortisol levels remain elevated. This test is helpful in differentiating between children who are obese and those who appear to have cushingoid features.

Therapeutic Management

Treatment depends on the cause. If the cause is an adrenal tumor, surgery involves bilateral adrenalectomy and postoperative replacement of the cortical hormones (as outlined for primary adrenocortical insufficiency). If a pituitary tumor is found, surgical extirpation or irradiation may be chosen. In either of these instances, treatment of panhypopituitarism with replacement of GH, TH, ADH, gonadotropins, and steroids may be necessary for an indefinite period (Lau, Rutledge, & Aghi, 2015).

Nursing Care Management

Nursing care also depends on the cause. When cushingoid features are caused by steroid therapy, the effects may be lessened with administration of the drug early in the morning and on an alternate-day basis. Giving the drug early in the day maintains the normal diurnal pattern of cortisol secretion. If given during the evening, it is more likely to produce symptoms because endogenous cortisol levels are already low, and the additional supply exerts more pronounced effects. An alternate-day schedule allows the anterior pituitary an opportunity to maintain more normal hypothalamic-pituitary-adrenal control mechanisms.

If an organic cause is found, nursing care is related to the treatment regimen. Although a bilateral adrenalectomy permanently solves one condition, it reciprocally produces another syndrome. Before surgery, parents need to be adequately informed of the operative benefits and disadvantages. Postoperative teaching on drug replacement is the same as discussed in the previous section.

! NURSING ALERT

Postoperative complications of adrenalectomy are related to the sudden withdrawal of cortisol. Observe for shocklike symptoms (e.g., hypotension, hyperpyrexia).

Anorexia and nausea and vomiting are common and may be improved with the use of nasogastric decompression. Muscle and joint pain may be severe, requiring use of analgesics. The psychologic depression can be profound and may not improve for months. Parents should be aware of the physiologic reasons behind these symptoms in order to be supportive of the child.

CONGENITAL ADRENAL HYPERPLASIA

Congenital adrenal hyperplasia (CAH) is a family of inherited disorders caused by decreased enzyme activity required for cortisol production in the adrenal cortex and is the most common cause of primary adrenal insufficiency in children (Kirkgoz & Guran, 2018). The adrenal gland produces excessive amounts of cortisol precursors and androgens to compensate. The most common defect is **21-hydroxylase deficiency**, which constitutes more than 90% of all cases of CAH (El-Maouche, Arlt, & Merke, 2017). This deficiency is an autosomal recessive disorder that results in improper steroid hormone synthesis (Mendes, Vaz Matos, Ribeiro, et al., 2015).

Excessive androgens cause masculinization of the urogenital system at approximately the tenth week of fetal development. The most pronounced abnormalities occur in girls, who are born with varying degrees of ambiguous genitalia. Masculinization of external genitalia causes the clitoris to enlarge so that it appears as a small phallus. Fusion of the labia produces a saclike structure resembling the scrotum without testes. However, no abnormal changes occur in the internal sexual organs, although the vaginal orifice is usually closed by the fused labia. The label *ambiguous genitalia* should be applied to any infant with hypospadias or micropenis and no palpable gonads, and a diagnostic evaluation for CAH should be contemplated (Witchel, 2017).

Increased pigmentation of skin creases and genitalia caused by increased ACTH may be a subtle sign of adrenal insufficiency. A salt-wasting crisis frequently occurs, usually within the first few weeks of life, and is often the first presentation in boys, who have normal genital development (White, 2020a; Witchel, 2017). Infants fail to gain weight, and hyponatremia and hyperkalemia may be significant. Cardiac arrest can occur.

Untreated CAH results in early sexual maturation, with enlargement of the external sexual organs; development of axillary, pubic, and facial hair; deepening of the voice; acne; and a marked increase in musculature with changes toward an adult male physique. However, in contrast to precocious puberty, breasts do not develop in girls, and they remain amenorrheic and infertile. In boys, the testes remain small, and spermatogenesis does not occur. In both sexes, linear growth is accelerated, and epiphyseal closure is premature, resulting in short stature by the end of puberty.

Diagnostic Evaluation

Clinical diagnosis is initially based on congenital abnormalities that lead to difficulty in assigning sex to the newborn and on signs and symptoms of adrenal insufficiency. Newborn screening is currently done in all 50 states by measurement of the cortisol precursor 17-hydroxyprogesterone. Definitive diagnosis is confirmed by evidence of increased 17-ketosteroid levels in most types of CAH (Kaye, Committee on Genetics, Accurso, et al., 2006). In complete 21-hydroxylase deficiency, blood electrolytes demonstrate loss of sodium and chloride and elevation of potassium. In older children, bone age is advanced, and linear growth is increased. Deoxyribonucleic acid (DNA) analysis for positive sex determination and to rule out any other genetic abnormality (e.g., Turner syndrome) is always done in any case of ambiguous genitalia.

Another test that can be used to visualize the presence of pelvic structures is ultrasonography, a noninvasive, painless imaging technique that does not require anesthesia or sedation. It is especially useful in CAH because it readily identifies the absence or presence of female reproductive organs or male testes in a newborn or child with ambiguous genitalia. Because ultrasonography yields immediate results, it has the advantage of determining the child's gender long before the more complex laboratory results for chromosome analysis or steroid levels are available.

Therapeutic Management

After diagnosis is confirmed, medical management includes administration of glucocorticoids to suppress the abnormally high secretions of ACTH and adrenal androgens. The goal of therapy is to achieve and maintain the timing of normal pubertal development and achieve adult height (Bomberg, Addo, Kyllo, et al., 2015; Witchel, 2017). If cortisone is begun early enough, it is very effective. Cortisone depresses the secretion of ACTH by the anterior pituitary, which in turn inhibits the secretion of adrenocorticosteroids, which stems the progressive virilization. The signs and symptoms of masculinization in girls gradually disappear, and excessive early linear growth is slowed. Puberty occurs normally at the appropriate age.

The recommended oral dosage is divided to simulate the normal diurnal pattern of ACTH secretion. Because these children are unable to produce cortisol in response to stress, it is necessary to increase the dosage during episodes of infection, fever, surgery, or other stresses. Acute emergencies require immediate IV or intramuscular administration. Children with the salt-losing type of CAH require aldosterone replacement, as outlined under chronic adrenal insufficiency, and supplementary dietary salt. Frequent laboratory tests are conducted to assess the effects on electrolytes, hormonal profiles, and renin levels. The frequency of testing is individualized to the child.

Gender assignment and surgical intervention in the newborn with ambiguous genitalia is complex and controversial. It is a significant stress for families, who need support from a multidisciplinary team of experienced specialists. Factors that influence gender assignment include genetic diagnosis, genital appearance, surgical options, fertility, and family and cultural preferences. Generally, genetically female (46XX) infants should be raised as girls. Early reconstructive surgery should be considered only in the case of severe virilization (El-Maouche et al., 2017). Emphasis is on functional rather than cosmetic outcomes, and surgery often can be delayed. Reports of sexual satisfaction after partial clitoridectomy indicate that the capacity for orgasm and sexual gratification is not necessarily impaired. Male infants may require phallic reconstruction by an experienced surgeon.

Unfortunately, not all children with CAH are diagnosed at birth and raised in accordance with their genetic sex. Particularly in the case of affected females, masculinization of the external genitalia may have led to sex assignment as a male. In males, diagnosis is usually delayed until early childhood, when signs of virilism appear. In these situations, it is advisable to continue rearing the child as a male in accordance with assigned sex and phenotype. Hormone replacement may be required to permit linear growth and to initiate male pubertal changes. Surgery is usually indicated to remove the female organs and reconstruct the phallus for satisfactory sexual relations. These individuals are not fertile.

Nursing Care Management

Of major importance is recognition of ambiguous genitalia and diagnostic confirmation in newborns. Parents need assistance in understanding and accepting the condition and time to grieve for the loss of perfection in their newborn child. As soon as the sex is determined, parents should be informed of the findings and encouraged to choose an appropriate name, and the child should be identified as a male or female with no reference to ambiguous sex.

In general, rearing a genetically female child as a girl is preferred because of the success of surgical intervention and the satisfactory results with hormones in reversing virilism and providing a prospect of normal puberty and the ability to conceive. This is in contrast to the choice of rearing the child as a boy, in which case the child is sterile and may never be able to function satisfactorily in heterosexual relationships. If the parents persist in their decision to assign a male sex to a genetically female child, a psychologic consultation should be requested to explore their motivations and ensure their understanding of the future consequences for the child.

Nursing care management regarding cortisol and aldosterone replacement is the same as discussed for chronic adrenocortical insufficiency. Because infants are especially prone to dehydration and salt-losing crises, parents need to be aware of signs of dehydration and the urgency of immediate medical intervention to stabilize the child's condition. Parents should have injectable hydrocortisone available and know how to prepare and administer the intramuscular injection (see Chapter 20).

In the unfortunate situation in which the sex is erroneously assigned and the correct sex is determined later, parents need a great deal of help in understanding the reason for the incorrect sex identification and the options for sex reassignment or medical-surgical intervention.

Parents should be referred for genetic counseling before they conceive another child because CAH is an autosomal recessive disorder. Prenatal diagnosis and treatment are available.

! NURSING ALERT

The parents should be advised that there is no physical harm in treating for suspected adrenal insufficiency that is not present, but the consequence of not treating acute adrenal insufficiency can be fatal.

PHEOCHROMOCYTOMA

Pheochromocytoma is a rare tumor characterized by secretion of catecholamines. The tumor most commonly arises from the chromaffin cells of the adrenal medulla but may occur wherever these cells are found, such as along the paraganglia of the aorta or thoracolumbar sympathetic chain. In children, they are frequently bilateral or multiple and are generally benign. Often there is a familial transmission of the condition as an autosomal dominant trait (White, 2020b).

The clinical manifestations of pheochromocytoma are caused by an increased production of catecholamines, producing hypertension, tachycardia, headache, decreased gastrointestinal activity and resulting constipation, increased metabolism with anorexia, weight loss,

hyperglycemia, polyuria, polydipsia, hyperventilation, nervousness, heat intolerance, and diaphoresis. In severe cases, signs of congestive heart failure are evident. A child with sustained hypertension, family history of endocrine tumors, or syndromic features associated with endocrine tumor development should be screened (Jain, Baracco, & Kapur, 2019).

Diagnostic Evaluation

The clinical manifestations mimic those of other disorders, such as hyperthyroidism or DM. Usually the tumor is identified by computed tomography (CT) scan or MRI. Diagnostic tests include a 24-hour measurement of urinary levels of the catecholamine metabolites and plasma metanephrine measurement (Jain et al., 2019).

Therapeutic Management

Definitive treatment consists of surgical removal of the tumor. In children, the tumors may be bilateral, requiring a bilateral adrenalectomy and lifelong glucocorticoid and mineralocorticoid therapy. The major complications that can occur during surgery are severe hypertension, tachyarrhythmias, and hypotension. The first two are caused by excessive release of catecholamines during manipulation of the tumor, and the latter results from catecholamine withdrawal and hypovolemic shock. Treatment with alpha-adrenergic receptor blockers 7 to 14 days prior to surgery, volume expansion preoperatively, followed by beta-blockade, is necessary to reduce the incidence of complications (Jain et al., 2019). Success of therapy is judged by lowering of blood pressure to normal, absence of hypertensive attacks (flushing or blanching, fainting, headache, palpitations, tachycardia, nausea and vomiting, profuse sweating), heat tolerance, a decrease in perspiration, and disappearance of hyperglycemia.

Nursing Care Management

Children with hypertension and hypertensive attacks should be assessed for pheochromocytoma. Because of behavioral changes (nervousness, excitability, overactivity, and even psychosis), increased cardiac and respiratory activity may appear to be related to an acute anxiety attack. Therefore a careful history of the onset of symptoms and association with stressful events is helpful in distinguishing between an organic and a psychologic cause for the symptoms.

Preoperative nursing care involves frequent monitoring of vital signs and observation for evidence of hypertensive attacks and congestive heart failure. Therapeutic effects are evidenced by normal vital signs and absence of glycosuria. Daily blood glucose levels, urine acetone, and any signs of hyperglycemia are noted and reported immediately.

! NURSING ALERT

Do not palpate the mass. Preoperative palpation of the mass releases catecholamines, which can stimulate severe hypertension and tachyarrhythmias.

The environment is made conducive to rest and free of emotional stress. This requires adequate preparation during hospital admission and before surgery. Parents are encouraged to room-in with their child and to participate in care. Play activities need to be tailored to the child's energy level without being overly strenuous or challenging, because these activities can increase metabolic rate and promote frustration and anxiety.

After surgery, the child is observed for signs of shock from removal of excess catecholamines. If a bilateral adrenalectomy was performed, the nursing interventions are those discussed for chronic adrenocortical insufficiency.

DISORDERS OF PANCREATIC HORMONE SECRETION

DIABETES MELLITUS

DM is a chronic disorder of metabolism characterized by hyperglycemia and insulin resistance. It is the most common metabolic disease, resulting in metabolic adjustment or physiologic change in almost all areas of the body. The most recent statistics indicate that in the United States, approximately 208,000 children younger than 20 years old have either type 1 or type 2 diabetes (National Institutes of Health 2017). Type 1 diabetes has the highest number of new cases in non-Hispanic white children at a 4.2% annual increase.

Traditionally, DM was classified according to the type of treatment needed. The old categories were insulin-dependent diabetes mellitus (IDDM), or type I, and non–insulin-dependent diabetes mellitus (NIDDM), or type II. In 1997 these terms were eliminated because treatment can vary (some people with NIDDM require insulin) and because the terms do not indicate the underlying problem. The new terms are *type 1* and *type 2,* using Arabic symbols to avoid confusion (e.g., type II could be read as type eleven) (American Diabetes Association, 2001). The characteristics of type 1 DM and type 2 DM are outlined in Table 28.2.

TABLE 28.2 Characteristics of Type 1 and Type 2 Diabetes Mellitus

Characteristic	Type 1	Type 2
Age at onset	<20 years	Increasingly occurring in younger children
Type of onset	Abrupt	Gradual
Sex ratio	Affects males slightly more than females	Females outnumber males
Percentage of diabetic population	5%-8%	85%-90%
Heredity:		
Family history	Sometimes	Frequently
Human leukocyte antigen	Associations	No association
Twin concordance	25%-50%	90%-100%
Ethnic distribution	Primarily whites	Increased incidence in American Indians, Hispanics, African Americans
Presenting symptoms	Three Ps common—polyuria, polydipsia, polyphagia	May be related to long-term complications
Nutritional status	Underweight	Overweight
Insulin (natural):		
Pancreatic content	Usually none	>50% normal
Serum insulin	Low to absent	High or low
Primary resistance	Minimum	Marked
Islet cell antibodies	80%-85%	<5%
Therapy:		
Insulin	Always	20%-30% of patients
Oral agents	Ineffective	Often effective
Diet only	Ineffective	Often effective
Chronic complications	>80%	Variable
Ketoacidosis	Common	Infrequent

Type 1 diabetes most commonly presents between 4 and 6 years of age and then at 10 to 14 years of age; about 45% of children diagnosed will present before their tenth birthday. In 2003 type 2 diabetes represented 20% of pediatric diabetes cases, and half of those cases were adolescents between 15 and 19 years old (Levitsky & Misra, 2019a).

Type 1 diabetes is characterized by destruction of the pancreatic beta cells, which produce insulin; this usually leads to absolute insulin deficiency. Type 1 diabetes has two forms. Immune-mediated DM results from an autoimmune destruction of the beta cells; it typically starts in children or young adults who are slim, but it can arise in adults of any age. **Idiopathic type 1** refers to rare forms of the disease that have no known cause.

Type 2 diabetes usually arises because of insulin resistance in which the body fails to use insulin properly combined with relative (rather than absolute) insulin deficiency. People with type 2 DM can range from predominantly insulin resistant with relative insulin deficiency to predominantly deficient in insulin secretion with some insulin resistance. It typically occurs in those who are older than 45 years of age, are overweight and sedentary, and have a family history of diabetes.

The symptomatology of diabetes is more readily recognizable in children than in adults, so it is surprising that the diagnosis may sometimes be missed or delayed. Diabetes is a great imitator; influenza, gastroenteritis, and appendicitis are the conditions most often diagnosed when it turns out that the disease is really diabetes (Box 28.13).

Pathophysiology

Insulin is needed to support the metabolism of carbohydrates, fats, and proteins, primarily by facilitating the entry of these substances into the cells. Insulin is needed for the entry of glucose into the muscle and fat cells, prevention of mobilization of fats from fat cells, and storage of glucose as glycogen in the cells of liver and muscle. Insulin is not needed for the entry of glucose into nerve cells or vascular tissue. The chemical composition and molecular structure of insulin are such that it fits into receptor sites on the cell membrane. Here it initiates a sequence of poorly defined chemical reactions that alter the cell membrane to facilitate the entry of glucose into the cell and stimulate enzymatic systems outside the cell that metabolize the glucose for energy production.

With a deficiency of insulin, glucose is unable to enter the cells, and its concentration in the bloodstream increases. The increased concentration of glucose (**hyperglycemia**) produces an osmotic gradient that causes the movement of body fluid from the intracellular space to the interstitial space and then to the extracellular space and into the glomerular filtrate to "dilute" the hyperosmolar filtrate. Normally, the renal tubular capacity to transport glucose is adequate to reabsorb all the glucose in the glomerular filtrate. When the glucose concentration in the glomerular filtrate exceeds the renal threshold (180 mg/dl), glucose spills into the urine (**glycosuria**) along with an osmotic diversion of water (**polyuria**), a cardinal sign of diabetes. The urinary fluid losses cause the excessive thirst (**polydipsia**) observed in diabetes. This water "washout" results in a depletion of other essential chemicals, especially potassium.

Protein is also wasted during insulin deficiency. Because glucose is unable to enter the cells, protein is broken down and converted to glucose by the liver (**glucogenesis**); this glucose then contributes to the hyperglycemia. These mechanisms are similar to those seen in starvation when substrate (glucose) is absent. The body is actually in a state of starvation during insulin deficiency. Without the use of carbohydrates for energy, fat and protein stores are depleted as the body attempts to meet its energy needs. The hunger mechanism is triggered, but increased food intake (polyphagia) enhances the problem by further elevating blood glucose.

BOX 28.13 Clinical Manifestations of Type 1 Diabetes Mellitus

Polyphagia
Polyuria
Polydipsia
Weight loss
Enuresis or nocturia
Irritability; "not himself" or "not herself"
Shortened attention span
Lowered frustration tolerance
Dry skin
Blurred vision
Poor wound healing
Fatigue
Flushed skin
Headache
Frequent infections
Hyperglycemia
- Elevated blood glucose levels
- Glucosuria

Diabetic ketosis
- Ketones and glucose in urine
- Dehydration in some cases

Diabetic ketoacidosis (DKA)
- Dehydration
- Electrolyte imbalance
- Acidosis
- Deep, rapid breathing (Kussmaul respirations)

Ketoacidosis

When insulin is absent or insulin sensitivity is altered, glucose is unavailable for cellular metabolism, and the body chooses alternate sources of energy, principally fat. Consequently, fats break down into fatty acids, and glycerol in the fat cells is converted by the liver to ketone bodies (β-hydroxybutyric acid, acetoacetic acid, acetone). Any excess is eliminated in the urine (**ketonuria**) or the lungs (**acetone breath**). The ketone bodies in the blood (ketonemia) are strong acids that lower serum pH, producing **ketoacidosis**.

Ketones are organic acids that readily produce excessive quantities of free hydrogen ions, causing a fall in plasma pH. Then chemical buffers in the plasma, principally bicarbonate, combine with the hydrogen ions to form carbonic acid, which readily dissociates into water and carbon dioxide. The respiratory system attempts to eliminate the excess carbon dioxide by increased depth and rate (Kussmaul respirations, or the hyperventilation characteristic of metabolic acidosis). The ketones are buffered by sodium and potassium in the plasma. The kidneys attempt to compensate for the increased pH by increasing tubular secretion of hydrogen and ammonium ions in exchange for fixed base, thus depleting the base buffer concentration.

With cellular death, potassium is released from the cells (intracellular fluid) into the bloodstream (extracellular fluid) and excreted by the kidneys, where the loss is accelerated by osmotic diuresis. The total body potassium is then decreased even though the serum potassium level may be elevated as a result of the decreased fluid volume in which it circulates. Alteration in serum and tissue potassium can lead to cardiac arrest.

If these conditions are not reversed by insulin therapy in combination with correction of the fluid deficiency and electrolyte imbalance, progressive deterioration occurs, with dehydration, electrolyte imbalance, acidosis, coma, and death. **Diabetic ketoacidosis (DKA)** should be diagnosed promptly in a seriously ill patient and therapy instituted in an intensive care unit.

Long-Term Complications

Long-term complications of diabetes involve both the microvasculature and the macrovasculature. The principal microvascular complications are **nephropathy**, **retinopathy**, and **neuropathy**. Microvascular disease develops during the first 30 years of diabetes, beginning in the first 10 to 15 years after puberty, with renal involvement evidenced by proteinuria and clinically apparent retinopathy. Macrovascular disease

develops after 25 years of diabetes and creates the predominant problems in patients with type 2 DM. The process appears to be one of glycosylation, wherein proteins from the blood become deposited in the walls of small vessels (e.g., glomeruli), where they become trapped by "sticky" glucose compounds (glycosyl radicals). The buildup of these substances over time causes narrowing of the vessels, with subsequent interference with microcirculation to the affected areas (Rosenson & Herman, 2008).

With poor diabetic control, vascular changes can appear as early as 2½ to 3 years after diagnosis; however, with good to excellent control, changes can be postponed for 20 or more years. Intensive insulin therapy appears to delay the onset and slow the progression of retinopathy, nephropathy, and neuropathy. Hypertension and atherosclerotic cardiovascular disease are also major causes of morbidity and mortality in patients with DM (Karnik, Fields, & Shannon, 2007).

Other complications have been observed in children with type 1 DM. Hyperglycemia appears to influence thyroid function, and altered function is frequently observed at the time of diagnosis and in poorly controlled diabetes. Limited mobility of small joints of the hand occurs in 30% of 7- to 18-year-old children with type 1 DM and appears to be related to changes in the skin and soft tissues surrounding the joint as a result of glycosylation.

! NURSING ALERT

Recurrent vaginal and urinary tract infections, especially with *Candida albicans*, are often an early sign of type 2 diabetes mellitus, especially in adolescents.

Diagnostic Evaluation

Three groups of children who should be considered candidates for diabetes are (1) those who have glycosuria, polyuria, and a history of weight loss or failure to gain despite a voracious appetite; (2) those with transient or persistent glycosuria; and (3) those who display manifestations of metabolic acidosis, with or without stupor or coma. In every case, diabetes must be considered if there is glycosuria, with or without ketonuria, and unexplained hyperglycemia.

Glycosuria by itself is not diagnostic of diabetes. Other sugars, such as galactose, can produce a positive result with certain test strips, and a mild degree of glycosuria can be caused by other conditions, such as infection, trauma, emotional or physical stress, hyperalimentation, and some renal or endocrine diseases.

DM is diagnosed based on any of the following four abnormal glucose metabolites: (1) 8-hour fasting blood glucose level of 126 mg/dl or more, (2) a random blood glucose value of 200 mg/dl or more accompanied by classic signs of hyperglycemia, (3) an oral glucose tolerance test (OGTT) finding of 200 mg/dl or more in the 2-hour sample, and (4) hemoglobin A1c of 6.5% or more (Laffel & Svoren, 2018). Postprandial blood glucose determinations and the traditional OGTTs have yielded low detection rates in children and are not usually necessary for establishing a diagnosis. Serum insulin levels may be normal or moderately elevated at the onset of diabetes; delayed insulin response to glucose indicates impaired glucose tolerance.

Ketoacidosis must be differentiated from other causes of acidosis or coma, including hypoglycemia, uremia, gastroenteritis with metabolic acidosis, salicylate intoxication encephalitis, and other intracranial lesions. DKA is a state of relative insulin insufficiency and may include the presence of hyperglycemia (blood glucose level ≥200 mg/dl), ketonemia (strongly positive), acidosis (pH <7.30 and bicarbonate <15 mmol/L), glycosuria, and ketonuria (Wolsdorf, Craig, Daneman, et al., 2009). Tests used to determine glycosuria and ketonuria are the glucose oxidase tapes (Keto-Diastix).

Therapeutic Management

The management of the child with type 1 DM consists of a multidisciplinary approach involving the family; the child (when appropriate); and professionals, including a pediatric endocrinologist, diabetes nurse educator, nutritionist, and exercise physiologist. Often psychologic support from a mental health professional is also needed. Communication among the team members is essential and extends to other individuals in the child's life, such as teachers, school nurse, school guidance counselor, and coach.

The definitive treatment is replacement of insulin that the child is unable to produce. However, insulin needs are also affected by emotions, nutritional intake, activity, and other life events, such as illnesses and puberty. The complexity of the disease and its management requires that the child and family incorporate diabetes needs into their lifestyle. Medical and nutritional guidance are primary, but management also includes continuing diabetes education, family guidance, and emotional support.

Insulin Therapy

Insulin replacement is the cornerstone of management of type 1 DM. Insulin dosage is tailored to each child based on home blood glucose monitoring. The goal of insulin therapy is maintaining near-normal blood glucose values while avoiding too frequent episodes of hypoglycemia. Insulin is administered as two or more injections per day or as continuous subcutaneous infusion using a portable insulin pump.

Healthy pancreatic cells secrete insulin at a low but steady basal rate with superimposed bursts of increased secretion that coincide with intake of nutrients. Consequently, insulin levels in the blood increase and decrease coincidentally, with the rise and fall in blood glucose levels. In addition, insulin is secreted directly into the portal circulation; therefore the liver, which is the major site of glucose disposal, receives the largest concentration of insulin. No matter which method of insulin replacement is used, this normal pattern cannot be duplicated. Subcutaneous injection results in absorption of the drug into the general circulation, thus reducing the concentrations of insulin to which the liver is exposed.

Insulin Preparations

Insulin is available in highly purified pork preparations and in human insulin biosynthesized by and extracted from bacterial or yeast cultures. Most clinicians suggest human insulin as the treatment of choice. Insulin is available in rapid-, intermediate-, and long-acting preparations; and all are packaged in the strength of 100 units/ml. Some insulins are available as premixed insulins, such as 70/30 and 50/50 ratios, the first number indicating the percentage of intermediate-acting insulin and the second number the percentage of rapid-acting insulin. The different types of insulin are outlined in Box 28.14.

! NURSING ALERT

The human insulins from various manufacturers may be interchangeable, but human insulin and pork insulin or pure pork insulin should never be substituted for one another.

Dosage. Conventional management is a twice-daily insulin regimen of a combination of **rapid-acting** and **intermediate-acting** insulin drawn up into the same syringe and injected before breakfast and before the evening meal. The amount of morning regular insulin is determined by patterns in the late morning and lunchtime blood glucose values. The morning intermediate-acting dosage is determined by patterns in the late afternoon and supper blood glucose values.

Fasting blood glucose patterns at breakfast help determine the evening dose of intermediate insulin, and the blood glucose patterns at bedtime help determine the evening dose of rapid-acting (regular) insulin. For some children, better morning glucose control is achieved by a later (bedtime) injection of intermediate-acting insulin.

Regular insulin is best administered at least 30 minutes before meals. This allows sufficient time for absorption and results in a significantly greater reduction in the postprandial rise in blood glucose than if the meal were eaten immediately after the insulin injection. Intensive therapy consists of multiple injections throughout the day with a once- or twice-daily dose of long-acting (Ultralente) insulin to simulate the basal insulin secretion and injections of rapid-acting insulin before each meal. A multiple daily injection program reduces microvascular complications of diabetes in young, healthy patients who have type 1 DM.

The precise dose of insulin needed cannot be predicted. Therefore the total dosage and percentage of regular- to intermediate-acting insulin should be determined empirically for each child. Usually 60% to 75% of the total daily dose is given before breakfast, and the remainder is given before the evening meal. Furthermore, insulin requirements do not remain constant but change continuously during growth and development; the need varies according to the child's activity level and pubertal status. For example, less insulin is required during spring and summer months when children are more active. Illness also alters insulin requirements. Some children require more frequent insulin administration. This includes children with difficult-to-control diabetes and children during the adolescent growth spurt.

Methods of administration. Daily insulin is administered subcutaneously by twice-daily injections, by multiple-dose injections, or by means of an insulin infusion pump. Insulin pumps are small computerized devices that deliver insulin in two ways: in a steady measured and continuous dose (the "basal" insulin) or as a surge ("bolus") dose, at your direction, around mealtime.

Doses are delivered through a flexible plastic tube called a catheter. With the aid of a small needle, the catheter is inserted through the skin into the fatty tissue and is taped in place. Pumps can be programmed to release small doses of insulin continuously (basal) or a bolus dose close to mealtime to control the rise in blood glucose after a meal. This delivery system most closely mimics the body's normal release of insulin (Insulin Pumps, 2018).

The system consists of a syringe to hold the insulin, a plunger, and a computerized mechanism to drive the plunger. The insulin flows from the syringe through a catheter to a needle inserted into subcutaneous tissue (the abdomen or thigh), and the lightweight device is worn on a belt or a shoulder holster. The needle and catheter are changed every 48 to 72 hours by the child or parent using aseptic technique and then taped in place.

Although the pump provides more consistent insulin delivery, it has certain disadvantages. Pump therapy is expensive and requires commitment from the parent and child. A certain level of math skills is required to calculate infusion rates. It should also not be removed for more than 1 hour at a time, which may limit some activities. Skin infections are common, and as with any other mechanical device, it is subject to malfunction. However, the pumps are equipped with alarms that signal problems, such as a depleted battery, an occluded needle or tubing, or a microprocessor malfunction.

BOX 28.14 Types of Insulin

There are four types of insulin, based on the following criteria:

- How soon the insulin starts working (onset)
- When the insulin works the hardest (peak time)
- How long the insulin lasts in the body (duration)

However, each person responds to insulin in his or her own way. That is why onset, peak time, and duration are given as ranges.

Rapid-acting insulin (e.g., NovoLog) reaches the blood within 15 minutes after injection. The insulin peaks 30 to 90 minutes later and may last as long as 5 hours.

Short-acting (regular) insulin (e.g., Novolin R) usually reaches the blood within 30 minutes after injection. The insulin peaks 2 to 4 hours later and stays in the blood for about 4 to 8 hours.

Intermediate-acting insulins (e.g., Novolin N) reach the blood 2 to 6 hours after injection. The insulins peak 4 to 14 hours later and stay in the blood for about 14 to 20 hours.

Long-acting insulin (e.g., Lantus) takes 6 to 14 hours to start working. It has no peak or a very small peak 10 to 16 hours after injection. The insulin stays in the blood between 20 and 24 hours.

Some insulins come mixed together (e.g., Novolin 70/30). For example, you can buy regular insulin and NPH insulins already mixed in one bottle, which makes it easier to inject two kinds of insulin at the same time. However, you cannot adjust the amount of one insulin without also changing how much you get of the other insulin.

NPH, Neutral protamine Hagedorn.

Monitoring

Daily monitoring of blood glucose levels is an essential aspect of appropriate DM management. Plasma blood glucose and hemoglobin A1c goal ranges are found in Table 28.3.

Blood glucose. **Self-monitoring of blood glucose (SMBG)** has improved diabetes management and is used successfully by children from the onset of their diabetes. By testing their own blood, children are able to change their insulin regimen to maintain their glucose level in the euglycemic (normal) range of 80 to 120 mg/dl. Diabetes

TABLE 28.3 Plasma Blood Glucose and Hemoglobin A1c Goals for Type 1 Diabetes Mellitus by Age-Group

Age	Value[a] Before Meals (mg/dl)	Value[a] at Bedtime/ Overnight (mg/dl)	Hemoglobin A1c (%)	Implications
Toddlers and preschoolers (<6 years)	100-180	110-200	≤8.5% (but ≥7.5%)	High risk and vulnerability to hypoglycemia
School age (6-12 years)	90-180	100-180	<8%	Risks of hypoglycemia and relatively low risk of complications before puberty
Adolescents (>12 years) and young adults	90-130	90-150	<7.5%	Risk of hypoglycemia Developmental and psychologic issues

[a]Plasma blood glucose goal range.

Modified from American Diabetes Association. (2005). Standards of medical care in diabetes. *Diabetes Care, 28*(Suppl), S4–S36.

management depends to a great extent on SMBG. In general, children tolerate the testing well.

Glycosylated hemoglobin. The measurement of glycosylated hemoglobin (hemoglobin A1c) levels is a satisfactory method for assessing control of the diabetes. As red blood cells circulate in the bloodstream, glucose molecules gradually attach to the hemoglobin A molecules and remain there for the lifetime of the red blood cell, approximately 120 days. The attachment is not reversible; therefore this glycosylated hemoglobin reflects the average blood glucose levels over the previous 2 to 3 months. The test is a satisfactory method for assessing control, detecting incorrect testing, monitoring the effectiveness of changes in treatment, defining patients' goals, and detecting nonadherence. Nondiabetic hemoglobin A1c values are generally between 4% and 6% but can vary by laboratory. Well-controlled diabetes has a hemoglobin A1c goal of less than 7.5% for most children and adolescents (Levitsky & Misra, 2018; Silverstein, Klingensmith, Copeland, et al., 2005).

Urine. Urine testing for glucose is no longer used for diabetes management; there is poor correlation between simultaneous glycosuria and blood glucose concentrations. However, urine testing can be carried out to detect evidence of ketonuria.

! NURSING ALERT

It is recommended that urine be tested for ketones every 3 hours during an illness or whenever the blood glucose level is greater than 240 mg/dl when illness is not present.

Nutrition

Essentially, the nutritional needs of children with diabetes are no different from those of healthy children. Children with diabetes need no special foods or supplements. They need sufficient calories to balance daily expenditure for energy and to satisfy the requirement for growth and development. Unlike children without diabetes, whose insulin is secreted in response to food intake, insulin injected subcutaneously has a relatively predictable time of onset, peak effect, duration of action, and absorption rate depending on the type of insulin used. Consequently, the timing of food consumption must be regulated to correspond to the timing and action of the insulin prescribed.

Meals and snacks must be eaten according to peak insulin action, and the total number of calories and proportions of basic nutrients must be consistent from day to day. The constant release of insulin into the circulation makes the child prone to hypoglycemia between the three daily meals unless a snack is provided between meals and at bedtime. The distribution of calories should be calculated to fit the activity pattern of each child. For example, a child who is more active in the afternoon will need a larger snack at that time. This larger snack might also be split to allow some food at school and some food after school. Food intake should be altered to balance food, insulin, and exercise. Extra food is needed for increased activity.

Concentrated sweets are discouraged, and because of the increased risk of atherosclerosis in persons with DM, fat is reduced to 30% or less of the total caloric requirement. Dietary fiber has become increasingly important in dietary planning because of its influence on digestion, absorption, and metabolism of many nutrients. It has been found to diminish the rise in blood glucose after meals.

For growing children, food restriction should never be used for diabetes control, although caloric restrictions may be imposed for weight control if the child is overweight. In general, the child's appetite should be the guide for the amount of calories needed, with the total caloric intake adjusted to appetite and activity.

Exercise

Exercise is encouraged and never restricted unless indicated by other health conditions. Exercise lowers blood glucose levels, depending on the intensity and duration of the activity. Consequently, exercise should be included as part of diabetes management, and the type and amount of exercise should be planned around the child's interests and capabilities. However, in most instances, children's activities are unplanned, and the resulting decrease in blood glucose can be compensated for by providing extra snacks before (and if the exercise is prolonged, during) the activity. In addition to a feeling of well-being, regular exercise aids in use of food and often results in a reduction in insulin requirements.

! NURSING ALERT

Hypoglycemic episodes most commonly occur before meals or when the insulin effect is peaking.

Hypoglycemia

Occasional episodes of hypoglycemia are an integral part of insulin therapy, and an objective of diabetes management is to achieve the best possible glycemic control while minimizing the frequency and severity of hypoglycemia. Even with good control, a child may frequently experience mild symptoms of hypoglycemia. If the signs and symptoms are recognized early and promptly relieved by appropriate therapy, the child's activity should be interrupted for no more than a few minutes.

The signs and symptoms of hypoglycemia are caused by both increased adrenergic activity and impaired brain function. The increased adrenergic nervous system activity plus increased secretion of catecholamines produces tremor, pallor, rapid heart rate, palpitations, and diaphoresis (Levitsky & Misra, 2019b). Weakness, dizziness, headache, drowsiness, irritability, loss of coordination, seizures, and coma are more severe responses and reflect CNS glucose deprivation and the body's attempts to elevate the serum glucose levels.

It is often difficult to distinguish between hyperglycemia and a hypoglycemic reaction (Table 28.4). Because the symptoms are similar and usually begin with changes in behavior, the simplest way to differentiate between the two is to test the blood glucose level. The blood glucose level is low in hypoglycemia, but in hyperglycemia, the glucose level is significantly elevated. Urinary ketones may be present after hypoglycemia as a result of starvation ketone production. In doubtful situations, it is safer to give the child some simple carbohydrate. This will help alleviate the symptoms in the case of hypoglycemia but will do little harm if the child is hyperglycemic.

Children are usually able to detect the onset of hypoglycemia, but some are too young to implement treatment. Parents should become adept at recognizing the onset of symptoms—for example, a change in a child's behavior, such as tearfulness or euphoria. In the majority of cases, 10 to 15 g of simple carbohydrate, such as 1 Tbsp of table sugar, will elevate the blood glucose level and alleviate the symptoms. The simpler the carbohydrate, the more rapidly it will be absorbed (8 oz of milk equals 15 g of carbohydrate). The rapidly releasing sugar is followed by a complex carbohydrate (such as a slice of bread or a cracker) and by a protein (such as peanut butter or milk).

For a mild reaction, milk or fruit juice is a good food to use in children. Milk supplies them with lactose or milk sugar, as well as a more prolonged action from the protein and fat (aids in decreased absorption). Other glucose sources include Insta-Glucose (cherry-flavored glucose), carbonated drinks (not sugarless), sherbet, gelatin, or cake icing. All children with diabetes should carry with them glucose tabs, Insta-Glucose, sugar cubes, or sugar-containing candy, such as

TABLE 28.4 Comparison of Manifestations of Hypoglycemia and Hyperglycemia

Variable	Hypoglycemia	Hyperglycemia
Onset	Rapid (minutes)	Gradual (days)
Mood	Labile, irritable, nervous, weepy	Lethargic
Mental status	Difficulty concentrating, speaking, focusing, coordinating Nightmares	Dulled sensorium Confusion
Inward feeling	Shaky feeling	Thirst
	Hunger	Weakness
	Headache	Nausea and vomiting
	Dizziness	Abdominal pain
Skin	Pallor Sweating	Flushed Signs of dehydration
Mucous membranes	Normal	Dry, crusty
Respirations	Shallow, normal	Deep, rapid (Kussmaul)
Pulse	Tachycardia, palpitations	Less rapid, weak
Breath odor	Normal	Fruity, acetone
Neurologic	Tremors	Diminished reflexes Paresthesia
Ominous signs	Late: Hyperreflexia, dilated pupils, seizure Shock, coma	Acidosis, coma
Blood:		
Glucose	Low: <60 mg/dl	High: ≥200 mg/dl
Ketones	Negative	High, large
Osmolarity	Normal	High
pH	Normal	Low (≤7.25)
Hematocrit	Normal	High
Bicarbonate	Normal	<20 mEq/L
Urine:		
Output	Normal	Polyuria (early) to oliguria (late)
Glucose	Negative	Enuresis, nocturia
Ketones	Negative or trace	High
Visual	Diplopia	Blurred vision

LifeSavers or Charms. A difficulty with candies or icing is that the child may learn to fake a reaction to get the sweets; therefore commercial treatment products such as Insta-Glucose or glucose tabs may be preferred.

Glucagon is sometimes prescribed for home treatment of hypoglycemia. It is available as an emergency kit that must be mixed at the time of use and is administered intramuscularly or subcutaneously. Glucagon functions by releasing stored glycogen from the liver and requires about 15 to 20 minutes to elevate the blood glucose level.

! NURSING ALERT

Vomiting may occur after administration of glucagon; therefore precautions against aspiration must be taken (e.g., placing the child on the side) because the child often becomes unconscious.

Morning hyperglycemia. The management of elevated morning blood glucose levels depends on whether the increase is a true dawn phenomenon, **insulin waning**, or a rebound hyperglycemia (the **Somogyi effect**). Insulin waning is a progressive rise in blood glucose levels from bedtime to morning. It is treated by increasing the nocturnal insulin dose. The true dawn phenomenon shows relatively normal blood glucose level until about 3 AM, when the level begins to rise. The Somogyi effect may occur at any time but often entails an elevated blood glucose level at bedtime and a drop at 2 AM, with a rebound rise following. The treatment for this phenomenon is decreasing the nocturnal insulin dose to prevent the 2 AM hypoglycemia. The rebound rise in the blood glucose level is a result of counterregulatory hormones (epinephrine, GH, and corticosteroids), which are stimulated by hypoglycemia. More frequent blood monitoring (especially at times of anticipated peak insulin action) will usually identify these conditions. Trace amounts of urinary ketones aid in identifying undetected hypoglycemia.

Illness Management

Illness alters diabetes management, and maintaining control is usually related to the seriousness of the illness. In a well-controlled child, an illness will run its course as it does in unaffected children. The goals during an illness are to restore euglycemia, treat urinary ketones, and maintain hydration. Blood glucose levels and urinary ketones should be monitored every 3 hours. Some hyperglycemia and ketonuria are expected in most illnesses, even with diminished food intake, and are an indication for increased insulin. Insulin should never be omitted during an illness, although dosage requirements may increase, decrease, or remain unchanged, depending on the severity of the illness and the child's appetite. Often the child will need supplemental insulin between usual dose times. If the child vomits more than once, if blood glucose levels remain above 240 mg/dl, or if urinary ketones remain high, the health care practitioner should be notified. Simple carbohydrates may be substituted for carbohydrate-containing exchanges in the meal plan. Although insulin and diet are important tools in sick-day care, fluids are the most important intervention. Fluids must be encouraged to prevent dehydration and to flush out ketones.

Therapeutic Management of Diabetic Ketoacidosis

DKA, the most complete state of insulin deficiency, is a life-threatening situation. Management consists of rapid assessment, adequate insulin to reduce the elevated blood glucose level, fluids to overcome dehydration, and electrolyte replacement (especially potassium).

DKA constitutes an emergency situation, thus a child should be admitted to an intensive care facility for management. The priority is to obtain a venous access for administration of fluids, electrolytes, and insulin. The child should be weighed, measured, and placed on a cardiac monitor. Blood glucose and ketone levels are determined at the bedside, and samples are obtained for laboratory measurement of glucose, electrolytes, BUN, arterial pH, PaO_2, $PaCO_2$, hemoglobin, hematocrit, white blood cell count and differential, calcium, and phosphorus.

Oxygen may be administered to patients who are cyanotic and in whom arterial oxygen is less than 80%. Gastric suction is applied to unconscious children to avoid the possibility of pulmonary aspiration. Antibiotics may be administered to febrile children after appropriate specimens are obtained for culture. A Foley catheter may or may not be inserted for urine samples and measurement. Unless the child is unconscious, a collection bag is usually sufficient for accurate assessments.

Fluid and Electrolyte Therapy

All patients with DKA experience dehydration (10% of total body weight in severe ketoacidosis) because of the osmotic diuresis,

accompanied by depletion of electrolytes, sodium, potassium, chloride, phosphate, and magnesium. Serum pH and bicarbonate reflect the degree of acidosis. Prompt and adequate fluid therapy restores tissue perfusion and suppresses the elevated levels of stress hormones.

The initial rehydration attempts should be 10 to 20 ml/kg of isotonic saline (normal saline or lactated Ringer solution given as an IV bolus). Repeat this bolus until fluid status is stable. Once stable, replace the remaining fluid deficit over the next 24 to 48 hours (Glaser, 2019).

! NURSING ALERT

Potassium must never be given until the serum potassium level is known to be normal or low and urinary voiding is observed. All maintenance intravenous (IV) fluids should include 30 to 40 mEq/L of potassium. Never give potassium as a rapid IV bolus, or cardiac arrest may result.

Serum potassium levels may be normal on admission, but after fluid and insulin administration, the rapid return of potassium to the cells can seriously deplete serum levels, with the attendant risk of cardiac arrhythmias. As soon as the child has established renal function (i.e., is voiding at least 25 ml/h) and insulin has been given, vigorous potassium replacement is implemented. The cardiac monitor is used as a guide to therapy, and configuration of T waves should be observed every 30 to 60 minutes to determine changes that might indicate alterations in potassium concentration (widening of the QT interval and the appearance of a U wave following a flattened T wave indicate hypokalemia; an elevated and spreading T wave and shortening of the QT interval indicate hyperkalemia).

Insulin should not be given until urinary ketones and a blood glucose level have been obtained. Continuous IV regular insulin is given at a dosage of 0.1 units/kg/h. Insulin therapy should be started after the initial rehydration bolus because serum glucose levels fall rapidly after volume expansion. Blood glucose levels should decrease by 50 to 100 mg/dl/h. When blood glucose levels fall to 250 to 300 mg/dl, dextrose is added to the IV solution. The goal is to maintain blood glucose levels between 120 and 240 mg/dl by adding 5% to 10% dextrose. Sodium bicarbonate is used conservatively; it is used for pH less than 7.0, severe hyperkalemia, or cardiac instability. Because sodium bicarbonate has been associated with an increased risk for cerebral edema, children receiving this substance must be carefully monitored for changes in level of consciousness.

When the critical period is over, the task of regulating the insulin dosage in relation to diet and activity is started. Children should be actively involved in their own care and are given responsibility according to their ability and the guidance of the nurse.

! NURSING ALERT

Because insulin can chemically bind to plastic tubing and in-line filters, thereby reducing the amount of medication reaching the systemic circulation, an insulin mixture is run through the tubing to saturate the insulin-binding sites before the infusion is started.

Nursing Care Management

Children with DM may be admitted to the hospital at the time of their initial diagnosis; during illness or surgery; or for episodes of ketoacidosis, which may be precipitated by any of a variety of factors (see Translating Evidence Into Practice box, which evaluates hospitalization compared with outpatient care for children newly diagnosed with type 1 DM). Many children are able to keep the disease under control with periodic assessment and adjustment of insulin, diet, and activity as needed under the supervision of a practitioner. Under most circumstances, these children can be managed well at home and require hospitalization only for serious illnesses or upsets.

However, a small number of children with diabetes exhibit a degree of metabolic lability and have repeated episodes of DKA that require hospitalization, which interferes with their education and social development. These children appear to display a characteristic personality structure. They tend to be unusually passive and nonassertive and to come from families that are inclined to smooth over conflicts without resolution. Children in this type of setting experience emotional arousal with little, if any, opportunity or ability to resolve it. Other children from psychosocially dysfunctional families display behavioral and personality problems. This emotional stress causes an increased production of endogenous catecholamines, which stimulate fat breakdown, leading to ketonemia and ketonuria.

TRANSLATING EVIDENCE INTO PRACTICE

Outpatient Treatment of Type I Diabetes

A *Cochrane Systematic Review* of seven studies evaluating whether children newly diagnosed with type 1 diabetes should be admitted to a hospital or treated in the outpatient setting found no disadvantages to allowing the child to remain an outpatient. Studies evaluated metabolic control, acute diabetic complications and hospitalizations, psychosocial variables and behavior, and total care costs (Clar, Waugh, & Thomas, 2007).

Hospital Management

Children with DKA require intensive nursing care. Vital signs should be observed and recorded frequently. Hypotension caused by the contracted blood volume of the dehydrated state may cause decreased peripheral blood flow, which can be particularly hazardous to the heart, lungs, and kidneys. An elevated temperature may indicate infection and should be reported so that treatment can be implemented immediately.

Careful and accurate records should be maintained, including vital signs (pulse, respiration, temperature, and blood pressure), weight, IV fluids, electrolytes, insulin, blood glucose level, and intake and output. A urine collection device or retention catheter is used to obtain the urine measurements, which include volume, specific gravity, and glucose and ketone values. The volume relative to the glucose content is important because 5% glucose in a 300-ml sample is a significantly greater amount than a similar reading from a 75-ml sample. A diabetic flowsheet maintained at the bedside provides an ongoing record of the vital signs, urine and blood tests, amount of insulin given, and intake and output. The level of consciousness is assessed and recorded at frequent intervals. The comatose child generally regains consciousness fairly soon after initiation of therapy but is managed like any unconscious child until then.

When the critical period is over, the task of regulating insulin dosage to diet and activity begins. The same meticulous records of intake and output, urine glucose and acetone levels, and insulin administration are maintained. Capable children should be actively involved in their own care and are given responsibility for keeping the intake and output record; testing the blood and urine; and, when appropriate, administering their own insulin—all under the supervision and guidance of the nurse (see the Next-Generation NCLEX® Examination-Style Unfolding Case Study box).

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY

The Child With Diabetes Mellitus

Day 1, 1:00 pm

1. An 8-year-old who has been healthy has lost weight in the past 2 weeks. His mother noticed that he is getting up several times during the night to go to the bathroom. He was drinking a great deal more in the past week, and she thought that was the reason for needing to use the bathroom. However, today he has a headache and is too tired to go to school. She also notices that he has wet the bed during the night. She becomes alarmed and calls the pediatrician for an appointment the next day. She has a brother with diabetes and thinks that the symptoms are similar to her brother's problems when he was first diagnosed as a child. The next day at the pediatrician's office the nurse performs a history and assessment. Which findings in the child's history and assessment findings would require the nurse to **immediately** investigate further? **Select all that apply.**
   - A. Tiredness
   - B. Headache
   - C. Increased thirst
   - D. Increased urination
   - E. Wetting the bed at night
   - F. Oral temperature 98.8 F
   - G. Pulse 60 beats per minute
   - H. Blood pressure= 94/60 mmHg
   - I. Respirations 20 breaths per minute

Day 1, 2:30 pm

2. At the pediatrician's office, several tests are completed, and results are listed below.
   - random blood glucose = 230 mg/dl
   - hemoglobin (Hgb) A1c level = 10.5%.
   - hematocrit = 35%
   - platelets= 250,000/mm^3
   - white blood cells= 8,000/mm^3
   - urine dip test is positive for glucose and ketones

   He is admitted to the hospital for further evaluation to establish a diagnosis.

   Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.

   Based on the child's history and physical assessment, along with laboratory findings, the nurse suspects a diagnosis of _____1_____ because his _____2_____ and _____2_____ are high. His symptoms may be caused by an increased concentration of _____3_____ in the bloodstream.

Options for 1	Options for 2	Options for 3
Diabetes mellitus	platelets	Insulin
Addison disease	hematocrit	Glucose
Cushing syndrome	blood glucose	Potassium
Hyperparathyroidism	A1c level	Calcium
Pituitary hyperfunction	white blood cells	Sodium

Day 2, 12:00 noon

3. An 8-year-old who has been healthy has lost weight in the past 2 weeks. His mother noticed that he is getting up several times during the night to go to the bathroom. He was drinking a great deal more in the past week, and she thought that was the reason for needing to use the bathroom. However, today he has a headache and is too tired to go to school. She also notices that he has wet the bed during the night. She becomes alarmed and calls the pediatrician for an appointment the next day. She has a brother with diabetes and thinks that the symptoms are similar to her brother's problems when he was first diagnosed as a child.

   He was admitted yesterday for further evaluation. To obtain a fasting blood glucose he was given nothing to eat or drink but water for 8 hours before the test this morning. Laboratory results from this AM include the following:
   - 8 hour fasting glucose level =145 mg/dl
   - Oral Glucose tolerance test (OGTT)= 240 mg/dl in 2 hr sample
   - urine dip test is positive for glucose and ketones
   - Hgb A1C level= 10.5%

   He has met the criteria for the diagnosis of Type 1 Diabetes Mellitus. He will start with a twice-daily insulin regimen combining a rapid-acting (regular) insulin with an intermediate-acting (neutral protamine Hagedorn [NPH]/Lente) insulin. The nurse meets with the mother and patient to begin insulin therapy teaching. The mother asks why two types of insulin are needed. What are the **most appropriate** responses for the nurse to provide to help the mother and child understand about types of insulin? **Select all that apply.**
   - A. "Rapid-acting insulin peaks in about 30-90 minutes and may last about 5 hours."
   - B. "Short-acting insulin reaches the blood in about 5 minutes and peaks in about an hour."
   - C. "Extended insulin takes 4 hours to start working and can stay in the blood for up to 14 hours."
   - D. "Intermediate-acting insulin peaks in about 4-14 hours and can stay in the blood for 14-20 hours."
   - E. "Long-acting insulin takes 6-14 hours to start working and can stay in the blood for up to 24 hours."
   - F. "The types of insulin are based on how soon they start working, when the insulin works the hardest and how long it lasts."

NEXT-GENERATION NCLEX® EXAMINATION-STYLE UNFOLDING CASE STUDY—cont'd

The Child With Diabetes Mellitus

Day 2, 4:30 pm

4. The insulin injections are ordered to be given at least 30 minutes before breakfast. The second one will be given 30 minutes before dinner. Even though the patient will start off receiving insulin twice daily, he will still need to check his blood glucose before meals and at bedtime. Based on his age, his glucose goal range before meals should be 90 to 180 mg/dl and at bedtime should be 100 to 180 mg/dl. The nurse is planning the teaching session and is preparing to give an injection of insulin before dinner after checking his blood glucose level. She will demonstrate to the child and parents how to administer the medication with this injection and discuss important aspects of insulin administration at home.

   Indicate which nursing action listed in the far-left column is appropriate for each potential complication listed in the middle column. Indicate the nursing action number in the far-right column.

   Note that ONLY one nursing action can be used for each potential complication and that NOT all nursing actions will be used.

Nursing Action	Potential Complication	Nursing Action for Complication
1. Obtain blood glucose level before meals and at bedtime.	normal blood glucose level is not maintained	
2. Administer insulin as prescribed.	appropriate dose of insulin is not administered	
3. Monitor urine glucose before each meal.	appropriate type of insulin is not administered	
4. Use aseptic techniques when preparing and administering insulin.	infection occurs	
5. Store insulin in the freezer to preserve the medication.	absorption of insulin is impaired	
6. Understand the action of insulin: differences in composition, time of onset, and duration of action for the various preparations.		
7. Rotate insulin injection sites.		
8. Give less insulin before physical activity		

Day 3, 8:00 am

5. Before breakfast, the blood glucose was checked by the mother with guidance from the nurse. The mother administers the insulin into his left thigh; the patient wanted to have his mother give the insulin the first few times so that he can observe. An hour later the nurse is called to the bed site because he feels funny and his head hurts. He is dizzy when he stands, and his hands are shaking. The parents tell the nurse he did not eat breakfast because he is hoping to be discharged and wanted to eat on the way home.

   For each nursing action, use an X to indicate whether it was Effective (helped to meet expected quality patient outcomes), Ineffective (did not help to meet expected quality patient outcomes), or Unrelated (not related to the quality patient outcomes).

Nursing Action	Effective	Ineffective	Unrelated
Immediately administer cup of fruit juice or a glass of nonfat or 1% milk.			
Check blood glucose after 15 minutes.			
Give a starch-protein snack.			
Start intravenous fluids with glucose.			
Provide information for the teacher on the child's diagnosis.			
Give parents instructions regarding signs and symptoms of hypoglycemia versus hyperglycemia.			
Teach parents how to administer intramuscular glucagon if unresponsive, unconscious, or seizing.			
Place the child on a portable insulin infusion pump.			

Day 3, 3:00 pm

6. The patient experienced hypoglycemia this morning after receiving the morning insulin injection. He did not eat breakfast after the injection. The nurse will use this experience to continue teaching the parents and child about how to monitor and manage his diabetes. What are the **most important** teaching topics for the nurse to include at this time? **Select all that apply.**

   A. "Signs of hyperglycemia or high blood sugar include fever, headache, seizures, and cough."
   B. " The blood sugar should be maintained within a target range of 90 to 180 mg/dl during the day."
   C. "Signs of hypoglycemia or low blood sugar include headache, dizziness, shaking, sweating and the pulse is fast."
   D. "Your child should no longer participate in any sports of physical activity that would cause his blood glucose to fall."
   E. "Learning how to plan meals, understanding specific good groups and making good food choices will be an important part of managing his diabetes."
   F. "The health care provider should be contacted when your child has fever for 2 days, vomiting and diarrhea, is unable to keep fluids down, and his glucose levels are above the target range."

Child and Family Education

Several organizations are prepared to assist with education and dissemination of knowledge about diabetes. The American Diabetes Association,[c] Canadian Diabetes Association,[d] Juvenile Diabetes Research Foundation International,[e] and American Association of Diabetes Educators[f] are valuable resources for a wide variety of educational materials. The National Institute of Diabetes and Digestive and Kidney Diseases[g] publishes a number of comprehensive annotated bibliographies, including "Educational Materials for and About Young People With Diabetes," a compilation of resource materials for children, siblings, parents, teachers, and health professionals, and "Sports and Exercise for People With Diabetes."

Medical Identification

One of the first things the nurse should call to the parents' attention is the need for the child to wear some means of medical identification. Usually recommended is the MedicAlert identification, a stainless steel or silver- or gold-plated identification bracelet that is visible and immediately recognizable. It contains a collect telephone number that medical personnel can call around the clock for medical records and personal information.

Nature of Diabetes

The better the parents understand the pathophysiology of diabetes and the function and action of insulin and glucagon in relation to caloric intake and exercise, the better they will understand the disease and its effects on the child. Parents need answers to a number of questions (voiced or unvoiced) to increase their confidence in coping with the disease. For example, they may want to know about the various procedures performed on their child and treatment rationale, such as what is being put in the IV bottle and the expected effect.

Meal Planning

Normal nutrition is a major aspect of the family education program. Diet instruction is usually conducted by the nutritionist, with reinforcement and guidance from the nurse. The emphasis is on adequate intake for age, consistent menus, complex carbohydrates, and consistent eating times. The family is taught how the meal plan relates to the requirements of growth and development, the disease process, and the insulin regimen. Meals and snacks are modified based on the child's preferences and current menu, preserving cultural patterns and preferences as much as possible. Extensive exchange lists that include foods compatible with most lifestyles are available.

Learning about foods within specific food groups helps in making choices. Weights and measures of foods are used as eye-training devices for defining serving sizes and should be practiced for about 3 months, with gradual progression to estimation of food portions. Even when the child and family become competent in estimating portion sizes, reassessment should take place weekly or monthly and when there is any change of brands.

Family members should also be guided in reading labels for the nutritional value of foods and food content. They need to become familiar with the carbohydrate content of food groups. Substitution with foods of equal carbohydrate content is the skill needed for successful carbohydrate counting. Substitution might be necessary if a food is not available in sufficient quantity or for the teenager who wishes to eat fast food with peers. The use of a multiple daily injection program lends flexibility to the timing of meals.

Lists of popular fast-food items and items served at the major fast-food chains can be obtained from the restaurants to help guide food selections. It is important that the child know the nutritional value of these items (the major chains are remarkably uniform), but the child should be cautioned to avoid high-fat and high-sugar/high-carbohydrate items; for example, the child could choose a plain hamburger instead of a double cheeseburger.

Children should use sugar substitutes in moderation in items such as soft drinks. Artificial sweeteners have been shown to be safe, but if there is any question about amounts, the physician, dietitian, or nurse specialist can provide guidelines based on body weight. Sugar-free chewing gum and candies made with sorbitol may be used in moderation by children with DM. Although sorbitol is less cariogenic than other varieties of sugar substitutes, it is an alcohol sugar that is metabolized to fructose and then to glucose. Furthermore, large amounts can cause osmotic diarrhea. Most dietetic foods contain sorbitol. They are more expensive than regular foods. Also, although a product may be sugar free, it is not necessarily carbohydrate free.

Traveling

Traveling requires planning, especially when a trip involves crossing time zones. A number of tips are included in pamphlets available free of charge. Suggestions for traveling encompass what will be needed from the practitioner before leaving, what and how much to take along, needs in transit, what to consider at the destination, and planning for when the child returns home. Planning is needed no matter what type of travel is considered—automobile, plane, bus, or train.

Insulin

Families need to understand the treatment method and the insulin prescribed, including the effective duration, onset, and peak action. They also need to know the characteristics of the various types of insulins, the proper mixing and dilution of insulins, and how to substitute another type when their usual brand is not available (insulin is a nonprescription drug). Insulin need not be refrigerated but should be maintained at a temperature between 15°C and 29.4°C (59°F and 85°F). Freezing renders insulin inactive.

Insulin bottles that have been "opened" (i.e., the stopper has been punctured) should be stored at room temperature or refrigerated for up to 28 to 30 days. After 1 month, these vials should be discarded. Unopened vials should be refrigerated and are good until the expiration date on the label. Diabetic supplies should not be left in a hot environment.

Injection Procedure

Learning to give insulin injections is a source of anxiety for both parents and children. It is helpful for the learner to know that this important aspect of care will become as routine as brushing the teeth. First, the basic injection technique is taught using an orange or similar item and sterile normal saline for practice. To gain children's confidence, the nurse can demonstrate the technique by giving a skillful injection to the parent and then having the parent return the demonstration by giving the nurse an injection. With practice and confidence, the parents will soon be able to give the insulin injection to their children, and their children will trust them. Another effective strategy is to instruct the children and then have them teach the technique to the parents while the nurse observes. Both parents should participate, and as little time as possible should elapse between instruction and the actual injection, especially with parents and teenage learners.

Insulin can be injected into any area in which there is adipose (fat) tissue over muscle; the drug is injected at a 90-degree angle. Newly diagnosed children may have lost adipose tissue, and care should be exerted not to inject intramuscularly. The pinch technique is the most effective method for tenting the skin to allow easy entrance of the needle to subcutaneous tissues in children. The site selected will sometimes depend on whether children or parents administer the insulin. The arms, thighs, hips, and abdomen are usual injection sites for insulin. The children can reach the thighs, abdomen, and part of the hip and arm easily but may require help to inject other sites. For example, a parent can pinch a loose fold of skin of the arm while the child injects the insulin.

The parents and child are helped to work out a rotation pattern to various areas of the body to enhance absorption because insulin absorption is slowed by fat pads that develop in overused injection areas. The most efficient rotation plan involves giving about four to six injections in one area (each injection about 2.5 cm [1 inch] apart, or the diameter of the insulin vial from the previous injection) and then moving to another area.

Remember that the absorption rate varies in different parts of the body (Table 28.5). The methodical use of one anatomic area and then movement to another (as described in the previous paragraph) minimizes variations in absorption rates. However, absorption is also altered by vigorous exercise, which enhances absorption from exercised muscles; therefore it is recommended that a site be chosen other than the exercising extremity (e.g., avoiding legs and arms when playing in a tennis tournament).

Injection sites for an entire month can be determined in advance on a simple chart. For example, a "paper doll" (body outline) can be constructed and insulin sites marked by the child. After injection, the child places the date on the appropriate site. To keep in practice, it is a good idea for the parent to give two or three injections a week in areas that are difficult for the child to reach. The same basic methodology is used when teaching children to give their own insulin injections (Fig. 28.3). They should practice first on an orange or a doll, building courage gradually. Other devices are available for insulin injection, and these may offer advantages to some children. Children who do not wish to give themselves injections can be taught to use a syringe-loaded injector (Inject-Ease). With the device, puncture is always automatic. Adolescents respond well to a self-contained and compact device resembling a fountain pen (NovoPen), which eliminates conventional vials and syringes.

Continuous subcutaneous insulin infusion. Some children are considered candidates for use of a portable insulin pump, and even some young children with unsatisfactory metabolic control can benefit from its use. The child and the parents are taught to operate the device, including the mechanics of the pump, battery changes, and alarm systems. A number of devices that vary in the basal rates they are able to deliver and in the cost of the equipment are on the market. Families can investigate the various devices and select the model that best suits their needs. Product information is available from pump manufacturers and distributors.[h]

[h]Medtronic MiniMed, http://www.medtronicdiabetes.com/home; Animas, http://www.animas.com.

Parents and children learn (1) the technical aspects of the pump and SMBG; (2) prevention and treatment for hyperglycemia, sick-day management, and meal planning; (3) the effects of exercise, stress, and diet on blood glucose levels; and (4) decision-making strategies to evaluate blood glucose patterns and make adjustments in all aspects of the regimen.

Numerous blood glucose measurements (at least four times per day) are an essential part of infusion pump use. Intensive education and supervision are critical to obtaining maximum efficiency and control. This is particularly important if the family has been accustomed to a conventional insulin regimen. They must realize that simply wearing the pump will not normalize blood glucose. The pump is merely an insulin delivery device, and frequent, routine blood glucose determinations are necessary to adjust the insulin delivery rate.

The major problems with use of the insulin pump are inflammation from irritation and infection at the insertion site. The site should be cleaned thoroughly before the needle is inserted and then covered with a transparent dressing. The site is changed and rotated every 48 to 72 hours (this may vary) or at the first sign of inflammation. Nurses working where pumps are part of the therapeutic regimen should become familiar with the operation of the specific device being used and the protocol of disease management. Others should be aware of this management technique and be prepared to assist patients using the pump.

Monitoring

Nurses should also be prepared to teach and supervise blood glucose monitoring. SMBG is associated with few complications, and although it does not necessarily lead to improved metabolic control, it provides a more accurate assessment of blood glucose levels than can be obtained with the historical urine testing. Blood glucose monitoring has the added advantage that it can be performed anywhere (see Atraumatic Care box).

ATRAUMATIC CARE

Minimizing Pain of Blood Glucose Monitoring

- To enhance blood flow to the finger, hold it under warm water for a few seconds before the puncture.
- When obtaining blood samples, use the ring finger or thumb (blood flows more easily to these areas) and puncture the finger just to the side of the finger pad (more blood vessels and fewer nerve endings).
- To prevent a deep puncture, press the platform of the lancet device lightly against the skin and avoid steadying the finger against a hard surface.
- Use lancet devices with adjustable-depth tips. Begin with the shallowest setting.
- Use glucose monitors that require small blood samples (e.g., Ascensia Elite) to avoid repeated punctures.

TABLE 28.5 Onset and Duration of Action Related to Injection Site

	SITE OF INJECTION			
	Abdomen	**Arm**	**Leg**	**Buttock**
Rate	Very fast	Fast	Slow	Very slow
Duration	Very short	Short	Long	Very long

From Albisser, A. M., & Sperlich, M. (1992). Adjusting insulins. *Diabetes Educator, 18*(3), 211–218.

Fig. 28.3 School-age children can administer their own insulin.

Blood for testing can be obtained by two different methods: manually or with a mechanical bloodletting device. A mechanical device is recommended for children, although the child and family should learn to use both methods in the event of mechanical failure. Several lancet devices are available, and each provides a means for obtaining a large drop of blood for testing (Fig. 28.4).

! NURSING ALERT

Caution children not to allow anyone else to use their lancet because of the risk of contracting hepatitis B virus or human immunodeficiency virus infection.

The blood sample may be obtained from fingertips or alternate sites, such as the forearm. Alternate site testing requires a meter that can test a small volume of blood. Not all meters are capable of this.

Signs of redness and soreness at the site of finger puncture should be examined by the practitioner. It may be evidence of poor technique, poor hygiene, or poor skin healing relative to poor control. Many types of blood-testing meters are available for home use. Newer technology has brought about improvements in meter size and ease of use. The family should be shown features of several meters, including advantages and disadvantages, and allowed to choose equipment that best meets their needs.

The least expensive testing method uses a reagent strip to which blood is applied (Fig. 28.5). After blotting, the color change is compared against a color scale for an estimation of the blood glucose level. The strips can be cut in half (although not all professionals recommend this) to obtain two readings per strip. This method is not accepted practice but may be necessary for some families or situations.

Urine testing. Testing for urinary ketones is recommended during times of illness and when blood glucose values are elevated. Information on a specific ketone-testing product should include correct procedure, storage, and product expiration. Families need a clear understanding of home management of ketones (fluids and additional insulin as directed by the health care team).

Signs of Hyperglycemia

Severe hyperglycemia is most often caused by illness, growth, emotional upset, or missed insulin doses. Emotional stress from school finals or examinations or physical response to immunizations are examples of causes of hyperglycemia. With careful glucose monitoring, any elevation can be managed by adjustment of insulin or food intake. Parents should understand how to adjust food, activity, and insulin at the time of illness or when the child is treated for an illness with a medication known to raise the blood glucose level (e.g., steroids). The hyperglycemia is managed by increasing insulin soon after the increased glucose level is noted. Health care professionals should be aware that adolescent girls often become hyperglycemic around the time of their menses and should be advised to increase insulin dosages if necessary.

Fig. 28.4 Child using a finger-stick device to obtain a blood sample.

Fig. 28.5 Child using a blood glucose monitor and reagent strips to test his blood for glucose.

Signs of Hypoglycemia

Hypoglycemia is caused by imbalances of food intake, insulin, and activity. Ideally, hypoglycemia should be prevented, and parents need to be prepared to prevent, recognize, and treat the problem. They should be familiar with the signs of hypoglycemia and instructed in treatment, including care of the child with seizures. Early signs are adrenergic, including sweating and trembling, which help raise the blood glucose level, similar to the reaction when an individual is startled or anxious. The second set of symptoms that follow an untreated adrenergic reaction is neuroglycopenic (also called *brain hypoglycemia*). These symptoms typically include difficulty with balance, memory, attention, or concentration; dizziness or lightheadedness; and slurred speech. Severe and prolonged hypoglycemia leads to seizures, coma, and possible death (Levitsky & Misra, 2019b). Hypoglycemia can be managed effectively as outlined in the Emergency Treatment box.

EMERGENCY TREATMENT

Hypoglycemia

Mild Reaction: Adrenergic Symptoms

Give child 10 to 15 g of a simple, high-carbohydrate substance (preferably liquid; e.g., 3 to 6 oz of orange juice).
Follow with starch-protein snack.

Moderate Reaction: Neuroglycopenic Symptoms

Give child 10 to 15 g of a simple carbohydrate as above.
Repeat in 10 to 15 minutes if symptoms persist.
Follow with larger snack.
Watch child closely.

Severe Reaction: Unresponsive, Unconscious, or Seizures

Administer glucagon as prescribed.
Follow with planned meal or snack when child is able to eat or add a snack of 10% of daily calories.

Nocturnal Reaction

Give child 10 to 15 g of a simple carbohydrate.
Follow with snack of 10% of daily calories.

It is advisable for parents to plan for anticipated excitement or exercise. In addition, gastroenteritis may decrease insulin needs slightly as a result of poor appetite, vomiting, or diarrhea. If the blood glucose level is low but urinary ketones are present, the family should be aware of the increased need for simple carbohydrates and liquids.

Hygiene

All aspects of personal hygiene should be emphasized for children with diabetes. Children should be cautioned against wearing shoes without socks, wearing sandals, and walking barefoot. Correct nail and extremity care tailored to the individual child (with the guidance of a podiatrist) can begin health practices that last a lifetime. These children's eyes should be checked once a year unless the child wears glasses and then as directed by the ophthalmologist. Regular dental care is emphasized, and cuts and scratches should be treated with plain soap and water unless otherwise indicated. Diaper rash in infants and *Candida* infections in teens may indicate poor diabetes control.

Exercise

Exercise is an important component of the treatment plan. If the child is more active at one time of the day than at another time, food or insulin can be altered to meet that activity pattern. Food should be increased in the summer, when children tend to be more active. Decreased activity on return to school may require a decrease in food intake or increase in insulin dosage. Children who are active in team sports will need a snack about a half-hour before the anticipated activity. Races or other competitions may call for a slightly higher food intake than at practice times.

Food intake will usually need to be repeated for prolonged activity periods, often as frequently as every 45 minutes to 1 hour. Families should be informed that if increased food is not tolerated, decreased insulin is the next course of action. If the timing of the exercise is changed so that the supper meal is delayed, the insulin in the second or third dose of the day may be moved back to precede the mealtime. Sugar may sometimes be needed during exercise periods for quick response. Elevated blood glucose levels after extreme activity may represent the body's adrenergic response to exercise. If the blood glucose level is elevated (>240 mg/dl) before planned exercise, urinary ketones should be checked, and the activity may need to be postponed until the blood glucose is controlled.

NURSING ALERT

Ketonuria in the presence of hyperglycemia is an early sign of ketoacidosis and a contraindication to exercise.

Record Keeping

Home records are an invaluable aid to diabetes self-management. The nurse and family devise a method to chart insulin administered, blood glucose values, urine ketone results, and other factors and events that affect diabetes control. The child and family are encouraged to observe for patterns of blood glucose responses to events such as exercise. If lapses in management occur (e.g., eating a candy bar), the child should be encouraged to note this and not be criticized for the transgression.

Self-Management

Self-management is the key to close control. Being able to make changes when they are needed rather than waiting until the next contact with health care professionals is important for self-management and gives the individual and family the feeling that they have control over the disease. Psychologically, this helps family members believe they are useful and participating members of the team. Allowing the child to learn to look at records objectively promotes independence in self-management support. As children grow and assume more responsibility for self-management, they develop confidence in their ability to manage their disease and confidence in themselves as persons. They learn to respond to the disease and to make more accurate interpretations and changes in treatment when they become adults.

Puberty is associated with decreased sensitivity to insulin that normally would be compensated for by an increased insulin secretion. Health care professionals should anticipate that pubertal patients will have more difficulty maintaining glycemic control. Higher doses of insulin are often needed in pubertal children (Levitsky & Misra, 2019b). Patients should be taught to give themselves additional doses of rapid-acting insulin (5% to 10% of their daily dose) when their blood glucose levels are increased. The use of supplemental rapid-acting insulin is preferred to withholding food in adolescents.

Child or Adolescent and Family Support

Just as the physiologic responses affect the child, the parents and other family members of the child with newly diagnosed DM experience various emotional responses to the crisis. Care in the acute setting is short but may create fears and frustrations. The prospect of a chronic illness in their child engenders all of the feelings and concerns that are faced by parents of children with other chronic illnesses (see Chapter 17). The threat of complications and death is always present, as is the continuing drain on emotional and financial resources.

Certain fears may develop as a result of past experiences with the disease. A severe insulin reaction with seizures can contribute to fear of repetition. If parents observe a seizure or the adolescent has one in a public place, the desire to maintain better control is reinforced. They must understand how to prevent problems and how to handle problems calmly and coolly if they occur, and they must understand the complexities of the body, the disease, and its complications. Young children usually adjust well to problems related to the disease. With toddlers and preschoolers, insulin injections and glucose testing may be difficult at first. However, they usually accept the procedures when the parents use a matter-of-fact approach, without calling attention to a "hurt," and treat the procedure like any other routine part of the child's life. After the injection, time with some special and positive attention, such as reading or talking, or another pleasant activity, is one way to convert children who initially refuse injections to those who accept them.

In the years before adolescence, children probably accept their condition most easily. They are able to understand the basic concepts related to their disease and its treatment. They are able to test blood glucose and urine, recognize food groups, give injections, keep records, and distinguish fear or excitement from hypoglycemia. They understand how to recognize, prevent, and treat hypoglycemia. However, they still need considerable parental involvement.

NURSING TIP: Ongoing motivation to adhere to a regimen is difficult. An older child and parent (or another caregiver) may enjoy negotiating a day off when the responsibility for testing and recording blood glucose is delegated from the child to the caregiver (or vice versa).

Adolescents appear to have the most difficulty adjusting. Adolescence is a time of stress in trying to be perfect and similar to one's peers, and no matter what others say, having diabetes is being different. Some adolescents are more upset about not being able to have a candy bar than about injections, diet, and other aspects of management. If children can accept the difference as a part of life—in other words, that each person is different in some way—then, with adequate parental support, they should be able to adjust well (see Critical Thinking Case Study box).

Camping and other special group activities are useful. At diabetes camp, children learn that they are not alone. As a result, they become more independent and resourceful in other settings. Useful information about such camps and organizations can be obtained from the American Diabetes Association. A list of accredited camps specifically for children and teenagers with diabetes is also available from the American Camping Association.[i]

CRITICAL THINKING CASE STUDY

Type 1 Diabetes Mellitus

Shelly, a 14-year-old adolescent with a 3-year history of type 1 diabetes mellitus (DM), has been admitted to the pediatric intensive care unit for treatment of diabetic ketoacidosis (DKA). This is her fifth hospital admission for DKA in the past year. Shelly's parents are divorced, and she has four younger siblings, none of whom has diabetes. Shelly's mother has maintained two jobs for the past 5 years and frequently leaves Shelly in charge of the household. In anticipation of her discharge, you are planning a patient education program for Shelly and her mother. What important issues regarding Shelly's unstable diabetes management must you consider to plan the education program?

Initial Assessment. What are the concerns related to Shelly's recurrent DKA episodes and family stressors?

Expected Nursing Action. What education is necessary for Shelly and her parents to decrease the frequent hospitalizations?

Teaching Points

- Adolescence is a time of increasing independence, so while encouraging adolescents to take control of their diabetes management, minimal or no adult involvement results in poor glycemic control (Levitsky & Misra, 2019b).
- Adolescents with diabetes have a threefold increased risk of depression and eating disorders (Levitsky & Misra, 2019b).
- Socioeconomic factors such as single-parent homes, poor socioeconomic status, and physical or mental health problems with one parent are associated with poorer diabetes control and increased hospitalizations (Levitsky & Misra, 2019a).

Critical Thinking Answers

Initial Assessment. An adolescent with diabetes living in a single-parent home with a poor socioeconomic status is at an increased risk of poor glycemic control and increased hospitalizations.

Expected Nursing Action. Work with the family to develop a family-focused teamwork approach to Shelly's care. Parental involvement along with increased responsibility for the management of her diabetes will promote Shelly to have better glycemic control.

CLINICAL JUDGMENT AND NEXT-GENERATION NCLEX® EXAMINATION-STYLE QUESTIONS

1. An 8-year-old boy is diagnosed with diabetes insipidus (DI) and is being discharged on hormone replacement using DDAVP. The nurse will be completing discharge teaching with the parents and patient. What are the **most important** teaching topics for the nurse to include at this time? **Select all that apply.**
   - **A.** Education and support regarding the rationale for fluid restrictions.
   - **B.** Understanding that treatment will be needed only until the child reaches puberty.
   - **C.** Knowing that school-age children may assume full responsibility for their care.
   - **D.** Information for school personnel regarding the diagnosis so that they can grant children unrestricted use of the lavatory.
   - **E.** A thorough explanation regarding the condition, with specific clarification that DI is a different condition from diabetes mellitus (DM).
   - **F.** For emergency purposes, the child should wear a medical alert identification.

2. You are working with a nurse who is new to your endocrine unit and has never worked with an infant born with congenital adrenal hyperplasia (CAH). You want to make sure that the nurse has a full understanding of this diagnosis before she takes care of a new patient. What health teaching would the nurse include when teaching the parents about the infant's diagnosis? **Select all that apply.**
   - **A.** "Insulin is used to suppress high secretions of the hormones and can be very effective."
   - **B.** "A definitive diagnosis is confirmed by evidence of increased 17-ketosteroid levels in most types of CAH."
   - **C.** "Blood studies to identify elevated calcium and decreased phosphorus levels are routinely performed."
   - **D.** "Another test that can be used to visualize the presence of pelvic structures, such as female reproductive organs, is ultrasonography."
   - **E.** "This deficiency is an autosomal recessive disorder that results in improper steroid hormone synthesis."
   - **F.** "Genetic counseling is recommended before they conceive another child because CAH is a genetic disorder.

3. A nurse working in a pediatric clinic is completing an assessment of a 7-year-old girl who has breast development and pubertal hair. Her mother is concerned and scheduled the visit. The nurse performs a physical assessment and findings include:
   - Oral temperature = 98.4F
   - Pulse = 62 beats/min
   - Respiration = 18 breaths/min
   - Blood pressure = 102/60 mm Hg
   - Breast enlargement, Tanner Stage 3
   - Hair over entire pubis, Tanner Stage 3

   Choose the most likely options for the information missing from the statements below by selecting from the lists of options provided.
   As a result of the physical findings, the nurse is aware that these are signs of _____1_____. This is treated with a _____2_____that is administered once every _____3_____depending on the medication preparation.

Options for 1	Options for 2	Options for 3
aplastic crisis	preparation of insulin	4-12 days
diabetes insipidus	luteinizing hormone-releasing hormone	2-3 weeks
diabetes mellitus	vasopressin injection	10-14 days
precocious puberty	vitamin-D injection	3-5 weeks
Cushing syndrome	corticosteroid agent	4-12 weeks

4. A 13-year-old girl is newly diagnosed with Graves disease based on her symptoms that gradually increased over the past 7 months. Her grades at school dropped and she was not able to concentrate. She was always restless and tired. Her appetite increased but she lost 20 lbs over the last several months. The diagnostic work up confirmed increased blood levels of T4 and T3 and the TCH level was low. The nurse will provide education to the child and parents before discharge. **Use an X to indicate whether the nursing education below is Indicated (appropriate or necessary), Contraindicated (could be harmful), or Non-Essential (makes no difference or not necessary).**

Nursing Action-Education	Indicated	Contraindicated	Non-Essential
When starting drug therapy encourage staying in a quiet, unstimulating environment that promotes rest.			
Heat tolerance is a common symptom experienced by individuals with Graves disease.			
Weight gain is a common symptom experienced by individuals with Graves disease.			
Mood swings and irritability are common symptoms experienced by individuals with Graves disease.			
Eating fruit and vegetables as part of a healthy diet is recommended for teenagers.

- Integrity
- Mobility

THE IMMOBILIZED CHILD

IMMOBILIZATION

One of the most difficult aspects of illness in children is the immobility it often imposes on a child. Children's natural tendency to be active influences all aspects of their growth and development. Impaired mobility presents a challenge to children, their families, and their caregivers.

Physiologic Effects of Immobilization

Many clinical studies, including space program research, have documented predictable consequences that occur after immobilization and the absence of gravitational force. Functional and metabolic responses to restricted movement can be noted in most of the body systems. Each has a direct influence on the child's growth and development because of homeostatic mechanisms that thrive on normal use and feedback to maintain dynamic equilibrium. Inactivity leads to a decrease in the functional capabilities of the whole body as dramatically as the lack of physical exercise leads to muscle weakness.

Disuse from illness, injury, or a sedentary lifestyle can limit function and potentially delay age-appropriate milestones. Most of the pathologic changes that occur during immobilization arise from decreased muscle strength and mass, decreased metabolism, and bone demineralization, which are closely interrelated, with one change leading to or affecting the others.

The major effects of immobilization are outlined briefly in Table 29.1 and are related directly or indirectly to decreased muscle activity, which produces numerous primary changes in the musculoskeletal system with secondary alterations in the cardiovascular, respiratory, skeletal, metabolic, and renal systems. The musculoskeletal changes that occur during disuse are a result of alterations in the effect of gravity and stress on the muscles, joints, and bones. Muscle disuse leads to tissue breakdown and loss of muscle mass (**atrophy**). Muscle atrophy causes decreased strength and endurance, which may take weeks or months to restore.

The daily stresses on bone created by motion and weight bearing maintain the balance between bone formation (osteoblastic activity) and bone resorption (osteoclastic activity). During immobilization, increased calcium leaves the bone, causing osteopenia (demineralization of the bones), which may predispose bone to pathologic fractures. A **joint contracture** begins when the arrangement of collagen, the main structural protein of connective tissues, is altered, resulting in a denser tissue that does not glide as easily. Eventually, muscles, tendons, and ligaments can shorten and reduce joint movement, ultimately producing contractures that restrict function. The major musculoskeletal consequences of immobilization are:

- Significant decrease in muscle size, strength, and endurance
- Bone demineralization leading to osteoporosis
- Contractures and decreased joint mobility

Circulatory stasis combined with hypercoagulability of the blood, which results from factors such as damage to the endothelium of blood vessels (Virchow's triad), can lead to thrombus and embolus formation. **Deep vein thrombosis (DVT)** involves the formation of a thrombus in a deep vein, such as the iliac and femoral veins, and can cause significant morbidity if it remains undetected and untreated. The larger the portion of the body immobilized and the longer the immobilization, the greater the risks of immobility.

Psychologic Effects of Immobilization

For children, one of the most difficult aspects of illness is immobilization. Throughout childhood, physical activity is an integral part of daily life and is essential for physical growth and development. It also serves children as an instrument for communication and expression and as a means for learning about and understanding their world. Activity helps them deal with a variety of feelings and impulses and

TABLE 29.1 Summary of Physical Effects of Immobilization With Nursing Interventions[a]

Primary Effects	Secondary Effects	Nursing Considerations
Muscular System		
Decreased muscle strength, tone, and endurance	Decreased venous return and cardiac output Decreased metabolism and need for oxygen	Use antiembolism stockings or intermittent compression devices to promote venous return (monitor circulatory and neurovascular status of extremities when such devices are used).
	Decreased exercise tolerance	Plan play activities to use uninvolved extremities.
	Bone demineralization	Place in upright posture when possible.
Disuse atrophy and loss of muscle mass	Catabolism Loss of strength	Have patient perform range-of-motion, active, passive, and stretching exercises.
Loss of joint mobility	Contractures, ankylosis of joints	Maintain correct body alignment. Use joint splints as indicated to prevent further deformity. Maintain range of motion.
Weak back muscles	Secondary spinal deformities	Maintain body alignment.
Weak abdominal muscles	Impaired respiration	See nursing considerations for respiratory system.
Skeletal System		
Bone demineralization—osteoporosis, hypercalcemia	Negative bone calcium uptake Pathologic fractures Calcium deposits Extraosseous bone formation, especially at hip, knee, elbow, and shoulder Renal calculi	With paralysis, use upright posture on tilt table. Handle extremities carefully when turning and positioning. Administer calcium-mobilizing drugs (diphosphonates) and normal saline infusions if ordered. Ensure adequate intake of fluid; monitor output. Acidify urine. Promptly treat urinary tract infections.
Negative bone calcium uptake	Life-threatening electrolyte imbalance	Monitor serum calcium levels. Provide electrolyte replacement as indicated.
Metabolism		
Decreased metabolic rate	Slowing of all systems Decreased food intake	Mobilize as soon as possible. Have patient perform active and passive resistance exercises and deep-breathing exercises. Ensure adequate food intake. Provide a high-protein, high-fiber diet.
Negative nitrogen balance	Decline in nutritional state Impaired healing	Encourage small, frequent feedings with protein and preferred foods. Prevent pressure areas.
Hypercalcemia	Electrolyte imbalance	See nursing consideration for skeletal system.
Decreased production of stress hormones	Decreased physical and emotional coping capacity	Identify causes of stress. Implement appropriate interventions to lower physical and psychosocial stresses.
Cardiovascular System		
Decreased efficiency of orthostatic neurovascular reflexes	Inability to adapt readily to upright position (orthostatic intolerance) Pooling of blood in extremities in upright posture	Monitor peripheral pulses and skin temperature changes. Use antiembolism stockings or intermittent compression devices to decrease pooling when upright.
Diminished vasopressor mechanism	Orthostatic intolerance with syncope, hypertension, deceased cerebral blood flow, tachycardia	Provide abdominal support. In severe cases, use antigravitational pants. Position horizontally.
Altered distribution of blood volume	Increased cardiac workload Decreased exercise tolerance	Monitor hydration, blood pressure, and urinary output.
Venous stasis	Pulmonary emboli or thrombi	Encourage and assist with frequent position changes. Elevate extremities without knee flexion. Ensure adequate fluid intake. Have patient perform active or passive exercises or movement as needed. Prescribe routine wearing of antiembolism stockings or intermittent compression devices. Monitor for signs of pulmonary embolism—sudden dyspnea, chest pain, respiratory arrest.

TABLE 29.1 Summary of Physical Effects of Immobilization With Nursing Interventions[a]—cont'd

Primary Effects	Secondary Effects	Nursing Considerations
		Promptly intervene to maintain adequate oxygenation if signs and symptoms of pulmonary emboli are noted. Measure circumference of extremities periodically. Give anticoagulant drugs as prescribed.
Dependent edema	Tissue breakdown and susceptibility to infection	Administer skin care. Turn every 2-4 h. Monitor skin color, temperature, and integrity. Use pressure-reduction surface as necessary to prevent skin breakdown (see Chapter 20).
Respiratory System		
Decreased need for oxygen	Altered oxygen/carbon dioxide exchange and metabolism	Promote exercise as tolerated. Encourage deep-breathing exercises.
Decreased chest expansion and diminished vital capacity	Diminished oxygen intake Dyspnea and inadequate arterial oxygen saturation; acidosis	Position for optimum chest expansion. Semi-Fowler position may assist in lung expansion if patient can tolerate. Use prone positioning without pressure on abdomen to allow gravity to aid in diaphragmatic excursion. Ensure that patient maintains proper alignment when sitting to prevent pressure on respiratory mechanism.
Poor abdominal tone and distention	Interference with diaphragmatic excursion	Avoid restriction of chest and abdominal musculature. Supply torso support to promote chest expansion.
Mechanical or biochemical secretion retention	Hypostatic pneumonia Bacterial and viral pneumonia Atelectasis	Change position frequently. Carry out chest percussion, vibration, and drainage (or suctioning) as necessary. Use incentive spirometer. Monitor breath sounds.
Loss of respiratory muscle strength	Poor cough	Encourage coughing and deep breathing. Support chest wall by splinting with pillow when patient coughs. Use incentive spirometer. Observe for signs of respiratory distress with pulse oximetry or blood gas measurement as necessary.
	Upper respiratory tract infection	Prevent contact with infected persons. Provide adequate hydration. Administer immunizations as necessary (pneumococcal, meningococcal).
Gastrointestinal System		
Distention caused by poor abdominal muscle tone	Interference with respiratory movements Difficulty in feeding in prone position	Monitor bowel sounds. Encourage small, frequent feedings.
No specific primary effect	Possible constipation caused by gravitational effect on feces through ascending colon or weakened smooth muscle tone	Have patient sit in upright position in bedside chair if possible. Carry out bowel training program with hydration, stool softeners, increased fiber intake, and mild laxatives if necessary.
	Anorexia	Stimulate appetite with favored foods.
Urinary System		
Alteration of gravitational force	Difficulty in voiding in prone position	Position as upright as possible to void.
Impaired ureteral peristalsis	Urinary retention in calyces and bladder Infection Renal calculi	Hydrate to ensure adequate urinary output for age. Stimulate bladder emptying with warm running water, as necessary. Catheterize only for severe urinary retention. Administer antibiotics as indicated.
Integumentary System		
Altered tissue integrity	Decreased circulation and pressure leading to tissue injury	Turn and reposition at least every 2-4 h. Frequently inspect total skin surface. Eliminate mechanical factors causing pressure, friction, moisture, or irritation. Place on pressure-reduction mattress.
	Difficulty with personal hygiene	Assess ability to perform self-care and assist with bathing, grooming, and toileting as needed. Encourage self-care to potential ability. Ensure adequate intake of protein, vitamins, and minerals.

[a]Individualize care according to child's needs; interventions may vary in different institutions.

provides a mechanism by which they can exert control over inner tensions. Children respond to anxiety with increased activity. Removal of this power deprives them of necessary input and a natural outlet for their feelings and fantasies. Through movement, children also gain sensory input, which provides an essential element for developing and maintaining body image.

When children are immobilized by disease or as part of a treatment regimen, they experience diminished environmental stimuli with a loss of tactile input and an altered perception of themselves and their environment. Sudden or gradual immobilization narrows the amount and variety of environmental stimuli children receive by means of all their senses: touch, sight, hearing, taste, smell, and proprioception (a feeling of where they are in their environment). This sensory deprivation frequently leads to feelings of isolation and boredom and of being forgotten, especially by peers.

The quest for mastery at every stage of development is related to mobility. Even speech and language skills require sensorimotor activity and experience. For toddlers, exploration and imitative behaviors are essential to developing a sense of autonomy. Preschoolers' expression of initiative is evidenced by the need for vigorous physical activity. School-age children's development is strongly influenced by physical achievement and competition. Adolescents rely on mobility to achieve independence.

Children may react to immobility by active protest, anger, and aggressive behavior, or they may become quiet, passive, and submissive. They may believe that the immobilization is a justified punishment for misbehavior. Children should be allowed to display their anger, but it should be within the limits of safety to their self-esteem and not damaging to the integrity of others (see Chapter 19, Providing Opportunities for Play and Expressive Activities). When children are unable to express anger, aggression is often displayed inappropriately through regressive behavior and outbursts of crying or temper tantrums.

Effect on Families

Even brief periods of immobilization may disrupt family function, and catastrophic illness or disability may severely tax a family's resources and coping abilities. The family's needs often must be met by the services of a multidisciplinary team, and nurses play a key role in anticipating the services that they will need and in coordinating conferences to plan care. Home management, including special considerations for addressing cultural, economic, physical, and psychologic needs, is frequently planned prior to discharge. A child with a severe disability is very dependent, and caregivers need respite to revitalize themselves. Individual and group counseling is beneficial for solving problems in advance and provides an emotional support system. Parent groups are also helpful and often allow nonthreatening social contact. The families of children with permanent disabilities need long-term resources because some of the most difficult problems arise as they try to sustain high-quality care for many years (see Chapter 17).

Nursing Care Management

Physical assessment of the child who is immobilized for any number of reasons (e.g., injury, illness) includes a focus not only on the injured part (e.g., fracture) but also on the functioning of other systems that may be affected secondarily—the circulatory, renal, respiratory, muscular, and gastrointestinal systems. With long-term immobilization, there may also be neurologic impairment and changes in electrolytes (especially calcium), nitrogen balance, and the general metabolic rate. The psychologic impact of immobilization should also be assessed.

Children who require prolonged total immobility and are unable to move themselves in bed should be placed on a pressure-reduction mattress to prevent skin breakdown. Frequent position changes also help prevent dependent edema and stimulate circulation, respiratory function, gastrointestinal motility, and neurologic sensation. Children at greater risk for skin breakdown include those with prolonged immobilization; mechanical ventilation; casts; and assistive devices including orthotics, prosthetics, and wheelchairs. Additional risk factors include poor nutrition, friction (from bed linens with traction), and moist skin (from urine or perspiration). Nursing care of children at risk includes strategies for preventing skin breakdown when such conditions are present. The Braden QD Scale is a reliable, objective tool that may be used in the assessment for pressure ulcer development in children who are acutely ill or who are at risk for skin breakdown from neurologic conditions and immobilization (Curley, Hasbani, Quigley, et al., 2018).

The use of antiembolism stockings or intermittent compression devices prevents circulatory stasis and dependent edema in the lower extremities and reduces the likelihood of developing a DVT. Anticoagulant therapy may also be implemented with low-molecular-weight heparin, unfractionated heparin, or vitamin K antagonists. The child should be allowed as much activity as possible within the limitations of the illness or treatment. Any functional mobility, however minimal, is preferred to total immobility.

High-protein, high-calorie foods are encouraged to prevent negative nitrogen balance, which may be difficult to correct by diet, especially if there is anorexia as a result of immobility and decreased gastrointestinal function (decreased motility and possibly constipation). Stimulating the appetite with small servings of attractively arranged, preferred foods may be sufficient. At times, supplementary nasogastric or gastrostomy feedings or intravenous (IV) nutrition or fluids may be needed, but these are reserved for serious disability in which oral intake is impossible. Adequate hydration and, when possible, an upright position and remobilization promote bowel and kidney function and help prevent complications in these systems.

Children are encouraged to be as active as their condition and restrictive devices allow. This poses few problems for children, whose innate ingenuity and natural inclination toward mobility provide them with the impetus for physical activity. They need the opportunity, the materials and objects to stimulate activity, and the encouragement and participation of others. Those who are unable to move may benefit from passive exercise and movement in consultation with a physical therapist.

Using dolls, stuffed animals, or puppets to illustrate and explain the immobilization method (e.g., traction, cast) is a valuable tool for small children. Placing a cast, tubing, or other restraining equipment on the doll offers the child a nonthreatening opportunity to express, through the doll, feelings about the restrictions and feelings toward the nurse and other health care providers. The doll or puppet may also be used for teaching the child and family procedures, such as IV therapy, procedural sedation, and general anesthesia.

Whenever possible, transporting the child outside the confines of the room increases environmental stimuli and allows social contact with others. Specially designed wheelchairs or carts for increased mobility and independence are available. While hospitalized, children benefit from visitors, computers, books, interactive video games, and other items brought from their own room at home. An activity center or slanting tray can be helpful for the child with limited mobility to use for drawing, coloring, writing, and playing with small toys, such as trucks and cars. Accessibility to clocks, calendars, and a program of diversional therapy are also beneficial. All of these interventions help children function in a more typical way while hospitalized. Children are able to express frustration, displeasure, and anger through play activities (see Chapter 19), which is helpful in their recovery. A child life specialist should be consulted for recreational planning.
